Sustainability Spotlight Statement

In the context of a growing global pursuit of sustainable food systems, the development of natural, efficient flavor precursors and antioxidants has become a critical direction for the food industry. The use of TTCA/ARP as natural flavor precursors and antioxidants can contribute to: (1) Reducing reliance on synthetic additives, supporting cleaner labels and potentially lowering the environmental burden associated with chemical synthesis; (2) Minimizing food waste through enhanced product stability and extended shelf-life; (3) Optimizing energy efficiency in food processing, as flavor formation can be regulated under varied, potentially milder thermal conditions. Utilizing natural and renewable precursors (cysteine and xylose) in a value-adding reaction.

Abstract

2-Threityl-thiazolidine-4-carboxylic acid (TTCA) and Amadori rearrangement product (ARP), as intermediates of xylose-cysteine (Cys-Xyl) Maillard reaction system, have been proven to form desirable flavor during thermal processing. The results showed that both TTCA and ARP revealed excellent environmental stability at low temperature (≤ 25℃), neutral pH (7), and low water activity (0.113). Under storage conditions of 40°C, pH 9, and water activity of 0.843, the loss rates of TTCA and ARP reached 7.06%/12.17%, 11.19%/21.25% and 35.77%/60.61%, respectively. Further research found that TTCA and ARP compounds have increased Fe^{2+} chelating ability, reducing power, and free radical scavenging ability within the concentration range from 0.5 to 3.0 mg/mL. Additionally, different heat treatment conditions as well as addition of different exogenous amino acids could regulate the flavor formation profile and characteristics of TTCA, making it adapt to different real food systems, broadening its processing adaptability. Especially when the pH increased from 5.5 to 8, the meaty flavor of the system gradually lightened, while flavor characteristics such as popcorn flavor, burnt flavor, and nutty flavor gradually strengthened. This research explored the potential of natural flavor precursors MRIs as a supplement and partial alternative to synthetic additives. The findings provide a theoretical basis for developing more sustainable food systems and may help reduce the environmental footprint of food processing.

Key words: sustainable food additives, Maillard reaction intermediate, flavor formation rules, storage stability, antioxidant characteristics.

D-xylose (PubChem CID: 135191); L-Cysteine (PubChem CID: 5862); Acetonitrile (PubChem CID: 6342); Methanol (PubChem CID: 887); Deuteroxide (PubChem CID: 24602); Ammonium formate (PubChem CID: 10904).

1. Introduction

In the context of a growing global pursuit of sustainable food systems, the development of natural and efficient additives has become a critical direction for the food industry. Maillard reaction intermediates (MRIs), Amadori/Heyns rearrangement compounds (ARPs/HRPs), as naturally derived compounds, hold significant potential as clean-label alternatives to synthetic flavor precursors and antioxidants. [1,2] Compared to complex and variable complete Maillard reaction products (MRPs), MRIs provide a stable and controllable source for generating ideal flavor and color upon thermal processing. [3] In particular, the Cys-Xyl system yields both the conventional ARP and a unique thiazolidine derivative, TTCA. [4,5] Current studies have investigated the fundamental aspects of TTCA and ARP, [6,7] including their aqueous-phase tracing preparation mechanism, characteristic patterns of flavor formation and yield enhancement. [8,9] These investigations have preliminarily demonstrated their advantages in controlled flavor formation, underscoring their potential as flavor precursors.

Existing studies confirmed that the flavor intensity in thermal processed MRIs exhibits significant advantages, however the profile of characteristic volatile compounds generated from MRIs remains less diverse compared to MRPs. [8,9] While adjusting reaction parameters is a common regulatory approach, its ability to fully compensate for the lack of flavor complexity may be limited. [10–13] The addition of exogenous amino acids presents a promising alternative for modulating flavor, which could promote the Strecker degradation

View Article Online
DOI: 10.1039/D5FB00932D

between regenerated amino acids derived from MRIs degradation and dicarbonyl compounds to form characteristic flavor. [14,15] Nevertheless, the systematic effect of different exogenous amino acids on the flavor profiles derived from specific intermediates, such as TTCA/ARP, is not yet clear. Moreover, comprehensive approaches for regulating the flavor profile of TTCA/ARP are currently lacking. Besides, to enable flavor formation exclusively during subsequent thermal processing, MRIs must maintain stability during storage. [16] However, MRIs can further degrade through rearrangement and condensation pathway. [17,18] Thus, understanding their behavior during storage and heating is essential for commercial application. Concurrently, developing natural antioxidants is crucial for food preservation. [19–21] MRPs exhibit confirmed antioxidant, antiallergic, and antibacterial activities, [22–24] due primarily to the chromophoric rings of melanoidins. [22,25] Certain low-molecular-weight compounds in MRPs, especially reductones and heterocycles, exhibit greater antioxidant activity than pure melanoidins. [19] However, the specific contribution and efficacy of defined intermediate compounds like TTCA and ARP have not been comparatively evaluated against MRPs.

Therefore, to address the current research gap regarding TTCA and ARP, this study adopts a unique perspective to investigate the regulatory mechanisms of their flavor characteristics, storage stability, and antioxidant properties, and aims to comprehensively evaluate the dual-function potential of TTCA and ARP as flavor precursors and antioxidants through the following objectives: (1) Systematically assess the storage stability of TTCA and ARP under different environmental stresses, providing essential data for their commercial storage; (2) Elucidate the directional regulation of TTCA thermal degradation flavor profiles by temperature, pH, and various exogenous amino acids,

View Article Online
DOI: 10.1039/D5FB00932D

thereby extending their processing adaptability; (3) Evaluate and compare the in vitro antioxidant activities of TTCA/ARP with those of MRPs, clarifying their roles and potential in different antioxidant pathways. This work provides essential data for the commercial storage and application of TTCA/ARP, extends their processing adaptability, and clarifies their dual-function potential as natural flavor precursors and potential antioxidants, thereby supporting their development as sustainable food additives.

2. Materials and Methods

2.1 Chemicals.

Analytical grade L-cysteine, D-xylose, sodium hydroxide, 1,2,4-benzenetrio, phenanthroline, potassium ferricyanide, trichloroacetic acid, $FeCl_3$, DPPH, ethanol, 1,10-phenanthroline, $FeSO_4$, ascorbic acid, lecithin, thiobarbituric acid, H_2O_2, NaOH and HCl were purchased from Sigma-Aldrich Chemical Co. (Shanghai, China). LC-MS grade water, acetonitrile, deuteroxide ammonium formate and 1,2-dichlorobenzene were purchased from Sinopharm Chemical Reagent Co. Ltd (Shanghai, China).

2.2. Synthesis, Purification and Characterization of Isomeric TTCA and ARP.

The preparation and characterization of TTCA and ARP purities were carried out referring to the methods of our previous studies. [4,26] An equimolar solution of Cys and Xyl (0.0827 mol/L) was prepared using deionized water. The prepared solution was maintained at pH 7.4 ± 0.01 using NaOH (6 mol/L), followed by the heat treatment for 40 min at 90 ℃. The reaction vessel was promptly transferred to an ice-bath to terminate the reaction immediately. The obtained reactant was employed to get TTCA and ARP purities, which were preliminarily separated using an ion exchange resin (H^+ Dowex 50WX4, 200-400 mesh, Acros Organics, SERVA, J&K, Beijing, China) with ammonium hydroxide (0.2

View Article Online
DOI: 10.1039/D5FB00932D

mol/L) as the eluent, and the further purification was carried out through a semi-preparative RP-HPLC equipped with an Xbridge Amide column (4.6 mm × 150 mm, 3.5 μm; Waters Co., Milford, MA, USA). The identification and characterization of TTCA and ARP purities were performed using UPLC-ESI-MS (Waters Synapt MALDI Q-TOF MS, USA) and NMR (Bruker DRX 400 MHz spectrometer). The specific procedures of the methods mentioned above were accomplished referring to our published study. The mass spectral and NMR spectral information were listed in the Supporting Information (Figure S1, Table S1).

2.3. Assessment of the browning index of the Maillard reaction solution.

To assess the browning degree of the melamine reaction solution under variable temperatures, the absorbance at 420 nm (A_{420}) was typically measured using a UV-visible spectrophotometer and served as the browning index. The absorbance was determined by diluting the sample to a suitable number of times so that the A_{420} value fell as close as possible to a reasonable range (0.05 to 1.0).

2.4. Construction of Maillard thermal reaction model system using TTCA as the base material.

Maillard thermal reaction model systems were established with TTCA as the base material. The pH of the TTCA solution (10 mmol/L) was adjusted to 5.5, 7, 8, respectively, using NaOH (6 mol/L). The prepared samples were then treated at varying temperatures (100°C, 120°C, and 140°C) for 120 minutes.

Additionally, an equimolar amount of different exogenous amino acids (Gly, Ala, Met, Leu, Ser, Thr, Pro, Val, Phe, His, Lys, Glu, Asp) was added to the TTCA solution (10

View Article Online
DOI: 10.1039/D5FB00932D

mmol/L). The pH of the system was adjusted to 7.0 using NaOH (6 mol/L), and the thermal reaction was conducted at 120°C for 120 minutes.

Using high-temperature/high-pressure resistant glass reaction vessels set in an oil bath, the aforementioned thermal reactions were carried out. Following this, to halt the reactions, all mixtures were immediately transferred to an ice bath. Afterwards, samples were gathered and kept under 4 ℃ for further analysis.

2.5. Determination of storage stability of TTCA and ARP.

To investigate the effect of different storage temperatures on the stability of TTCA and ARP intermediates in solid and solution forms, the solid pure lyophilized powder of TTCA and ARP was placed in self-sealing bags or dissolved in deionized water and configured as a solution with a concentration of 100 mmol/L, and placed in the ambient temperatures of 4℃, 25℃ and 40℃, and the changes in concentration, A_{420}, A_{294}, and color were recorded at intervals of 10 days in the storage process. The concentration, A_{420}, A_{294} and color changes during storage were recorded every 10 days, and the storage stability was investigated over a 60-day period.

In addition, the storage stability of the TTCA and ARP system was observed by varying the pH of the system while maintaining the same ambient temperature, and the same metrics were also examined. For TTCA and ARP solid samples, the effect of ambient humidity on their storage stability was investigated. A fixed mass of dried powder of the intermediate was taken in an open glass petri dish and transferred to a sealed desiccator, where the bottom of the desiccator was filled with different saturated salt solutions configured to maintain the ambient moisture activity of the system, where the comparison

View Article Online
DOI: 10.1039/D5FB00932D

table of the moisture activity of different saturated salt solutions at 25°C is shown in Table S2.

2.6. Determination of antioxidant properties of intermediates.

(1) Measurement of Fe^{2+} chelating capacity.

Determination of the Fe^{2+} chelating capacity was conducted based on a previously established method.[27] 1 mL of sample was combined with 1.85 mL of deionized water, followed by the addition of 0.05 mL of $FeCl_2$ phenanthroline solution (5 mmol/L). After standing at 28 °C for 30 seconds, the mixture was allowed to react for an additional 10 minutes under the same temperature. It was then centrifuged at 3000 rpm for 5 minutes. Absorbance of the supernatant was measured at 562 nm using a UV-Vis spectrophotometer. A blank control was prepared by replacing the sample with deionized water and analyzed identically. The chelating capacity was calculated using the following formula:

$$Fe^{2+}\text{chelation Rate} = \frac{A_0 - A_1}{A_0} \times 100\%$$

Where A_0 and A_1 are the absorbance of the blank and sample, respectively.

(2) Measurement of reducing power.

The assay was initiated by mixing 1 mL of sample solution with 2.5 mL of phosphate buffer (pH 6.6) and 2.5 mL of 1% potassium ferricyanide solution. The resulting mixture was incubated in a 50 °C water bath for 20 minutes, followed by the addition of 2.5 mL of 10% trichloroacetic acid. After centrifugation at 3000 rpm for 10 minutes, 2.5 mL of the supernatant was collected and combined with 2.5 mL of 0.1% $FeCl_3$ solution and 2.5 mL of deionized water. Following a 10-minute reaction period, the absorbance at 700 nm (A_{700}) was measured using a UV-Vis spectrophotometer to indicate the sample's reducing power.[28]

View Article Online
DOI: 10.1039/D5FB00932D

(3) Measurement of DPPH free radical scavenging capacity.

The assay was initiated by combining 3 mL of 100 μmol/L DPPH ethanol solution with 1 mL of the sample. The mixture was then incubated in the dark at room temperature for 25 minutes. Its absorbance at 517 nm (Ai) was measured using a UV-visible spectrophotometer, with ethanol serving as the blank. Similarly, the absorbance of a control mixture containing 1 mL of ethanol and 3 mL of DPPH solution was recorded as A_0. Additionally, a sample background absorbance (Aj) was obtained by measuring a mixture of 1 mL of sample and 3 mL of ethanol. The DPPH radical scavenging capacity was calculated using the following formula:

$$\text{DPPH• Clearance Rate} = \left(1 - \frac{A_i - A_j}{A_0}\right) \times 100\%$$

(4) Measurement of hydroxyl radical scavenging capacity.

For the assay, 1 mL of 2.5 mmol/L 1,10-phenanthroline was combined sequentially with 2 mL of phosphate buffer (pH 7.40), 1 mL of 2.5 mmol/L $FeSO_4$ solution, 1 mL of deionized water, and 1 mL of 20 mmol/L H_2O_2. Following a 60-minute incubation at 37°C in a water bath, the absorbance of the mixture at 536 nm was recorded immediately on a UV-Vis spectrophotometer. The scavenging capacity against hydroxyl radicals was calculated using the formula below:

$$\text{•OH Clearance Rate} = \frac{A_S - A_1}{A_0 - A_1} \times 100\%$$

where A_S represents the absorbance of the sample; A_1 denotes the absorbance of the control reaction solution, which containing 1, 10-phenanthroline, $FeSO_4$ and H_2O_2; and A_0 corresponds to the absorbance of the blank solution, composed solely of $FeSO_4$ and 1, 10-phenanthroline.[7]

View Article Online
DOI: 10.1039/D5FB00932D

(5) Measurement of superoxide anion radical scavenging capacity.

The method is grounded in the principle that antioxidants bind to superoxide anion radicals, forming stable species and thereby terminating the radical chain reaction, which releases chromogenic products. According to this principle, 9 mL of 50 mmol/L Tris-HCl buffer (pH 8.2) was combined with 0.5 mL sample and incubated in a water bath at 25°C for 20 minutes. Immediately thereafter, 0.04 mL of a pre-warmed (25°C) 1,2,4-benzenetriol solution (prepared by dissolving 0.45 mmol of 1,2,4-benzenetriol in 10 mL of 10 mmol/L hydrochloric acid) was added. After a 3-minute standing period, one drop of 10 mmol/L ascorbic acid solution was introduced. Following an additional 5-minute incubation, the mixture's absorbance at 327.2 nm (A_{327}) was measured using a UV-Vis spectrophotometer. The superoxide anion radical scavenging capacity was calculated using the following formula:

$$O_2^{-}\bullet \text{ Clearance Rate} = \frac{A_0 - A_1}{A_0} \times 100\%$$

Where A_0 represents A_{327} of the blank and A_1 represents the A_{327} of sample.[7]

(6) Measurement of lipid peroxidation inhibition capacity.

A 10.0 mg/mL lecithin dispersion (denoted S_1) was prepared in 0.01 mol/L phosphate buffer (pH 7.4) using a magnetic stirrer. Separately, solution S_2 was prepared by dissolving 15 g trichloroacetic acid, 0.37 g thiobarbituric acid, and 2 mL concentrated hydrochloric acid in deionized water, followed by dilution to a final volume of 100 mL. For the assay, 1.0 mL of S_1 was mixed sequentially with 1.0 mL of 400 μmol/L $FeCl_3$ solution, 1.0 mL of 400 μmol/L ascorbic acid solution, and 1.0 mL of sample solution. The mixture was incubated at 37°C in a water bath for 60 minutes. Subsequently, 2.0 mL of S_2 was added, and the mixture was heated at 95°C for 15 minutes. After cooling in an ice-water bath for

View Article Online
DOI: 10.1039/D5FB00932D

10 minutes and centrifugation, the absorbance of the supernatant at 532 nm (A_{532}) was measured using a UV-Vis spectrophotometer. The lipid peroxidation inhibition rate was calculated as follows:

$$\text{Inhibition Rate} = \frac{A_0 - A_1}{A_0} \times 100\%$$

Where A_0 and A_1 denote the absorbance of the blank (deionized water as substitute) and the sample, respectively.[7]

2.7. Identification and Quantification of Characteristic Volatile Compounds.

The analysis of volatile flavor compounds was conducted using headspace solid-phase microextraction coupled with gas chromatography-mass spectrometry (HS-SPME-GC-MS). The sample solution (3 g) was added with 3 μL internal standard (1,2-dichlorobenzene, 0.018 μg/μL in methanol), which was then placed in the 20 mL headspace vial. The extraction and desorption procedures followed a previously published method,[15] employing a divinylbenzene/carboxen/polydimethylsiloxane (CAR/PDMS/DVB, 75 μm) SPME fiber. Compound separation and identification were achieved using an Agilent 7890B gas chromatograph interfaced with a 5977B mass selective detector. Following a 10-minute thermal desorption at 250 °C in the injection port, the volatiles were transferred onto the analytical column. Chromatographic separation was performed on a 30 m DB-Wax capillary column (0.25 mm i.d., 0.25 μm film thickness). Specific instrumental conditions were adopted from our prior research.[15]

Compound identification was based on matching mass spectra against the NIST 17, and WILEY 07 databases, comparing calculated Kovats retention indices (RI) with literature values, and referencing literature data. To facilitate accurate RI matching, the retention indices of target compounds were calculated by analyzing a C_7-C_{30} *n*-alkanes

View Article Online
DOI: 10.1039/D5FB00932D

series under identical chromatographic conditions. For compounds with available reference standards, their contents were determined by the standard curve method with internal standard calibration (see Table S3); for those without reference standards, quantification was performed just using the internal standard method.

2.8. Data analysis.

We performed all experiments in triplicate and report data as mean ± standard deviation. Data processing involved the following steps: 1) analysis using SPSS Statistics 22.0 and Microsoft Excel 2010; and 2) multiple comparison via Duncan's Multiple Range Test, where a *p*-value of less than 0.05 indicated statistical significance.

3. Results and Discussion

3.1 Regulating the characteristic flavors formation of TTCA intermediate through parameter regulation.

Given the established similarity in flavor formation pathways between TTCA and ARP (differing primarily in rate), TTCA was selected to investigate the effects of temperature and pH. As a key parameter, temperature is a key kinetic parameter in controlling the reaction progress. The appropriate increase of temperature is beneficial for accelerating effective collisions between substrates and the thermal degradation of cysteine.[29] Comparatively studying of heated TTCA models at 100°C, 120°C, and 140°C revealed that the total volatile flavor substances increased markedly, with sulfur-containing compounds showing a leapfrog increase (Table S4, Figure 1a). The content of furfural (the dominant furan) increased significantly, reaching 11.039 μg/L at 140°C, which was 3.3 times that at 100°C. The concentrations of 2-methyl-3-furanthiol and 2-furfurylthiol also increased accordingly. This is because high temperatures promote the enolization of ARPs,

View Article Online
DOI: 10.1039/D5FB00932D

leading to the rapid generation and accumulation of the direct precursors like 3-DX and 1-DX for furfural and 4-hydroxy-5-methyl-3(2H)-furanone (Figure 1f).[30] They also increase the generation of furan and 2-methylfuran, which are precursors to thiophene compounds (Figure 1f). Furthermore, elevated temperatures intensified the thermal degradation of TTCA and free Cys (Figure S2, S3), resulting in increased release of H_2S. The boosted supply of these key precursors (α-dicarbonyls, furans, H_2S) strengthened their interactions, thereby promoting the formation of corresponding thiols and thiophenes (Figure 1f).

Key steps such as enolization, retro-aldolization, and Strecker degradation are pH-dependent, the activity of key precursors like H_2S and NH_3 also varies with pH values.[3] Therefore, the influence of different reaction pH (5.5, 7, and 8) on the TTCA thermal reaction system was studied. The characteristic volatile compounds were predominantly sulfur-containing (Table S5). Figure 5b details the concentrations of key flavor classes. Under acidic condition (pH 5.5), thiols were most abundant, followed by thiophenes; no nitrogen-containing heterocycles were detected. As pH increased from 5.5 to 8, thiol and furan contents decreased, while thiazoles increased sharply to 10.952 μg/L. Notably, 2-acetylthiazole (nutty/popcorn odor) increased significantly with pH, comprising 27.01% of total thiazoles at pH 8. Pyrazines were only detected at pH 8 (0.838 μg/L), a much lower concentration compared to sulfur-containing flavors. Post-reaction, the system pH dropped (to 5.1, 4.9, and 4.7, respectively), due to organic acid formation from accelerated TTCA degradation at higher initial pH. Under acidic conditions, TTCA undergoes 1,2-enolization, generating thiol and furan precursors (Figure 1f).[15] The low thiazoles and pyrazines contents under acidic conditions is due to the superior competitiveness of H_2S over NH_3/amines in capturing reactive α-dicarbonyl intermediates including glyoxal,

View Article Online
DOI: 10.1039/D5FB00932D

methylglyoxal, 2,3-butandione, and so on.[17] In contrast, alkaline conditions enhanced the nucleophilicity of deprotonated NH_3/amines, enabling them to successfully compete for intermediates and drive the formation of thiazoles and pyrazines, imparting roasted notes. [17] Alkaline conditions also favor the regeneration of Cys during TTCA degradation, promoting Strecker degradation with α-dicarbonyls and further amplifying thiazoles/pyrazines formation (Figure 1f).[3]

In summary, increased temperature universally intensified flavor formation by elevating precursor supply and reaction rates. In contrast, increased pH altered the fundamental reaction pathway, shifting the flavor profile from sulfur-rich/meaty notes toward nitrogen-containing heterocycles associated with roasted characteristics. These findings confirmd that targeted parameter control (temperature, pH) can effectively steer the flavor formation pathways of TTCA, demonstrating its adaptable potential for generating diverse flavor profiles under different processing conditions.

3.2 Addition of exogenous amino acids regulating the formation of characteristic flavors of TTCA reaction system.

While TTCA intermediates produce intense flavors surpassing those of typical MRPs, their volatile compound diversity is limited.[31] The formation of key flavor compounds such as pyrazines, pyridines, pyrroles, thiazoles, and Strecker aldehydes may require sufficient exogenous amino acids to participate in subsequent thermal reactions of the intermediates.[15,31] To further elucidate the effects of different amino acids, types with varying isoelectric points and side chain groups were selected to combine with TTCA for thermal reactions. Browning intensity was significantly higher ($p < 0.05$) in systems with

View Article Online
DOI: 10.1039/D5FB00932D

added amino acids than in the TTCA control (Figure 1c), likely because amino acids react with carbonyl compounds in later stages to form colored polymers. [32]

Volatile analysis revealed that all systems predominantly generated sulfur-containing compounds (Table 1, Figure 1d, e), driven by the high reactivity of H_2S and NH_3 released from TTCA degradation (Figure 1f). [10] Results showed that side chains of the added amino acids had a negligible influence on sulfur-containing flavor formation (Table 1). High levels of 2-methyl-3-furanthiol and 2-furfuryl thiol were detected across all systems. This consistent presence indicated that added amino acids did not inhibit the key pathway leading to these furans—namely, the dehydration and cyclization of deoxyosones during TTCA degradation (Figure 1f).[33] Furthermore, sulfur heterocycles requiring the participation of α-dicarbonyls (e.g., 2-methyl-thiophene, thieno[3,2-b]thiophene, thiazole) were detected and were common to all systems supplemented with Gly, Lys, or Glu (Figure 1f).[34] This reinforces that the core pathway for sulfur-containing flavor generation is governed by α-dicarbonyl formation rather than by the specific side chains of the added amino acids. The addition of the three exogenous amino acids can promote the retro-aldol cleavage of deoxyosones, yielding more short-chain α-dicarbonyl compounds and reductive ketones, which expanded flavor diversity (including sulfur compounds and pyrazines), and contributed to enhanced browning.[13] Gly supplementation produced the greatest variety of flavor compounds, possibly due to its propensity to form short-chain reactive aldehydes.[35] Lys significantly increased flavor variety ($p < 0.05$), likely because its additional amino group boosted α-dicarbonyl formation via reactions with sugar chains.[36]

View Article Online
DOI: 10.1039/D5FB00932D

316 Compared to the TTCA control, systems with Gly, Lys, or Glu showed reduced
317 thiazole content/variety but increased nitrogenous heterocycles, confirming greater NH_3
318 participation in pyrazine formation (Figure 1f).[37] The TTCA-Lys thermal reaction system
319 could generate pyrazines. At the system pH (7.0), some Lys remained undissociated and
320 acts as a nucleophile, reacting with sugar residues to produce short-chain α-dicarbonyls
321 that subsequently formed pyrazines[38](Figure 1f). In contrast, TTCA-His produced less
322 meat or roasting aroma (Table 1), as its imino group is less reactive than amino group to
323 form carbonyl compounds as a nucleophile.[29] Moreover, the imidazole group with strong
324 basic properties has lower reactivity and is less likely to participate in the formation of
325 flavor compounds. [35] In addition to Lys, the TTCA thermal reaction system supplemented
326 with Glu also detected a considerable amount of pyrazine compounds, which is consistent
327 with previous research.[39] Beyond pyrazines, pyrroles were detected in all three systems,
328 linked to reactions between α-dicarbonyls (MGO/GO) and NH_3 (Figure 1f).[40] Among them,
329 2-methylpyrrole and pyrrole were synthesized via an aldol condensation between
330 MGO/GO and acetaldehyde, followed by nucleophilic addition with NH_3 and dehydration.
331 2-Pyrrolecarboxaldehyde was produced by nucleophilic addition of NH_3 to a 3-DX isomer,
332 followed by dehydration and cyclization (Figure 1f).[41] The large amount of pyridine
333 compounds in the TTCA-Lys reaction system was generated by the Strecker degradation
334 reaction between Lys and α-dicarbonyl compounds, followed by subsequent dehydration
335 reactions (Figure 1f).[42]

336 Furans (mainly 2-methylfuran and furfural) were formed in TTCA reaction systems
337 with Gly, Lys, or Glu but not in a TTCA-Cys system, indirectly confirming the critical role
338 of H_2S from Cys degradation in diverting precursors toward sulfur-containing flavors. In

summary, supplementing TTCA with Gly or Lys enriched the overall flavor profile (sulfur compounds and pyrazines), while Glu specifically promoted pyrazine formation ($p < 0.05$). Exogenous amino acids help shift the reaction equilibrium by ensuring sufficient α-dicarbonyl precursors for key flavor pathways.[43] Simultaneously, incorporating various exogenous amino acids can markedly enhance the browning development in the TTCA thermal reaction system. These results suggest that combining Gly, Lys, or Glu with TTCA could enhance TTCA's versatility for generating desired colors and flavors in diverse food applications.

3.3 Extremely high environmental stability of TTCA and ARP intermediate to act as natural flavoring additives.

The storage environment is a key factor affecting the structure, content and physicochemical properties of all kinds of chemical products in the storage process.[44] In this study, the storage stability of TTCA and ARP was investigated . The key finding is that TTCA exhibits superior storage stability compared to ARP across all conditions tested, attributable to its stable cyclic molecular structure. [3] Both intermediates were highly stable at 4°C and 25°C. Degradation became noticeable only under stress conditions: at 40°C, TTCA concentration decreased by 7.06% after 60 days, less than ARP's 12.17% loss. The increased degradation at elevated temperature is linked to water autoionization, [45] which catalyzes the enolization and ring-opening of ARP.[44] Corresponding increases in A_{294} and A_{420} values at 40°C (Figure 2c and 2d) indicate the formation of carbonyl intermediates and browning products. [21]

The stability of TTCA and ARP solutions stored at pH 5.5, 7 and 9 was monitored for 60 days at room temperature (Figures 2e-h). The intermediates maintained stable

View Article Online
DOI: 10.1039/D5FB00932D

concentrations under acidic and neutral conditions (pH 5.5, 7). In contrast, at pH 9, the concentrations of TTCA and ARP decreased by 11.19% and 21.25% after 60 days, respectively. Meanwhile, the rise of A_{294} and A_{420} also indicate the alkaline-promoted degradation into downstream products. The slight decrease in TTCA concentration at pH 5.5—accompanied by opposing trends in A_{420} (increase) and A_{294} (decrease)—suggested a transformation distinct from degradation, potentially due to acid-catalyzed hydrolysis or reversion to *N*-xylosylamine.[45] This phenomenon is attributed to the formation of rearrangement reaction by deprotonation of imine positive ions, so the presence of H^+ under acidic conditions could promote the reverse reaction. [21]

Moisture content and water activity values of food products are key indicators of their shelf life and eating quality.[46] The stability of solid TTCA and ARP was assessed for 60 days under varying humidity levels. When stored under dry conditions (a_w 0.113) for 60 days, the TTCA content decreased by only 13.5% (Fig. 2i). This exceptional stability implies lower storage losses, reduced packaging demands, and potentially extended shelf-life in food applications. Elevated moisture activity significantly accelerated the degradation and browning of both TTCA and ARP. Colorimetric analysis (L^*, a^*, b^*, ΔE) showed that increased a_w led to darker samples (decreased L^*) and more pronounced overall color change (ΔE) (Table 2). Notably, the ΔE values for ARP were consistently higher than for TTCA under all humidity conditions, further corroborating TTCA's superior stability. A semi-quantitative estimate indicates TTCA's degradation rate in high humidity (a_w 0.843) is approximately 60% slower than that of ARP (Figure 2j).

In summary, TTCA possesses significantly greater environmental stability than ARP. Optimal storage conditions are low temperature, acidic-to-neutral pH, and low humidity,

View Article Online
DOI: 10.1039/D5FB00932D

while high temperature, alkaline pH, and high moisture accelerate degradation. These results confirm TTCA's extended effective shelf life and underscore the necessity of cool, dry, and sealed storage for practical application as a stable flavor precursor.

3.4 Antioxidant properties of MRIs demonstrate promising potential as alternative to synthetic antioxidants.

The antioxidant capacities of TTCA and ARP intermediates, complete Maillard reaction products (MRPs) were evaluated in this study. The chelating ability of Fe^{2+} helps to reduce the occurrence of lipid oxidation and is an important indicator for evaluating antioxidants.[7] A concentration-dependent Fe^{2+} chelating ability was observed for TTCA and ARP (Figure 3a). Fe^{2+} can coordinate with the carbonyl oxygen on the xylose segment of Amadori compounds, forming a five-membered chelating ring. [7] Compared to the ARP molecule, the TTCA compound can provide stronger overall molecular polarity and more polar sites (including hydroxyl and carbonyl groups) in its possible tautomeric forms (Table S1). [36] This enhanced polar characteristic allowed the TTCA molecule to interact more effectively with solvent water molecules in aqueous solutions through electrostatic interactions and dynamic hydrogen-bonding networks, thereby forming more stable solvated complexes. [47] Therefore, TTCA compound molecules have more sites that can form complexes with Fe^{2+}, and the complexes formed may be more stable than those formed by ARP, which likely directly leads to the higher Fe^{2+} chelating ability of TTCA (71.35%) compared to ARP (51.03%) (Figure 3a). Besides, MRPs always revealed a higher Fe^{2+} chelating ability than TTCA and ARP compounds. Some melanoidins in MRPs can be natural free radical scavengers in the food system.

View Article Online
DOI: 10.1039/D5FB00932D

The reducing power, reflecting a substance's electron transfer ability, was measured to further evaluate antioxidant activity.[7] A positive correlation was observed between the concentration of MRIs (0.5-3 mg/mL) and their reducing power (Figure 3b). This can be attributed to reductive ketones and hydroxyl-containing compounds in the intermediates, which can donate electrons or hydrogen atoms to reduce the ferricyanide complex. [23] Notably, ARP exhibited stronger reducing properties than TTCA. This difference likely stems from the role of free thiol groups in ARP, which possess strong electron-donating ability due to their S–H bonds. In contrast, the thiol groups in TTCA are involved in forming a stable five-membered ring, leaving no exposed free thiols available for reduction.[48] Furthermore, MRPs exhibited stronger reducing power compared to intermediates at all tested concentrations, with a rapid increase as concentration rose, which is consistent with the existing research results.[47]

The chelating action on transition metals and the reducing action can inhibit lipid oxidation. Within the concentrations of 0.5 to 2.5 mg/mL, ARP/TTCA inhibited lipid peroxidation more than the MRPs, indicating ARP's better efficacy (Figure 3c). As the concentration increased to 3.0 mg/mL, the inhibition rate for lipid peroxidation of MRPs increased from 2.18% to 36.39%, exceeding that of ARP (29.18%) and TTCA (31.30%) at 3.0 mg/mL (Figure 3c). The increased concentration of TTCA or ARP beyond a certain point did not lead to a corresponding significant improvement in the inhibition of lipid peroxidation. This observed plateau in efficacy could result from several factors, such as potential solubility limitations of TTCA and ARP comparing to MRPs (rich in aldehydes and ketones) in the emulsion system, [27,30] or the attainment of a saturation point for their antioxidant action under these specific conditions. The results confirmed that TTCA or

View Article Online
DOI: 10.1039/D5FB00932D

ARP could be one reason for the antioxidant activity of Maillard reaction during food processing and storage. However, at higher concentrations, the MRPs demonstrated superior performance compared to their precursors, suggesting that they possess better emulsion system compatibility and contain a greater number of compounds with strong antioxidant activity.

The DPPH free radical scavenging ability typically reflects the hydrogen-donating ability of antioxidants.[49] The scavenging rates of TTCA and ARP increased with its concentration during the range of 0.5 to 3.0 mg/mL (Figure 4a). Their effect was weaker than that of MRPs, and considerably lower than ascorbic acid, which achieved nearly 100% scavenging across the same range. Similar concentration-dependent trends were observed for superoxide anion and hydroxyl radical scavenging (Figures 4a and 4b). At a concentration of 3.0 mg/mL, the superoxide anion radical scavenging activities of TTCA and ARP are functionally comparable to that of 0.5 mg/mL ascorbic acid, suggesting that approximately 6 g of TTCA could theoretically replace 1 g of ascorbic acid in antioxidant applications. MRPs consistently demonstrated stronger radical scavenging ability than the intermediates, with activity rising sharply at higher concentrations (Figures 4a, 4b and 4c), consistent with prior reports.[47] This enhanced activity is attributed to the complex mixture of cross-linked polymers, aldehydes, ketones, and heterocyclic compounds formed in later Maillard stages, which exert antioxidant effects through multiple pathways. [27] In summary, while MRIs such as TTCA and ARP contribute to controlled flavor formation, the final MRPs exhibit superior antioxidant properties. Therefore, a combination of MRIs and MRPs holds potential as dual-function ingredients, serving as both natural flavor enhancers and antioxidants in food systems.

DOI: 10.1039/D5FB00932D

TTCA and ARP compounds, derived from xylose and cysteine, exhibit antioxidant properties distinct from a simple xylose-cysteine mixture, indicating that structural differences at the molecular level are responsible.[50] While free sugars like pentoses, hexoses, and ketoses predominantly exist in a closed-ring form in solution, with minimal reactive open-chain carbonyls. [51] For MRIs, the conjugated electron cloud structure between the enol and aminium ion leads to an equilibrium of isomeric interconversion between their open-ring and closed-ring forms, with the open-chain conformation becoming a significant configuration in aqueous media.[52] This provides abundant free carbonyl groups capable of donating electrons to neutralize free radicals.[7] Based on this, a possible pathway for the intermediates to scavenge free radicals is proposed (Figure 4d). TTCA and ARP can donate hydrogen atoms to free radicals, stabilizing them and terminating chain reactions. The radical electron can localize on the carbon adjacent to the carbonyl group on the xylose residue, where resonance and intramolecular hydrogen bonding lead to a thermodynamically stable intermediate. Alternatively, the carbonyl group itself may be attacked, with the radical electron transferring to the oxygen atom, followed by stabilization via intramolecular hydrogen bonding.[7,53,54] Research also found that the free radical scavenging ability of ARP is consistent with its electron-donating or hydrogen-donating properties, and specifically proposed that its metal chelating ability may also be related to this principle.[39] Although this study indicates that TTCA and ARP exhibited certain antioxidant activity, its long-term stability in complex food systems and the production costs at scale still require further evaluation. Therefore, MRIs can serve as natural flavor precursors to achieve controlled formation of processing flavors and provide partial antioxidant function, suggesting potential practical value.

4. Conclusion

This study demonstrates that the Xyl-Cys MRIs including TTCA and ARP could act as dual-functional, sustainable platform, which integrating efficient flavor precursor properties with certain natural antioxidant activity. The flavor profile released from TTCA can be regulated from "meaty" to "roasted nutty" notes through simply modulating thermal processing parameters (pH, temperature). The addition of exogenous amino acids can further enrich the diversity of roasted flavor compounds, such as pyrazines. This significantly enhances the processing adaptability of the flavor precursors of MRIs. Compared to MRPs, TTCA or ARP exhibits superior stability for commercial application, which can retain over 90% of its content after 60 days of storage under ambient, neutral, and dry conditions. This stability ensures consistent performance and reliability during the storage, transportation, and use of TTCA or ARP as an ingredient, significantly reducing the risks of raw material loss and flavor variability due to degradation. TTCA and ARP compounds revealed increased Fe^{2+} chelating ability, reducing power, and free radical scavenging ability with increasing concentration, demonstrating certain antioxidant capabilities. By combining flavor enhancement with moderate oxidative stability contributed by MRIs, this approach provides a new direction for “clean-label” food development that may enable a partial reduction in reliance on synthetic antioxidants and flavor additives. In summary, this work supports the potential of TTCA or ARP to act as a sustainable platform for natural flavoring and supporting antioxidant properties. It offers a feasible strategy for improving food quality and stability and aligns with the pursuit of greener food processing practices.

Notes: Results were presented as means ± standard deviation, data within a row with different letters are significantly different ($p < 0.05$) using Duncan's multiple comparison test ($n = 3$).

a: Linear retention indices calculated using a series of n-alkanes on the DB-W AX column (30 m × 0.25 mm× 0.25 μm).

b: Linear retention indices searched from http:// www.flavornet.org and http://webbook.nist.gov/chemistry/.

c: ID: Identification methods. d: "ND", not detected.

e: Compounds marked with an asterisk (*) were quantified using the standard curve method with internal standard calibration.
