## Growing $\text{Li}_2\text{O}_2$ surfaces on discharge cause electrolyte degradation and capacity loss in $\text{Li}-\text{O}_2$ batteries

Chloe Chau,<sup>a</sup> Tammy Nimmo,<sup>a</sup> Daniel Dewar,<sup>a</sup> Gregory J. Rees,<sup>a</sup> Chuan Tan,<sup>b</sup> Kieran D. Jones,<sup>c,d</sup> Lee R. Johnson,<sup>c,d</sup> Xiangwen Gao<sup>\*b</sup> and Peter G. Bruce<sup>id \*a,e</sup>

Ether-based solvents have shown promise as the most stable candidates for the electrolyte solution in the  $\text{Li}-\text{O}_2$  battery. However, the yield of  $\text{Li}_2\text{O}_2$  after discharge is less than 100%, despite achieving a near-ideal ratio of charge passed to  $\text{O}_2$  consumed ( $2e^-/\text{O}_2$ ) for the reduction of  $\text{O}_2$  to  $\text{Li}_2\text{O}_2$ . The loss of  $\text{Li}_2\text{O}_2$  leads to the observed capacity fade on cycling and is associated with electrolyte degradation. Here we investigate the chemical formation of  $\text{Li}_2\text{O}_2$  from superoxide in two commonly used ether solutions, dimethoxyethane and tetraethylene glycol dimethyl ether. The results indicate that it is the freshly growing  $\text{Li}_2\text{O}_2$  surface reacting with the electrolyte solution that is the dominant source of  $\text{Li}_2\text{O}_2$  loss and electrolyte degradation. Additionally, we quantify common side products from the degradation, including  $\text{Li}_2\text{CO}_3$ ,  $\text{HCO}_2\text{Li}$ ,  $\text{CH}_3\text{CO}_2\text{Li}$  and  $\text{H}_2\text{O}$ , and identify the composition of ethylene oxides formed during the reaction.

### Broader context

The current state of the art in lithium-ion battery technology is approaching its theoretical capacity limit in terms of the energy delivered per unit mass.  $\text{Li}-\text{O}_2$  batteries represent one of the most promising alternatives beyond lithium-ion systems.  $\text{Li}-\text{O}_2$  batteries have attracted considerable research interest due to their exceptionally high theoretical specific energy of  $3505 \text{ Wh kg}^{-1}$  of  $\text{Li}_2\text{O}_2$ , which is approximately 6–8 times greater than that of conventional lithium-ion batteries. However, electrolyte degradation remains a significant challenge, as it limits the cycle life and practical viability of  $\text{Li}-\text{O}_2$  cells. The aim of this work is to identify the primary causes of capacity fade during discharge and cycling, and to help consolidate research efforts towards the development of durable and commercially competitive  $\text{Li}-\text{O}_2$  battery technologies.

## Introduction

Among the challenges that face the  $\text{Li}-\text{O}_2$  battery, arguably the greatest are degradation and the associated capacity fade on cycling.<sup>1–3</sup> On discharge, the desired reaction at the cathode is the reduction of  $\text{O}_2$  to  $\text{Li}_2\text{O}_2$ , with the process being reversed on charge. The most stable electrolyte solutions to date are based on ethers.<sup>4–6</sup> However, even in such electrolytes, the yield of  $\text{Li}_2\text{O}_2$  on discharge is less than 100%, resulting in

capacity loss on cycling and the formation of a range of side-reaction products, involving decomposition of the electrolyte solution.<sup>7–9</sup>

$\text{Li}_2\text{CO}_3$ ,  $\text{HCO}_2\text{Li}$ ,  $\text{CH}_3\text{CO}_2\text{Li}$ , ethylene oxides and  $\text{H}_2\text{O}$  have all been identified as degradation products after cycling.<sup>10–15</sup> The origin of degradation and low  $\text{Li}_2\text{O}_2$  yields on discharge has been attributed to possible reactions involving  $\text{LiO}_2$ , the intermediate in the  $\text{O}_2/\text{Li}_2\text{O}_2$  reaction, and singlet oxygen ( $^1\text{O}_2$ ), the latter of which is produced during disproportionation of  $\text{LiO}_2$ .<sup>16–24</sup> In this work, we show that electrolyte degradation does not arise significantly from reactivity with the  $\text{LiO}_2$  intermediate. We also confirm the results of a recent study of chemically generated  $^1\text{O}_2$  with ether electrolytes, which suggested that  $^1\text{O}_2$  does not react significantly with the electrolyte.<sup>25</sup> Instead, degradation arises from the reactivity between the growing  $\text{Li}_2\text{O}_2$  surface and the electrolyte solution, with degradation competing successfully against  $\text{Li}_2\text{O}_2$  particle growth. Degradation is greater in tetraethylene glycol dimethyl ether (TEGDME) than in dimethoxyethane (DME). This is due

to the slower formation of  $\text{Li}_2\text{O}_2$  in TEGDME, in accord with the higher viscosity of the solution and therefore slower diffusivity of species reacting in TEGDME. The role of kinetics is reinforced by observations in  $\text{Li}-\text{O}_2$  cells that show higher current rates leading to less degradation, as expected from processes that involve the growing  $\text{Li}_2\text{O}_2$  surface. The quantities of the main degradation products ( $\text{Li}_2\text{CO}_3$ ,  $\text{HCO}_2\text{Li}$ ,  $\text{CH}_3\text{CO}_2\text{Li}$  and  $\text{H}_2\text{O}$ ) and the composition of the ethylene oxide species that form from side reactions with ethers are determined.

## Results and discussion

The reduction of  $\text{O}_2$  to form  $\text{Li}_2\text{O}_2$  at the cathode is a two-step process:

Step 1:

Step 2(a) – spontaneous disproportionation:

Or 2(b) –  $2^{\text{nd}}$  electron reduction:

Overall:

The overall reaction results in a ratio of charge passed to  $\text{O}_2$  consumed of  $2\text{e}^-/\text{O}_2$ . It has been shown previously that the dominant reaction on discharge is the consumption of  $\text{O}_2$  in the ideal  $2\text{e}^-/\text{O}_2$  ratio.<sup>26–28</sup> To affirm this, cells were constructed as described in the Methods and discharged with *in situ* gas monitoring. The amount of  $\text{O}_2$  consumed is plotted against the charge passed and the dotted line corresponds to the predicted  $2\text{e}^-/\text{O}_2$  ratio for the  $\text{O}_2/\text{Li}_2\text{O}_2$  reaction, which these cells adhered to within experimental errors (DME:  $2.02 \pm 0.02$ ; TEGDME:  $2.03 \pm 0.02$ ) (Fig. S1), in accord with previous studies.<sup>26–28</sup> The significance of adherence to the  $2\text{e}^-/\text{O}_2$  ratio is that there can be very little reaction between the superoxide intermediate,  $\text{LiO}_2$ , and the electrolyte solution or carbon electrode. Had such a reaction taken place, the overall amount of  $\text{O}_2$  consumed would deviate from the ideal ratio of  $2\text{e}^-/\text{O}_2$ . The results are also consistent with singlet oxygen, which is known to be generated as  $\text{LiO}_2$  disproportionates to form  $\text{Li}_2\text{O}_2$ , not playing a significant role in electrolyte or carbon electrode degradation on discharge. If it did so, again the overall amount of  $\text{O}_2$  consumed would deviate from the theoretical  $2\text{e}^-/\text{O}_2$ .

Despite the well-acknowledged  $2\text{e}^-/\text{O}_2$  ratio within the field, many researchers still report and suggest that superoxide and singlet oxygen could play a significant role in  $\text{Li}_2\text{O}_2$  loss.<sup>17,20,29,30</sup> To confirm the lack of  $\text{O}_2^-$  or  $^1\text{O}_2$  reactivity during the formation of  $\text{Li}_2\text{O}_2$ , the latter was generated chemically by adding a solution of  $\text{LiTFSI}$  in DME or TEGDME to  $\text{KO}_2$  powder while stirring. The evolution of  $\text{O}_2$  was followed by

online mass spectrometry, as described in the Methods. The reaction is:

The experiments were conducted with and without 9,10-dimethylantracene (DMA), a trap for  $^1\text{O}_2$ , and the results are shown in Fig. 1. 100%  $\text{O}_2$  evolution would correspond to the quantity expected if all the  $\text{KO}_2$  reacted to form  $\text{Li}_2\text{O}_2$  (*i.e.* the lithium electrolyte solution was in excess in all cases). The amount of  $\text{O}_2$  detected in the absence of the trap is very close to 100% for both DME ( $99.7 \pm 0.2\%$ ) and TEGDME ( $99.8 \pm 0.2\%$ ) as shown in Fig. 1(a). If  $\text{O}_2^-$  or  $^1\text{O}_2$  had reacted with the electrolyte solution, then the  $\text{O}_2$  yield would be below 100%. These results further confirm that neither  $\text{O}_2^-$  nor  $^1\text{O}_2$  are major sources of degradation. These are more challenging conditions under which  $\text{O}_2^-$  might have reacted with the electrolyte solution than in  $\text{Li}-\text{O}_2$  cells since  $\text{KO}_2$  persists in the solution longer than the transient formation of  $\text{LiO}_2$  during  $\text{O}_2$  reduction to  $\text{Li}_2\text{O}_2$  in cells due to the greater solubility of the former over the latter.<sup>31,32</sup> In the presence of the trap,  $^1\text{O}_2$  is quenched to form  $\text{DMA}-\text{O}_2$  and the mass spectrometer detects only  $^3\text{O}_2$ , leading to less  $\text{O}_2$  detected in both cases ( $98.6 \pm 0.2\%$  in DME and  $95.4 \pm 0.2\%$  in TEGDME). By comparing the yield of  $\text{O}_2$  with and without the trap, we confirm that  $^1\text{O}_2$  is indeed formed in the reaction and that the amount of  $^1\text{O}_2$  produced is

**Fig. 1** (a) Oxygen and (b)  $\text{Li}_2\text{O}_2$  yields after  $\text{KO}_2$  disproportionation in DME (blue) and TEGDME (green) without and with singlet oxygen trap, showing no evidence of  $^1\text{O}_2$  or  $\text{O}_2^-$  reactivity.

greater in the case of TEGDME ( $4.4 \pm 0.3\%$ ) compared with DME ( $1.1 \pm 0.3\%$ ). Yet even this greater amount of  $^1\text{O}_2$  does not induce observable degradation in the case of TEGDME. The yield of  $\text{Li}_2\text{O}_2$  was determined for the cases of DME and TEGDME with and without a  $^1\text{O}_2$  trap by photometric titration using  $\text{TiOSO}_4$ .<sup>33,34</sup> The results are shown in Fig. 1(b). In all cases, the  $\text{Li}_2\text{O}_2$  yield is lower than 100%, as expected given side reactions, but does not vary significantly with and without the  $^1\text{O}_2$  trap (DME:  $89.6 \pm 0.8\%$  vs.  $88.6 \pm 0.8\%$ ; TEGDME:  $76.8 \pm 0.7\%$  vs.  $75.4 \pm 0.7\%$ ). This further supports the conclusion that singlet oxygen is not a major source of degradation.

The absence of degradation arising from a reaction with  $\text{O}_2^-$  or  $^1\text{O}_2$  points to  $\text{Li}_2\text{O}_2$  as the possible source of degradation. To investigate the reactivity of ethers with already formed  $\text{Li}_2\text{O}_2$  surfaces, a known amount of  $\text{Li}_2\text{O}_2$  (synthesised in-house, see Methods) was added separately to solutions of 0.1 M LiTFSI in DME and TEGDME. After 24 hours of stirring, the quantity of  $\text{Li}_2\text{O}_2$  remaining was determined again by photometric titration. The amounts of  $\text{Li}_2\text{O}_2$  that remained, as a percentage of the amounts added initially, were  $98.0 \pm 0.8\%$  (DME) and  $97.7 \pm 0.8\%$  (TEGDME). This shows that the as-prepared  $\text{Li}_2\text{O}_2$  does not react with the electrolyte solution to an extent that explains the yield loss both in the chemical disproportionation reaction and on discharge.

The lack of reactivity with already formed  $\text{Li}_2\text{O}_2$  implies that it is the reaction between the electrolyte solution and the growing surface of the  $\text{Li}_2\text{O}_2$  particles that is primarily responsible for the  $\text{Li}_2\text{O}_2$  loss. If it is the freshly growing  $\text{Li}_2\text{O}_2$  surface that reacts with the electrolyte solution, then the rate of  $\text{Li}_2\text{O}_2$  particle growth should affect the extent of the side reactions and therefore the yield of  $\text{Li}_2\text{O}_2$ . If particles grow more rapidly, then less time is available for reaction with the electrolyte solution and the degree of degradation should be lower. To investigate this, the rate of  $\text{Li}_2\text{O}_2$  formation in the two different electrolyte solutions, LiTFSI in TEGDME and DME, were investigated. The same quantity of the electrolyte solution and  $\text{KO}_2$  were reacted for both systems with the pressure change monitored as a function of time to follow the  $\text{O}_2$  evolution and rate of  $\text{Li}_2\text{O}_2$  formation. The results are shown in Fig. 2, where it is clear that  $\text{Li}_2\text{O}_2$  grows significantly more rapidly in DME than in TEGDME, in accord with the higher yield of  $\text{Li}_2\text{O}_2$  and consequently lower amount of degradation products in the case of DME compared with TEGDME. The formation of larger particles in TEGDME (Fig. S2) is in accord with the slower growth rate. The two solvents have similar donor numbers (20 for DME and 16.6 for TEGDME)<sup>35</sup> and hence similar  $\text{Li}^+$  solvation, however the viscosity of TEGDME is much higher than DME (3.73 and 0.42 mPa s respectively)<sup>36</sup> which is primarily responsible for the slower formation of  $\text{Li}_2\text{O}_2$  and the larger particle sizes observed. Note that despite the larger particles and therefore lower surface area for  $\text{Li}_2\text{O}_2$  formed in TEGDME, the degradation is greater in TEGDME compared with DME, further emphasising the role of the  $\text{Li}_2\text{O}_2$  growth kinetics.

The importance of  $\text{Li}_2\text{O}_2$  growth rate on the  $\text{Li}_2\text{O}_2$  yield within a single solvent system was also examined. The same  $\text{KO}_2$  dispropo-

**Fig. 2** *In situ* pressure monitoring of the gas evolution during  $\text{KO}_2$  disproportionation in DME (blue) and TEGDME (green). The pressure was monitored in a sealed reaction vessel equipped with a pressure transducer, containing  $\text{KO}_2$  powder to which an electrolyte of 0.8 M LiTFSI in the relevant solvent was added whilst stirring. The pressure increase was expressed as a percentage of the total pressure increase that would be expected if all the  $\text{KO}_2$  reacted to form  $\text{O}_2$ .

portionation experiments with *in situ* pressure monitoring were performed in TEGDME with the lithium salt concentration modulated from 0.1 M to 2 M to change the reaction rate (Fig. S3). The rate of  $\text{O}_2$  evolution increased with increasing salt concentration, Fig. S3(a), while simultaneously the  $\text{Li}_2\text{O}_2$  yield also increased, Fig. S3(b). This reinforces the conclusion that the  $\text{Li}_2\text{O}_2$  growth rate is a critical factor that governs the overall extent of degradation and final  $\text{Li}_2\text{O}_2$  yield in ethers. Consistent with the growth rate, the morphology of the products showed smaller particles formed with higher salt concentration as the nucleation of  $\text{Li}_2\text{O}_2$  was more rapid (Fig. S4).

**Fig. 3** Quantity of  $\text{Li}_2\text{O}_2$  as a percentage of the theoretical yield of  $\text{Li}_2\text{O}_2$  after the  $\text{KO}_2$  disproportionation reaction, in DME (blue) and TEGDME (green), has gone to completion. The quantity of  $\text{Li}_2\text{O}_2$  was determined immediately after the reaction was complete (0 hours), and after a further 8, 16 and 24 hours of ageing.

As well as the rate of  $\text{Li}_2\text{O}_2$  particle growth, the degree of  $\text{Li}_2\text{O}_2$  loss will depend on the rate of reaction between the growing  $\text{Li}_2\text{O}_2$  surface and the electrolyte solution. To probe this, after the reaction between the lithium electrolyte solutions (0.8 M LiTFSI) and  $\text{KO}_2$  went to completion in DME and TEGDME (*i.e.* the time at which  $\text{O}_2$  evolution had reached the plateau in Fig. 2), the quantity of  $\text{Li}_2\text{O}_2$  was monitored as a function of time (Fig. 3). There is very little change in the amount of  $\text{Li}_2\text{O}_2$  in the case of DME, but for TEGDME, the amount of  $\text{Li}_2\text{O}_2$  continues to decrease in the first 8 hours, indicating further degradation on a slower timescale than in DME. Despite the slower reaction between  $\text{Li}_2\text{O}_2$  and TEGDME compared with DME, the  $\text{Li}_2\text{O}_2$  yield in TEGDME is lower, indicating that the increased length of exposure time of the freshly growing  $\text{Li}_2\text{O}_2$  surface due to the slow  $\text{Li}_2\text{O}_2$  growth in TEGDME is largely responsible for the difference in yield.

While the products of degradation associated with  $\text{O}_2$  reduction on discharging Li- $\text{O}_2$  cells with ether-based electrolytes have been identified previously, here we quantify their

relative amounts and compare them for the disproportionation of  $\text{KO}_2$  with LiTFSI in DME and TEGDME respectively.<sup>13–15</sup> Full experimental details of the characterisation procedures are provided in the Methods. PXRD and FTIR spectra of the collected solid products at the end of the reaction are shown in Fig. 4a and b. They confirm the formation of  $\text{Li}_2\text{O}_2$  as the main product along with  $\text{Li}_2\text{CO}_3$ ,  $\text{HCO}_2\text{Li}$  and  $\text{CH}_3\text{CO}_2\text{Li}$  as the side products in both DME and TEGDME. Solid-state  $^{13}\text{C}$  NMR identified the presence of ethylene oxides as an additional side-product (Fig. 4c). Following an established procedure, the peaks corresponding to the terminal  $-\text{CH}_3$  and chain  $-\text{CH}_2$  moieties were integrated, and by taking the ratios of the integrated areas, the ethylene oxide species detected were confirmed to have different average chain lengths in the two electrolytes;  $\text{CH}_3(\text{OCH}_2\text{CH}_2)_{1.3}\text{OCH}_3$  for DME and  $\text{CH}_3(\text{OCH}_2\text{CH}_2)_{4.8}\text{OCH}_3$  for TEGDME.<sup>37</sup> Solution  $^1\text{H}$  NMR spectra of the electrolytes after disproportionation of the  $\text{KO}_2$  powder show no evidence of solution-soluble organic products (Fig. S5). Karl Fischer titrations of electrolytes after the reac-

**Fig. 4** (a) PXRD, (b) ATR-FTIR and (c) solid-state  $^{13}\text{C}$  NMR spectra of solid products formed from  $\text{KO}_2$  disproportionation in an electrolyte of 0.8 M LiTFSI in DME (blue) and TEGDME (green). PXRD shows  $\text{Li}_2\text{O}_2$  is the main solid product with side products identified through ATR-FTIR as lithium formate, acetate, carbonate, and residual ether solvent molecules. Solid-state  $^{13}\text{C}$  NMR spectra of the solid products are compared to reference spectra of 1:1 commercial  $\text{C}_2\text{H}_3\text{LiO}_2$  and  $\text{CHLiO}_2$ , showing side products formed from degradation of  $\text{Li}_2\text{O}_2$  and glyme solvent, identified as lithium formate, acetate and ethylene oxides.

tions show the formation of  $\text{H}_2\text{O}$  as a product of degradation (Fig. 5).

The amount of  $\text{Li}_2\text{CO}_3$  formed was determined using mass spectroscopy to quantify the amount of  $\text{CO}_2$  evolved from its stoichiometric reaction with  $\text{H}_3\text{PO}_4$ .  $\text{HCO}_2\text{Li}$  and  $\text{CH}_3\text{CO}_2\text{Li}$  were quantified by  $^1\text{H}$  NMR of the dissolved solid product in  $\text{D}_2\text{O}$ , as described in the Methods. The amount of  $\text{Li}_2\text{CO}_3$ ,  $\text{HCO}_2\text{Li}$  and  $\text{CH}_3\text{CO}_2\text{Li}$  and  $\text{H}_2\text{O}$  are reported in Fig. 5. They are expressed as mole percentages of the theoretical amount of  $\text{Li}_2\text{O}_2$  expected from the quantity of  $\text{KO}_2$  used in the reaction. The amount of side products identified is greater in the case of TEGDME than in DME, in accord with the lower  $\text{Li}_2\text{O}_2$  yield in TEGDME.  $\text{HCO}_2\text{Li}$  is the dominant degradation product in both DME and TEGDME. The order of the prevalence of the side products,  $\text{HCO}_2\text{Li}$ ,  $\text{CH}_3\text{CO}_2\text{Li}$ ,  $\text{H}_2\text{O}$  and  $\text{Li}_2\text{CO}_3$ , are also similar.

We propose the origin of these degradation products to be by a surface confined hydrogen atom transfer (HAT) reaction at a secondary carbon site by  $\text{Li}_2\text{O}_2$ , forming an  $\alpha$ -alkoxyalkyl radical and hydroperoxide (Fig. 6). This initiation step is well

**Fig. 5** Moles of side-reaction products ( $\text{HCO}_2\text{Li}$ ,  $\text{CH}_3\text{CO}_2\text{Li}$ ,  $\text{H}_2\text{O}$  and  $\text{Li}_2\text{CO}_3$ ) quantified in the product formed from  $\text{KO}_2$  disproportionation in the electrolytes of 0.8 M LiTFSI in DME and TEGDME. The quantities of each side-reaction product are expressed as a percentage of the theoretical number of moles of  $\text{Li}_2\text{O}_2$  expected from the disproportionation reaction when all the  $\text{KO}_2$  reacts.

supported computationally, where facile dissociation of hydroperoxide to an electron rich  $\text{Li-O-Li}$  site and hydroxide (a potential source of  $\text{H}_2\text{O}$ ) is suggested.<sup>38,39</sup> The resulting  $\alpha$ -alkoxyalkyl radical participates in complex branching pathways, with two initial stages.<sup>40,41</sup> Firstly, radical recombination with an oxo-species gives hemiacetal-type structures, which are susceptible to base-mediated decomposition yielding reactive aldehydic compounds.<sup>38,39</sup> Simultaneously,  $\beta$ -scission of the alkoxy radical intermediate is known to yield carbonyl compounds while releasing a carbon-centred radical.<sup>40,42</sup> The latter propagates further reactions such as HAT or terminating radical processes which may account for contracted or extended ethylene oxides.<sup>43</sup> Both summarised pathways produce carbonyl bearing compounds which are susceptible to multiple degradation routes including enolisation to formate and alkoxides,<sup>44</sup> and reactions with peroxides, such as the Baeyer-Villiger or Dakin oxidations, that tend to yield carboxylates, *gem*-dihydroperoxides, or similar hemiacetal functionality.<sup>11,45,46</sup> Ultimately, the journey following HAT of the parent ether is nonlinear, eventually arriving at the common terminus of fragmented and highly oxidised hydrocarbons (formate, acetate, carbonate, *etc.*), coupled with the release of water. Although the yield of  $\text{Li}_2\text{O}_2$  and the amount of these degradation products can be determined, the number of possible branching degradation pathways, and volatile organic intermediates formed, makes it difficult to rationalise the relationship between the two. Furthermore, the reactivity between the solvent and the  $\text{Li}_2\text{O}_2$  surface could depend on which  $\text{Li}_2\text{O}_2$  surface facets are exposed, which in turn depends on the growth rate of the peroxide.<sup>38,39,47–49</sup> Disentangling these different phenomena is beyond the scope of this work, but future avenues for investigation are discussed more fully in SI Note 1.

Given that the differences in the rates of  $\text{Li}_2\text{O}_2$  formation between DME and TEGDME play a role in the extent of degradation, this implies that degradation will depend on the rate of discharge in  $\text{Li-O}_2$  cells. Electrochemical cells were constructed using 0.8 M LiTFSI in DME and TEGDME as electrolytes, as described in the Methods. The DME cells were discharged at two different rates and the TEGDME cell was dis-

**Fig. 6** Summary of the proposed degradation pathway of alkyl ethers at the  $\text{Li}_2\text{O}_2$  surface.

**Fig. 7** Li<sub>2</sub>O<sub>2</sub> yield quantified in cathodes discharged in electrolytes of 0.8 M LiTFSI in DME (blue) and TEGDME (green). Cells were discharged under O<sub>2</sub> at 0.13 mA cm<sup>-2</sup> and 0.52 mA cm<sup>-2</sup> in DME and 0.13 mA cm<sup>-2</sup> in TEGDME to a fixed capacity of 5.2 mA h cm<sup>-2</sup>. The Li<sub>2</sub>O<sub>2</sub> yield is expressed as a percentage of the theoretical moles of Li<sub>2</sub>O<sub>2</sub> expected for the amount of charge passed following an ideal 2e<sup>-</sup>/Li<sub>2</sub>O<sub>2</sub> reaction.

charged at the lower of the two rates. All were discharged to the same fixed capacity. The TEGDME cell could not reach this capacity at the higher rate. The yields of Li<sub>2</sub>O<sub>2</sub> at the end of discharge were determined and are reported in Fig. 7. The higher rate of discharge, 0.52 mA cm<sup>-2</sup> compared with 0.13 mA cm<sup>-2</sup> in DME, resulted in a higher Li<sub>2</sub>O<sub>2</sub> yield. TEGDME, compared with DME at the same lower discharge rate resulted in a lower Li<sub>2</sub>O<sub>2</sub> yield.

The discharged cathodes were characterised using the same methods as for the solid products of KO<sub>2</sub> disproportionation, which revealed identical side-products formed in both cases (Fig. S6 and S7). Unlike the KO<sub>2</sub> chemical results, when formed electrochemically the growth rate of Li<sub>2</sub>O<sub>2</sub> is controlled by the current density which in turn controls the morphology of the products. Similar toroidal particles were produced on cathodes discharged at the same current density of 0.13 mA cm<sup>-2</sup> in both DME and TEGDME (Fig. S8), emphasising that it is the rate of growth that primarily determines the particle size. From previous studies, it is known that increasing the discharge current rate tends to smaller Li<sub>2</sub>O<sub>2</sub> particle sizes and smaller capacities.<sup>48,50</sup> While faster discharge and hence growth of Li<sub>2</sub>O<sub>2</sub> may therefore provide a strategy to mitigate degradation to an extent, this is not a practical solution to the problem as large capacities at different discharge currents are required in a cell in practice. The results of this study therefore highlight that improving solvent stability is the critical requirement to achieving a competitive cycle life in Li–O<sub>2</sub> cells.

## Conclusions

Loss of Li<sub>2</sub>O<sub>2</sub> (*i.e.* low yields) and degradation of the electrolyte arise from the reaction between the growing surfaces of Li<sub>2</sub>O<sub>2</sub>

particles and the electrolyte. There is no evidence that O<sub>2</sub><sup>-</sup> or singlet O<sub>2</sub> play a significant role in the electrolyte degradation or low Li<sub>2</sub>O<sub>2</sub> yield. The Li<sub>2</sub>O<sub>2</sub> growth rate in dimethoxyethane is faster and the degree of electrolyte degradation is lower than that in tetraethylene glycol dimethyl ether, in accord with the lower viscosity of dimethoxyethane. This work expands upon previous studies by showing that the relative prominence of the degradation products, Li<sub>2</sub>CO<sub>3</sub>, HCO<sub>2</sub>Li, CH<sub>3</sub>CO<sub>2</sub>Li and H<sub>2</sub>O are similar in both solvents, emphasising that the rate of Li<sub>2</sub>O<sub>2</sub> formation only affects the overall extent of degradation. The composition of the ethylene oxide species that form was also determined for both solvents. By demonstrating that the origin of degradation and loss of Li<sub>2</sub>O<sub>2</sub> (*i.e.* low yields) arises from the reaction between the growing Li<sub>2</sub>O<sub>2</sub> particle surfaces and the electrolyte solution, and not from O<sub>2</sub><sup>-</sup> or singlet O<sub>2</sub>, we direct future research towards informed electrolyte solvent design with an emphasis on stability at the growing Li<sub>2</sub>O<sub>2</sub> surface, potentially leading to an improvement in Li–O<sub>2</sub> cell cycle life.

## Experimental

### Materials and methods

Bis(trifluoromethane)sulfonyl imide lithium salt (LiTFSI), 1,2-dimethoxyethane (DME), tetraethylene glycol dimethyl ether (TEGDME), 9,10-dimethylantracene (DMA) were purchased from Sigma Aldrich. DME and TEGDME were dried over activated molecular sieves (type 4 Å, Aldrich) before use. LiTFSI was dried at 120 °C under vacuum for 3 days before transferring and storage inside an Ar-filled glovebox (H<sub>2</sub>O and O<sub>2</sub> content ~1 ppm). The water content of all electrolyte solutions formed within the salt and solvent was <8 ppm, determined by Karl-Fischer (KF) titration. Potassium dioxide (KO<sub>2</sub>) and lithium formate monohydrate were purchased from Sigma Aldrich, and lithium acetate and lithium carbonate were purchased from Thermo Scientific. Li<sub>2</sub>O<sub>2</sub> was synthesised in-house following established methods as reported previously.<sup>51,52</sup> All materials were stored in an Ar-filled glovebox before use.

### Chemical disproportionation reaction

Chemical disproportionation of KO<sub>2</sub> to Li<sub>2</sub>O<sub>2</sub> in Li<sup>+</sup>-containing electrolytes was carried out by reacting samples of 3.0 mg of KO<sub>2</sub> powder with 1 mL of 0.8 M LiTFSI in DME or TEGDME under stirring. *In situ* pressure monitoring during disproportionation was used to determine the reaction kinetics and the time taken to reach the endpoint of the reaction in each electrolyte. The pressure was monitored in a sealed reaction vessel equipped with a pressure transducer (Omega Engineering Ltd). The time for the reaction to reach completion was marked by the time at which the pressure stopped increasing, indicating no further O<sub>2</sub> evolution.

The amount of O<sub>2</sub> liberated during the reaction was quantified by online mass spectrometry (Thermo Scientific) using Ar carrier gas at a flow rate of 1 mL min<sup>-1</sup>. The Li<sub>2</sub>O<sub>2</sub> yield was

quantified by photometric titration with UV-vis spectrometry (Thermo Fisher Evolution 220), following a method reported previously.<sup>33,34</sup> The UV-vis absorbance was calibrated against solutions containing known amounts of  $\text{Li}_2\text{O}_2$ , to which the same quantity of electrolyte was added as was present in the reaction mixtures to correct for its contribution to the absorbance signal. Errors in determining the  $\text{Li}_2\text{O}_2$  and  $\text{O}_2$  yields are estimated based on the errors from the gas flow regulator, weighing of  $\text{KO}_2$  powder and pipetting.

### Electrochemical measurements

Airtight Swagelok-type Li– $\text{O}_2$  cells were assembled as reported previously<sup>12</sup> and consisted of a porous carbon gas diffusion cathode to which high-purity  $\text{O}_2$  (BOC, N5.5) was supplied in a sealed tube. 3 glass fiber separators (Whatman GF/C) of 13 mm diameter were filled with 250  $\mu\text{L}$  of electrolyte and a partially oxidised  $\text{LiFePO}_4$  electrode was used as a substitute for a Li-metal anode. When partially delithiated,  $\text{Li}_x\text{FePO}_4$  has a fixed potential of 3.45 V vs.  $\text{Li}^+/\text{Li}$  and is stable in contact with the electrolyte solution. The remaining de-lithiation capacity of the  $\text{Li}_x\text{FePO}_4$  electrode was ensured to be greater than the targeted discharge capacity of the cathodes. The use of such a  $\text{Li}_x\text{FePO}_4$  electrode has been described previously.<sup>12</sup> The porous cathodes were composed of carbon black (Super P, Alfa Aesar), which was pre-treated under an Ar :  $\text{H}_2$  (95 : 5 v/v) gas at 900 °C for 6 hours, and PTFE binder (Sigma-Aldrich) in an 85 : 15 w/w ratio. The electrodes were prepared from a slurry of carbon and PTFE (60 wt% dispersion in  $\text{H}_2\text{O}$ ) in isopropanol, which was dried, and the resulting mixture was pressed into 5 mm diameter discs of 2.0 mg mass. All electrodes and cell components were dried at 120 °C under vacuum for 24 hours before use and were stored in an Ar-filled glovebox without exposure to air. Cells were assembled and discharged inside the glovebox. Galvanostatic discharge was carried out using a VMP3 Biologic potentiostat. *In situ* pressure monitoring during discharge was performed by attaching a pressure transducer to the airtight Swagelok-type cell. After discharge, a similar protocol was applied to quantify the  $\text{Li}_2\text{O}_2$  yield in the discharged cathodes using UV-Vis spectroscopy. Discharged cathodes were rinsed with DME twice and dried under vacuum at room temperature for further characterisation.

### Characterisation and quantification of reaction products

The mixture after the chemical disproportionation reaction was centrifuged and the supernatant filtered through a 1  $\mu\text{m}$  pore glass filter for solution-state  $^1\text{H}$  nuclear magnetic resonance (NMR) analysis on a 600 MHz Bruker spectrometer. The solids after centrifugation were rinsed with DME twice before drying under vacuum at room temperature. Powder X-ray diffraction (PXRD) patterns of dried solids were acquired using a Rigaku Miniflex X-ray diffractometer and ATR-FTIR spectra were acquired with a Thermo Fisher Nicolet iS50 spectrometer, both in a  $\text{N}_2$ -filled glovebox. Solid-state  $^{13}\text{C}$  NMR spectra were acquired with a 400 MHz Bruker spectrometer, where dried solids were packed into an airtight sample holder before being transported outside of the glovebox for measurements. The

morphologies of the solid products were observed by FE-SEM (Zeiss-Merlin) with an airtight transfer to avoid any exposure to air.

The amount of  $\text{Li}_2\text{CO}_3$  in the dried solids and dried cathodes were quantified by treating them with 1 M  $\text{H}_3\text{PO}_4$  (which reacts specifically with  $\text{Li}_2\text{CO}_3$ , not the organic carbonates) and monitoring the  $\text{CO}_2$  evolution by online mass spectrometry using Ar carrier gas at a flow rate of 1  $\text{mL min}^{-1}$ .  $\text{HCO}_2\text{Li}$  and  $\text{CH}_3\text{CO}_2\text{Li}$  in the solids were quantified by solution-state  $^1\text{H}$  NMR measurements. 5 mg of the solid was dissolved in 1 mL  $\text{D}_2\text{O}$ , and the solutions sealed inside airtight J-Young NMR tubes in an Ar-filled glovebox for measurement on a 600 MHz Bruker spectrometer equipped with a cryoprobe. Calibration curves were obtained from reference samples of  $\text{HCO}_2\text{Li}$  and  $\text{CH}_3\text{CO}_2\text{Li}$  of known concentrations. The amount of  $\text{Li}_2\text{CO}_3$ ,  $\text{HCO}_2\text{Li}$  and  $\text{CH}_3\text{CO}_2\text{Li}$  per unit mass of solid product formed is then correlated to the  $\text{Li}_2\text{O}_2$  yield through quantifying the amount of  $\text{Li}_2\text{O}_2$  in a unit mass of solid product. An equivalent protocol was applied to discharged cathodes for analysis of the side product species formed after discharge.

## Author contributions

C. C. performed chemical and electrochemical measurements. C. C. and T. N. performed pressure monitoring measurements on chemical disproportionation reaction and analysed the data. C. C. characterised reaction products and discharged cathodes with contributions from T. N. and D. D. D. D. performed pressure monitoring measurements on discharge and analysed the data. G. R. performed solid state NMR measurements and analysed the data. C. C., D. D., C. T., and T. N. analysed data. K. J. and L. J. analysed data and visualised the degradation mechanism. P. G. B., X. G., C. C., and D. D. interpreted the data. X. G. and P. G. B. wrote the manuscript with contributions from D. D., C. T., and C. C.

## Conflicts of interest

There are no conflicts to declare.

## Data availability

The datasets used and analysed during the current study are available from the corresponding author upon reasonable request.

Supplementary information is available. See DOI: <https://doi.org/10.1039/d5eb00137d>.

## Acknowledgements

P. G. B. acknowledges financial support from the EPSRC, the Henry Royce Institute for Advanced Materials (EP/R00661X/1,

EP/S019367/1, EP/R010145/1, EP/L019469/1) and from the Faraday Institution, as well as the use of characterisation facilities within the David Cockayne Centre for Electron Microscopy, Department of Materials, University of Oxford. X. G. acknowledges financial support from the National Natural Science Foundation of China (22309110) and Shanghai Rising-Star Program. KDJ & LRJ acknowledge financial support from the Faraday Institution (FIRG065).
