Carbon foams derived from biomass with ultra-high adsorption capacity for the removal of tetracycline

Meena Choudhary,^{ab} Nandana Chakinala,*^{ac} Pooja Saini,^{ab} Praveen K. Surolia*^b and Anand Gupta Chakinala  ^a

This study focusses on the development of carbon foams (CFs) derived from carbohydrates evaluated for their adsorptive removal of model pollutants. The influence of different metal nitrates (cobalt, zinc, iron, magnesium, and chromium) and carbon precursors (cellulose, agar, sucrose, and starch) on the CF preparation and their effects on the adsorptive removal of tetracycline is extensively studied. CF derived from zinc nitrate catalyzed agar was studied extensively. Batch adsorption experiments were conducted to assess the effectiveness of CF under varying initial feed concentrations (25–500 mg L⁻¹), adsorbent loadings (0.25–1.00 g L⁻¹), pH range (4.5–9.8), and temperature range (20–35 °C). A maximum adsorption capacity of 1822 mg g⁻¹ was achieved at 500 mg L⁻¹ of feed and with an adsorbent loading of 0.25 g L⁻¹. The adsorption data were well-described by the Freundlich isotherm, indicating the heterogeneous nature of the CF surface, with multiple adsorption sites resulting in a non-uniform distribution of adsorbate molecules. The adsorption kinetics followed a pseudo-second-order model, suggesting that chemisorption was the predominant mechanism in the process. Thermodynamic analysis indicated that the adsorption process was endothermic and spontaneous, with a positive entropy change. Additionally, CF demonstrated excellent reusability, maintaining adsorption efficiency over three consecutive cycles.

1. Introduction

Water is essential for sustaining life and ensuring a sustainable society. However, rapid industrialization and population growth have led to severe water scarcity and pollution challenges. Among the various pollutants, soluble and insoluble organic compounds are particularly significant.¹ The rising global population, coupled with increased prevalence of viral infections and declining immunity, has led to higher antibiotic usage. This results in elevated levels of antibiotics in wastewater, particularly in developing countries, where monitoring is often inadequate. Additionally, several low and mid-scale industries discharge water without any effective treatment into the river/water bodies despite having stringent laws. Such unregulated pollutant presence can have severe consequences

for human health and environmental ecosystems, especially aquatic life.²

Synthetic pharmaceutical effluents have been extensively studied to remove various pollutants using different techniques in the literature that include, ion-exchange,³ advanced oxidation processes,⁴ biological treatment,⁵ adsorption, and several other integrated approaches. Adsorption is considered one of the most effective techniques for the removal of antibiotics due to its high efficiency, cost-effectiveness, and ease of operation. Several carbon-based materials have been widely investigated for tetracycline removal due to their large surface area, tunable porosity, and diverse surface functionalities. Foundational work comparing CNTs, activated carbon and graphite established that tetracycline adsorption on graphenic surfaces is driven by π - π electron-donor-acceptor, cation- π and van der Waals interactions, with accessibility of sites strongly affecting affinity.⁶ These interactions highlight the potential of defect-rich carbonaceous frameworks in providing abundant active sites for efficient antibiotic removal. Among the several approaches, adsorption technology is a widely used and promising technology due to its cost-effectiveness, ease of operation, high efficiency, and lack of secondary pollution.⁷ However, for commercial scale operations it is important to

have a low-cost adsorbent that is abundant in nature that possess a very high adsorption capacity with robust and effective treatment with real industrial effluents. Activated carbons derived from various biomass streams (e.g., coconut shell, walnut shell) are used extensively in industries as an adsorbent but they are found to be expensive and need to be improved in terms of their adsorption capacity as well as lowering the costs of these adsorbents. In this aspect, a variety of materials have been developed to enhance the adsorption capacity for the removal of antibiotics from wastewater, including carbon-based substances, polymeric materials, clay minerals, metal oxides and metals, and chitosan.^{8–11} Carbon based materials are recognized for their effectiveness in removing various pollutants due to their large surface areas, strong interactions with pollutants, and numerous pores. Common carbon materials used for the removal of different pollutants include carbon nanotubes, activated carbon, graphene, CF and their composites.¹²

Recent studies have looked into different kinds of 3D porous materials for cleaning up pollutants like antibiotics, dye, oil separation *etc.* CF is a type of porous carbon material that has a 3D interconnected network structure.¹³ CF is a strong, lightweight, sponge-like material with excellent thermal and electrical management capabilities and a large surface area, making it ideal for use as catalyst supports, filters for molten metals and corrosive chemicals, porous electrodes, and absorbers of impact, energy, and sound.¹⁴

Different types of precursors for CF include synthetic organic polymers made of petroleum-based materials, such as furfural resin, phenol-formaldehyde, and poly arylacetylene, and agricultural or waste biomass such as tannins, fruit waste, and lignocellulosic materials.^{15–17} Another good precursor for creating CF is carbohydrates such as agar, sucrose, starch *etc.* A common disaccharide with 42.1% carbon content, sucrose readily dehydrates in acidic environments. A macro-porous carbon structure is produced by this method, which may then be further carbonized to make a glassy CF.^{18,19} Direct carbonization, hydrothermal treatment, and freeze-drying are just a few of the techniques that have been successfully used to produce CF in which direct carbonization is the most effective technique.²⁰

The significance of the present work lies in demonstrating a rapid, low-temperature, and cost-effective strategy for synthesizing ZnO–carbon foam (CF) from a renewable carbohydrate precursor (agar), tailored for the efficient removal of tetracycline as a model antibiotic. Antibiotic contamination is a critical global challenge, not only due to its persistence in aquatic systems but also because of its contribution to antimicrobial resistance. Although a wide variety of biomass-derived carbon materials have been reported for water purification, most existing approaches suffer from inherent drawbacks such as high-temperature carbonization ($>500\text{--}800\text{ }^{\circ}\text{C}$), extended processing times, multi-step activation/post-treatments, or reliance on hazardous activating agents, which hinder their scalability and sustainability. To address this research gap, our study introduces a one-step synthesis completed within 10 minutes at only $180\text{ }^{\circ}\text{C}$, yielding a hierarchical macro-meso-microporous CF structure with *in situ*

embedded ZnO nanoparticles. This eliminates the need for additional chemical treatments, reduces energy input and cost, and minimizes environmental burden. Beyond establishing an effective proof of concept, this study suggests a sustainable and scalable pathway for developing multifunctional carbonaceous adsorbents that can be extended for the removal of a broader range of emerging organic pollutants from water.

2. Experimental

2.1. Materials

All chemicals and reagents used in this study were of analytical grade with high purity ($>98\%$). Agar powder, zinc nitrate hexahydrate ($\text{Zn}(\text{NO}_3)_2 \cdot 9\text{H}_2\text{O}$), ferric nitrate nonahydrate ($\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$), and chromium nitrate nonahydrate ($\text{Cr}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$) were purchased from Loba Chemie Pvt. Ltd. Cobalt nitrate hexahydrate ($\text{Co}(\text{NO}_3)_2 \cdot 9\text{H}_2\text{O}$) was obtained from Fisher Scientific and magnesium nitrate hexahydrate ($\text{Mg}(\text{NO}_3)_2 \cdot 9\text{H}_2\text{O}$), sucrose, and starch were received from Merck life science private limited. Cellulose was purchased from Bangalore fine chem. Tetracycline was procured from Cipla Ltd. Distilled water was used for the synthesis of all adsorbents, while reverse osmosis (RO) water was used for the preparation of feed solution.

2.2. Synthesis of carbon foam

The synthesis of CF typically involved mixing of agar and metal nitrate (here: zinc) precursors in different weight ratios (1:2) in a 100 mL beaker and heating on a hotplate. This mixture was gradually heated and melted into a uniform, thick liquid at a set temperature of $180\text{ }^{\circ}\text{C}$. As the temperature increases, the solution turns into a yellowish homogenous mixture that eventually converts into a carbonized black foam. Zinc-based CF was synthesized within 10 min through a direct reaction between agar and zinc nitrate. Due to its strong oxidizing properties, metal nitrate precursors in the above mixture break down and interact with the agar powder. Dehydration and polymerization reactions during the pyrolysis of agar will eventually result in the formation of a complex foam-like structure that is densely embedded with zinc oxide particles.²¹

2.3. Experimental procedure

Tetracycline adsorption studies were carried out in batch mode in which a stock solution of tetracycline (500 mg L^{-1}) was initially prepared, and it was further diluted to the desired concentrations depending on the experiments. Adsorption studies were carried out in conical flasks containing a known amount of CF as an adsorbent and 50 mL of tetracycline solution for a constant time, with different initial concentrations of tetracycline ($25\text{--}500\text{ mg L}^{-1}$), different adsorbent dosages ($0.25\text{--}1\text{ g L}^{-1}$), different pH (4.5–9.8) and different temperatures (298, 303, 308 K) in deionized water. Two flasks of identical samples in replicate were placed on a magnetic stirrer at 250 rpm for 24 h. After the desired time, the mixtures were filtered through a $0.22\text{ }\mu\text{m}$ filter membrane, and the residual tetracycline solutions were analyzed using a UV-visible

spectrophotometer (HACH-DR6000) at a maximum absorption wavelength of 358 nm. At equilibrium, the amount of adsorbed q_e (mg g⁻¹) pollutant onto the adsorbent was calculated using the following eqn (1):

$$q_e = \frac{(C_i - C_e)V}{m} \quad (1)$$

where C_i and C_e are the initial and final concentrations of the antibiotic solution (mg L⁻¹) at equilibrium state, and V and m are the volumes of the antibiotic solution (L) and mass of the adsorbent (g), respectively. Among the non-linear isotherm equations that were used to evaluate the experimental adsorption data were the Langmuir, Freundlich, and Temkin models. These equations were used as a means of explaining the characteristics and processes of the adsorption process. The pseudo first order model (PFOM), the pseudo second order model (PSOM), and the intra particle diffusion model (IPDM) were the four kinetic models used to evaluate the adsorption kinetics.

2.4. Characterization techniques

Various techniques were used to characterize all the catalysts synthesized in this study, focusing on their functional groups, crystallinity, and surface area analysis. The structural and chemical states of the adsorbent were examined using X-ray powder diffraction (XRD) with a Rigaku Smart Lab model, scanning in the 2θ range of 10–80° at a speed of 0.1 s⁻¹. Additionally, Fourier transform infrared (FTIR) analysis was performed using a Bruker ALPHA instrument, recording spectra in the range of 500 to 4000 cm⁻¹. The Brunauer–Emmett–Teller (BET) surface area was measured using a micrometrics Tristar 3000 V6.08 apparatus. A HACH DR6000 UV-vis spectrophotometer was used to evaluate liquid samples. The morphology was determined, and the elements were subjectively identified using field emission scanning electron microscopy (FESEM; JEOL manufacture JSM-7610 F-Plus equipped with an EDX detector).

2.5. Statistical analysis

Initial preliminary studies were carried out more than 5 times to test the reproducibility of the tests which demonstrated >95% confidence level. Based on these initial observations further tests reported in this study were carried out in replicates. More details of the statistical analysis are mentioned in the supplementary information.

3. Results and discussion

In this section, we discuss the results of CFs prepared using different metal precursors and carbon precursors. These different CFs were initially tested for adsorption of tetracycline as a model pharmaceutical pollutant. The best performing CF was studied in detail under different operating conditions as follows.

3.1. Adsorption studies

3.1.1. Effect of different metal precursors.

Structured carbons or CFs were prepared under mild conditions where the

organic carbon precursor was catalytically converted in the presence of metal nitrate salts resulting in the formation of ordered structures with high surface areas. Thermal dissociation of these metal nitrates into gases during the process plays a vital role in the foaming process. This study evaluates the role of various catalytic metal precursors such as zinc, cobalt, ferric, chromium, and magnesium in the preparation of CF derived from agar as a carbon precursor in terms of their adsorptive removal of tetracycline. The adsorptive removal of 200 mg L⁻¹ of tetracycline studied with 0.25 g L⁻¹ under neutral pH conditions is shown in Fig. 1. Among the various CFs prepared maximum removal efficiencies >~92% were achieved using cobalt and zinc-based CF. Iron based CF was found to have a removal efficiency up to 78%, whereas magnesium and chromium were found to have relatively lower removal efficiencies of 23 and 35% respectively. These differences in adsorption efficiency are attributed to the distinct structural and chemical characteristics imparted by each metal precursor during the carbonization process. Zinc based CFs were studied further in detail due to their high removal efficiency, low cost and ease of availability, and less toxicity, making them more economical for large scale applications. The overall removal efficiency of tetracycline is in the order of cobalt > zinc > iron > magnesium > chromium.

Agar, a polysaccharide rich in hydroxyl groups, forms a uniform hydrogel that undergoes gelation and carbonization to produce a stable three-dimensional carbon network. When zinc nitrate is incorporated, the Zn²⁺ ions dissolve completely and distribute evenly within the agar matrix. These ions coordinate with the hydroxyl and glycosidic oxygen atoms of agar, reinforcing the gel network and promoting dehydration and crosslinking at lower temperatures. This accelerates the aromatization of carbon structures, leading to improved structural order. During carbonization, zinc nitrate decomposes to form ZnO nanoparticles and releases gaseous by-products such as NO₂ and O₂. The evolved gases act as pore-forming agents, creating interconnected macro- and mesopores, while the ZnO particles serve as rigid templates that prevent structural collapse.²²

Previous studies in the literature have reported²³ the role of transition metals, such as copper, iron, and nickel, as catalysts in influencing the foaming properties of sugar-based CF. These studies revealed a decrease in micro-pore content with increasing iron concentration after carbonization and activation. Among the metals studied, nickel exhibited the highest foam rise, while iron showed the lowest. Although the activated CFs demonstrated remarkably high surface areas (868 m² g⁻¹), their adsorption capacity for methylene blue was relatively low (max 85 mg g⁻¹). A magnetic CF derived from phenolic foam catalyzed with iron acetylacetone was reported²⁴ to have a surface area of 227.5 m² g⁻¹ with an adsorption capacity of 258 mg g⁻¹ of rhodamine-B dye. A hierarchically porous iron containing carbon foam (Fe-CF) synthesized through the carbonization of a nano-magnesium oxide/epoxy resin mixture,

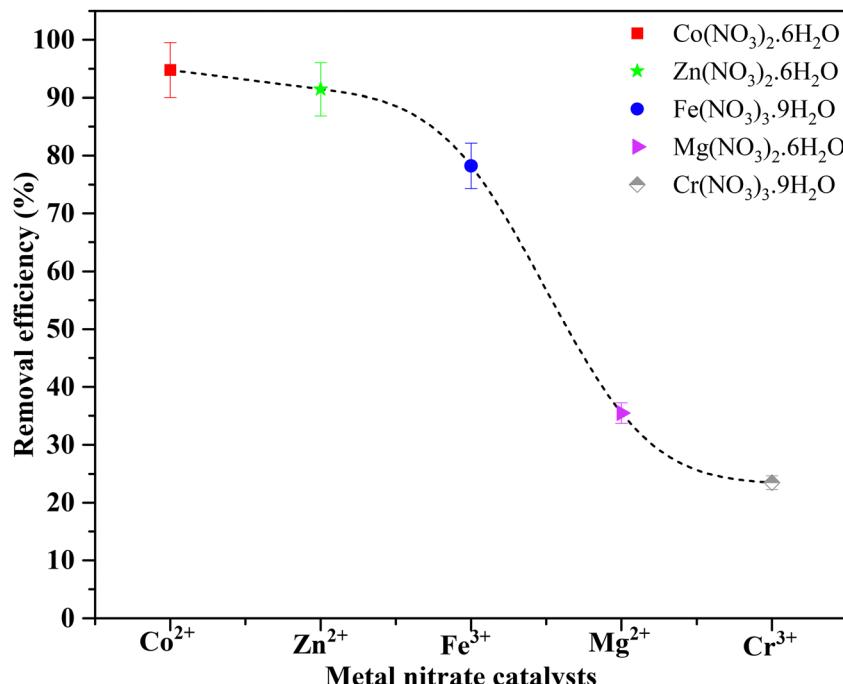

Fig. 1 The removal efficiency of tetracycline with an agar based CF catalyzed with different metal nitrates (experimental conditions: feed concentration = 200 mg L⁻¹, adsorbent loading = 0.25 g L⁻¹, pH = 7).

followed by activation with ferric nitrate activation was reported to²⁵ exhibit high adsorption capacities for Congo red (CR) (1263 mg g⁻¹), malachite green (MG) (679 mg g⁻¹), and methylene blue (MB) (484 mg g⁻¹).

3.1.2. Role of different carbon precursors. Structured CF can be prepared from different carbon precursors such as disaccharides, starch and carboxylic acids, by direct polymerization in the presence of metal catalysts. The foaming reactions are usually exothermic in nature, and they typically occur within the temperature range of 120–160 °C leading to a variety of structured CF depending on the carbon precursors used. The purpose of this study is to evaluate the performance of the CF derived from various carbon precursors such as cellulose, sucrose, starch and agar on the adsorptive removal of tetracycline, as shown in Fig. 2. The findings revealed that the CF derived from cellulose exhibited the highest removal efficiency of ~94%, followed by agar at ~93%, sucrose at ~91%, and starch powder at ~90% with 200 mg L⁻¹ of tetracycline feed and 0.25 g L⁻¹ of adsorbent. These results suggest that the CFs with different precursors have the least impact on the adsorption behavior in terms of tetracycline removal and this can be attributed to the maximum and equivalent amounts of functional groups present in all the CFs prepared with different carbon precursors [see Section 3.2].

CFs derived from different precursors exhibit varying structural properties due to the distinct polymerization reactions that occur with each type of carbon precursor. Polymerization generally proceeds in two steps. The first step involves the evaporation of the solvent (in this case, water), leading to the cleavage of glycosidic bonds between individual monosaccharide units,

yielding glucose and fructose.²³ In the second step, the polymerization of hydroxyl (OH) groups occurs, facilitated by catalytic materials. This process forms C–O–C bonds that link the sugar units, constructing the backbone structure of the foam.

Previous reports of CF synthesis from different carbon precursors based on carbohydrates such as glucose, sucrose and starch have been reported²⁶ to achieve more or less similar adsorption capacities for nickel removal. The adsorption capacities of 48.5, 42.4 and 41.1 mg g⁻¹ were obtained with glucose, sucrose and starch derived CF that are activated using phosphoric acid. These CFs had a maximum surface area of 700 m² g⁻¹. CFs derived from agar and table salt in 1 : 4 ratio were reported²⁷ to have a surface area of 365 m² g⁻¹ and they exhibited a high oil/organic solvent adsorption capacity ranging from 84 to 202 times its own weight. While CFs prepared using zinc nitrate catalyst with different carbohydrates such as glucose, maltose, and starch were reported²⁸ to have similar adsorption capacities of 376, 378, and 377 mg g⁻¹ for tetracycline removal. The surface areas of these CFs were found to be 48.9, 40.9 and 38.1 m² g⁻¹ with glucose, maltose and sucrose respectively. Similar observations were made when the CF was prepared from sucrose and zinc nitrate hexahydrate (1:2), which demonstrated a removal efficiency of 77% for malachite green.²⁹ Therefore, CFs derived from various carbon precursors exhibited comparable adsorption capacities for pollutants, due to their similar functional group content and structural properties influenced by precursor-specific polymerization reactions.

3.1.3. Adsorption of different antibiotics. Based on the above screening studies, further detailed studies were conducted with agar-based CF prepared in the presence of zinc

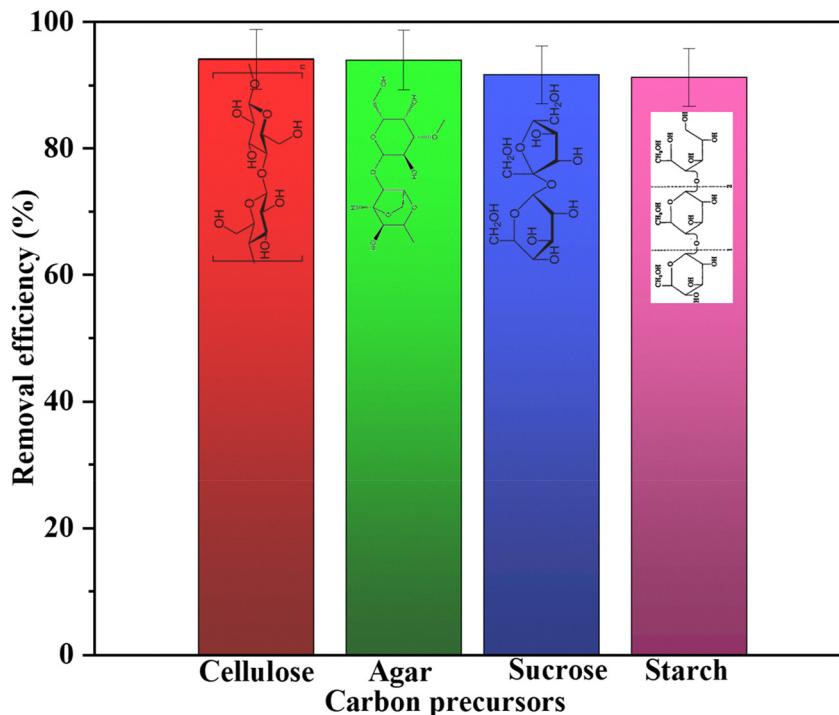

Fig. 2 Influence of different CF derived from various carbon-based precursors catalyzed with zinc nitrate on the removal efficiency of tetracycline [experimental conditions: feed concentration = 200 mg L⁻¹, adsorbent loading = 0.25 g L⁻¹, pH = 7].

nitrate catalyst. Preliminary studies were focused on evaluating the performance and efficiency of the CF in the removal of various synthetic pharmaceutical model compounds. The adsorption studies with CF derived from agar catalyzed by zinc

catalyst were carried out for the removal of different antibiotics such as ciprofloxacin, tetracycline, azithromycin, and amoxicillin and the results are presented in Fig. 3. The results indicate that the removal efficiencies for tetracycline and ciprofloxacin

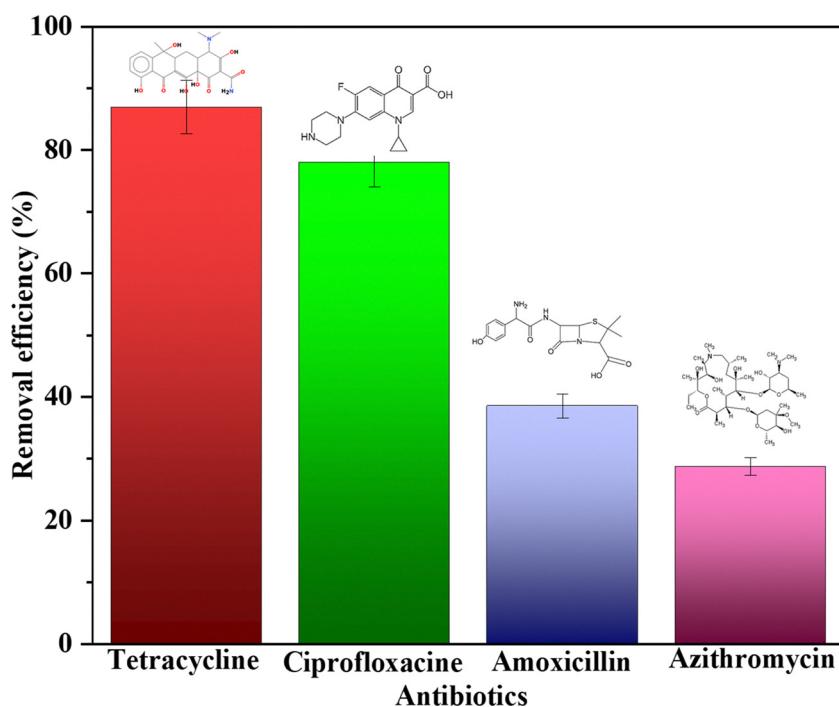

Fig. 3 Removal efficiency of different antibiotics with zinc catalyzed agar derived CF [experimental conditions: feed concentration = 50 mg L⁻¹, absorbent loading = 1 g L⁻¹, temperature = 30 °C, pH = 7].

are notably high, at $\sim 87\%$ and $\sim 78\%$, respectively. In contrast, the removal efficiency for amoxicillin and azithromycin are considerably lower, at 39% and 29%, respectively. These notable changes in the removal efficiency highlight the selective adsorption capability of CF towards different antibiotics, likely attributable to the pollutant's molecular structure, interactions with the CF's porous network and surface functionality.

Tetracycline and ciprofloxacin possess relatively compact molecular structures with multiple functional groups, such as hydroxyl, amine, and carboxyl groups, capable of forming hydrogen bonds with the zinc-catalyzed CF surface. The presence of oxygenated functional groups (e.g., $\text{C}=\text{O}$, $-\text{OH}$) on the CF, along with residual zinc species, facilitates hydrogen bonding and electrostatic interactions with these antibiotics. Additionally, the pore size of the CF is an important parameter, likely aligning well with the smaller molecular dimensions of tetracycline and ciprofloxacin, enabling their efficient diffusion into the porous structure. In contrast, azithromycin, with its bulky macrolide structure, and amoxicillin, with a larger amine side chain, face steric hindrance that impedes their diffusion into the CF's micropores. These synergistic factors collectively account for the higher adsorption efficiencies observed for tetracycline and ciprofloxacin compared to the bulkier molecules, such as azithromycin and amoxicillin. These structure-dependent differences are consistent with the overall adsorption mechanism proposed in this study. While smaller, planar antibiotics (tetracycline and ciprofloxacin) can exploit hydrogen bonding, electrostatic interactions, and π - π stacking with the CF surface, bulkier molecules such as azithromycin and amoxicillin are sterically hindered from accessing micropores and forming such interactions. This highlights that the selective adsorption capability of CF arises from the interplay between

its hierarchical porous structure, surface functionality, and the molecular architecture of the pollutants.

3.1.4. Effect of adsorbent loading. The influence of different adsorbent loadings ranging from 0.25 to 1 g L⁻¹ on the removal efficiencies of tetracycline is shown in Fig. 4. It is evident from the figure that the removal efficiency reduced slightly from 92 to 89% with decreasing the adsorbent dosage from 1 to 0.25 g L⁻¹. It is noteworthy that the adsorbent capacity increases by four fold from 174 mg g⁻¹ to 724 mg g⁻¹ with a drop in adsorbent loading from 1 to 0.25 g L⁻¹. This trend suggests that, at lower dosages, the adsorbent's ultra-high capacity enables more efficient utilization of its active sites, leading to a higher adsorption capacity per unit mass. Excessive dosages provide more active sites than necessary, which remain underutilized and result in a lower specific adsorption capacity. Nevertheless, the overall removal efficiency remains high due to the increased mass of adsorbent in the system. Indeed, similar adsorption characteristics were reported²¹ elsewhere with adsorbents exhibiting super adsorption capacities under different adsorbent loadings.

3.1.5. Effect of feed concentration. The impact of feed concentration on the adsorption of tetracycline was studied within the range of 25–500 mg L⁻¹ at a constant adsorbent dosage of 0.25 g L⁻¹ and the results are shown in Fig. 5. As the initial concentration increased from 25 to 500 mg L⁻¹, the adsorption capacity rose significantly from 48 to 1822 mg g⁻¹. The notable increase in adsorption capacity with higher initial feed concentrations can be attributed to the increased concentration gradient, which provides a stronger driving force for adsorption. At elevated concentrations, there is a greater availability of tetracycline molecules, which increases the likelihood of adsorption onto the available active sites of the adsorbent.

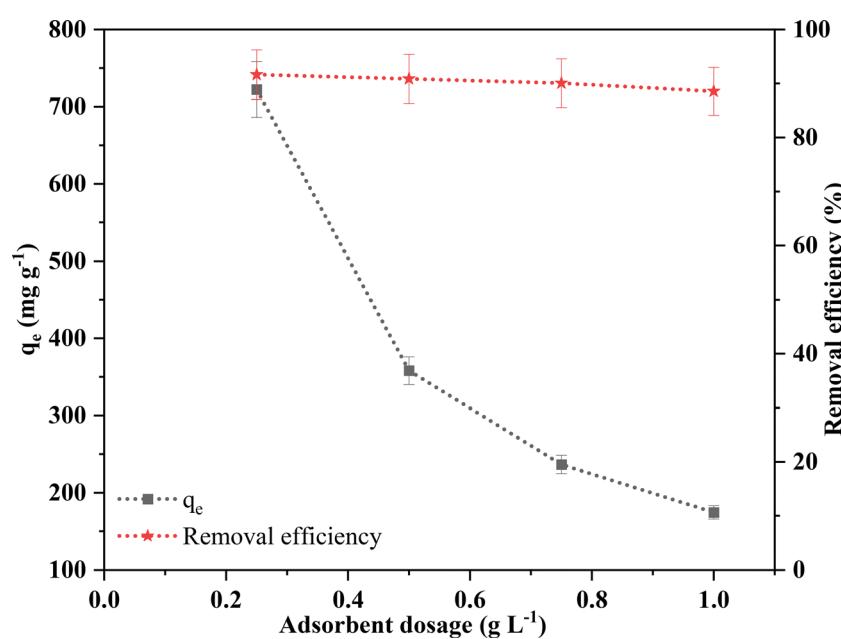

Fig. 4 Effect of adsorbent loading on the adsorption capacity of CF and the removal efficiency of tetracycline [experimental conditions: feed concentration = 200 mg L⁻¹, adsorbent loading = 0.25 to 1 g L⁻¹, pH = 7].

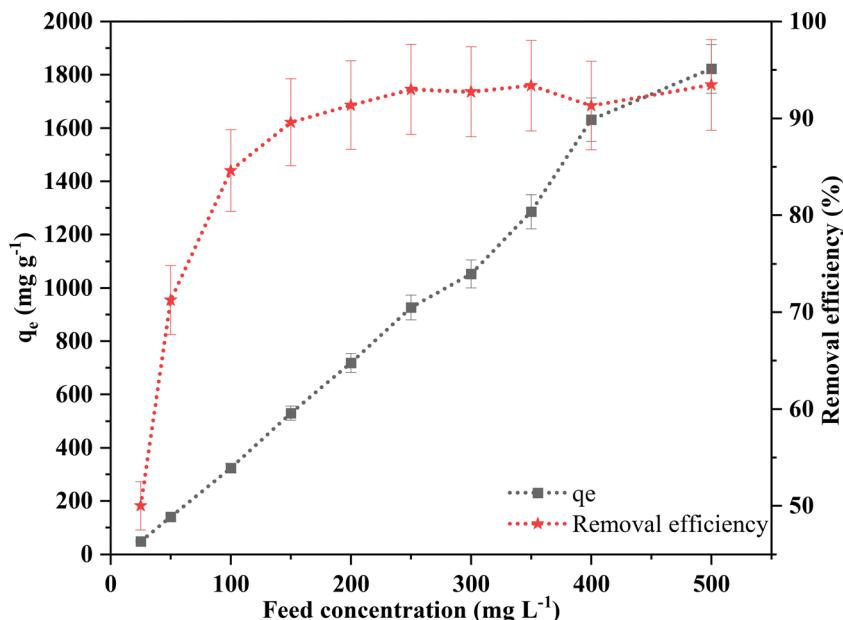

Fig. 5 Effect of initial feed concentration of tetracycline on the equilibrium adsorption capacity and removal efficiency with CF (experimental conditions: feed concentration = 25 to 500 mg L⁻¹, adsorbent loading = 0.25 g L⁻¹, pH = 7).

This enhanced interaction results in a more effective utilization of the adsorbent's capacity until equilibrium is reached. As a result, the equilibrium adsorption capacity significantly increases as the feed concentration rises.³⁰

3.1.6. Effect of contact time. The equilibrium adsorption capacity was determined by studying the variation in the adsorption capacity with time over a 24 h period with three different feed concentrations of tetracycline (100, 200 and 500 mg L⁻¹).

Both removal efficiency and the adsorption capacity increased with increasing contact time until the equilibrium was reached (Fig. 6). Initially, a sharp increase in adsorption capacity was observed, which can be attributed to the rapid occupation of available adsorption sites on the adsorbent, facilitated by the high availability of unoccupied sites during the early stages. The results indicate that equilibrium for tetracycline adsorption was achieved within 3 h. These observations are reported³¹ in the

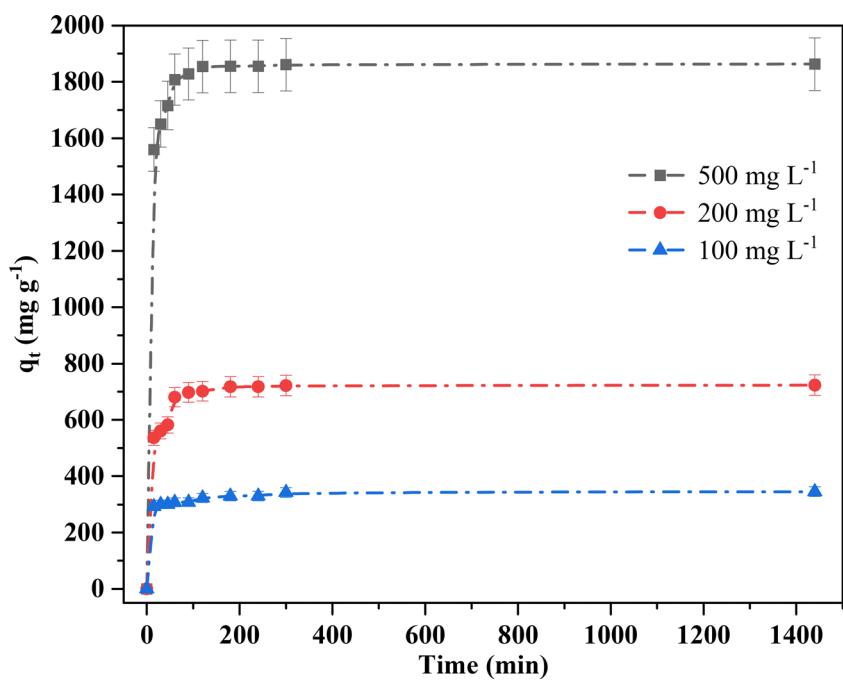

Fig. 6 Effect of contact time on the adsorption capacity of tetracycline over CF (experimental conditions: feed concentration = 100, 200, 500 mg L⁻¹, adsorbent loading = 0.25 g L⁻¹, pH = 7).

literature where the equilibrium adsorption capacity depends on the type of pollutant, adsorbent, and initial feed concentration.

3.1.7. Effect of pH. The initial pH of the solution is a critical parameter influencing the adsorption process, as it affects both the surface charge of the adsorbent and the ionization state of the adsorbate, thereby impacting interaction mechanisms and overall efficiency. The pH effect on tetracycline adsorption was studied by adjusting the solution pH from 4.5 to 9.8 with 0.25 g L^{-1} of adsorbent. The pH range of 4.5–9.8

was selected as it encompasses slightly acidic, neutral, and basic conditions commonly encountered in natural waters and wastewater effluents (typically pH 6–9). This range allows evaluation of adsorption behavior across environmentally relevant conditions, ensuring practical significance for real water treatment applications. As shown in Fig. 7a, the adsorption capacity increased from 664 mg g^{-1} at pH 4.5 to 725 mg g^{-1} at pH 7 and reached $\sim 731 \text{ mg g}^{-1}$ at pH 9.8. At higher pH, both the carbon foam surface and tetracycline molecules become

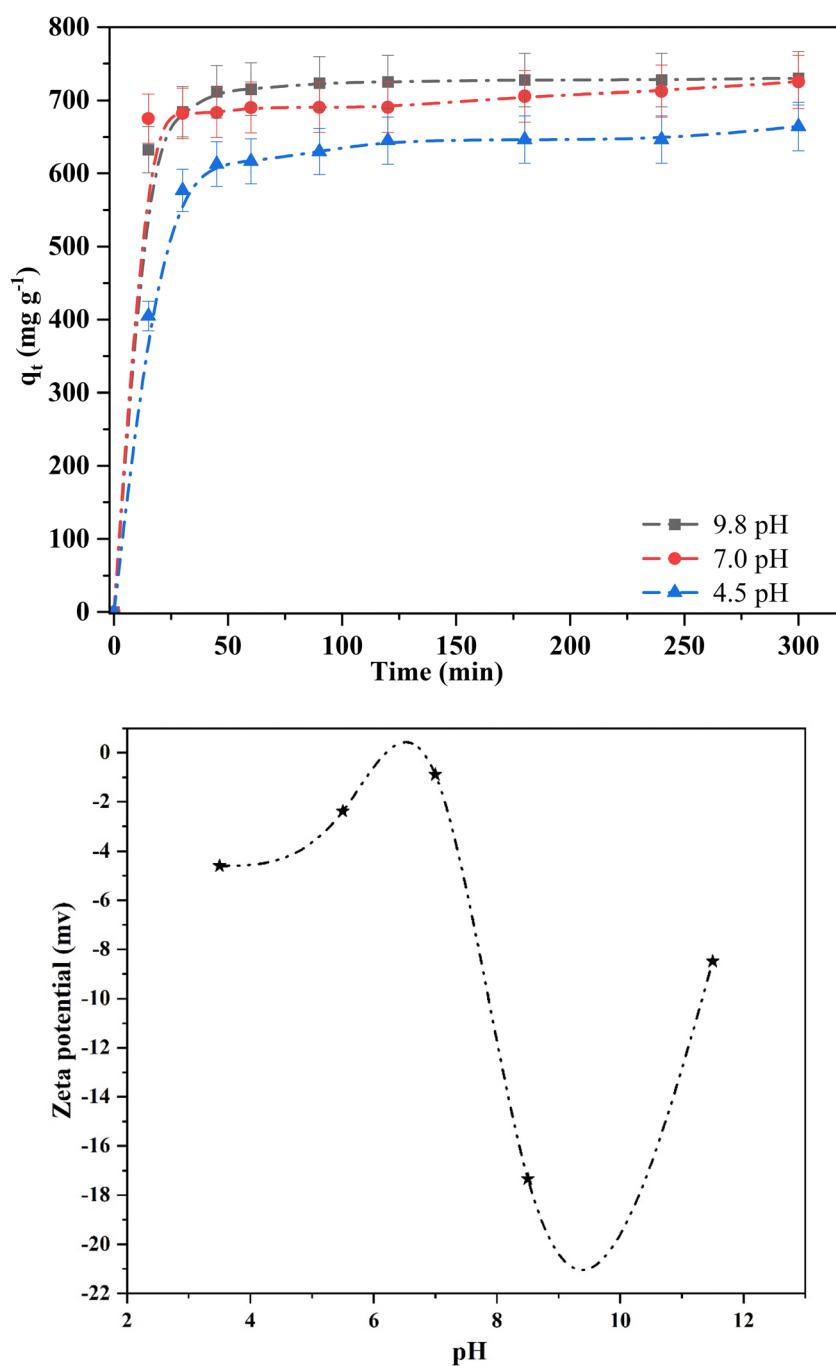

Fig. 7 Effect of different solution pH on (a) the adsorption capacity of tetracycline over CF and (b) zeta potential values of CFs (experimental conditions: feed concentration = 200 mg L^{-1} , adsorbent loading = 0.25 g L^{-1}).

negatively charged, which typically leads to electrostatic repulsion. However, strong surface complexation/chemisorption and π - π interactions can overcome these barriers, enabling selective uptake even under unfavorable conditions.^{32,33} The presence of abundant surface defects and functional groups further provides additional binding sites, contributing to the high adsorption efficiency. Conversely, at acidic pH, the removal efficiency slightly decreased due to increased protonation of active sites and electrostatic repulsion, though hydrogen bonding and π - π interactions still facilitated adsorption. These results highlight the significant role of pH in controlling tetracycline uptake by carbon foam, with neutral to alkaline conditions being optimal. A similar trend was reported^{34,35} in another study, where the adsorption capacity increased from 76.3 to 215 mg g⁻¹ as the pH rose from 2 to 7 and remained around 205 mg g⁻¹ at pH 10. At lower pH, increased protonation of active sites led to enhanced electrostatic repulsion, thereby decreasing adsorption efficiency.

The zeta potential data for CFs across different pH values provides insight into their surface charge and interaction with tetracycline pollutant (Fig. 7b). The CFs show a point of zero charge (PZC) around pH 7, indicating minimal surface charge at neutral pH. At acidic pH (3.5 to 7), the CF surface is slightly negative, while tetracycline exists in its cationic form. This creates favorable conditions for electrostatic attraction, particularly at lower pH levels like 3.5, where the negative surface charge of the CF supports adsorption. As pH increases, the zeta potential becomes more negative where CFs are highly negatively charged at pH 8.5. However, at this pH, tetracycline begins to transition into its anionic form, leading to electrostatic repulsion and a decrease in adsorption. At highly alkaline pH (11.5), both the CF surface and tetracycline are negatively charged, further inhibiting adsorption due to repulsive forces.

3.1.8. Effect of temperature. To understand the adsorption behavior of CFs towards tetracycline, adsorption capacity was studied over a temperature range of 293–308 K at different initial concentrations of tetracycline (50, 100, and 200 mg L⁻¹). The tested temperatures (20–35 °C) were chosen to reflect realistic environmental and operational conditions in aquatic systems and wastewater treatment processes. This range covers typical seasonal and climatic variations, from temperate regions (~20 °C) to tropical/subtropical conditions (~35 °C), thereby ensuring the relevance of the adsorption results to actual field applications. Adsorption studies at a range of temperatures are crucial for determining the thermodynamic feasibility and understanding the nature of interactions between the adsorbent and the adsorbate. It provides insights into the endothermic or exothermic nature of the adsorption process and reveals how temperature influences the spontaneity and mechanism of adsorption that is essential for designing efficient adsorption systems. Thermodynamic analysis was conducted to determine the mechanism of adsorption by calculating key thermodynamic parameters, including Gibbs free energy (ΔG), enthalpy change (ΔH), and entropy change (ΔS).

The change in Gibbs free energy (ΔG) was calculated using eqn (3), while the adsorption entropy (ΔS) and adsorption enthalpy (ΔH) were calculated from the slope and intercept of

Table 1 Thermodynamic analysis of tetracycline adsorption on carbon foam

C_o (mg L ⁻¹)	ΔH° (kJ mol ⁻¹)	ΔS° (kJ mol ⁻¹ K ⁻¹)	ΔG° (kJ mol ⁻¹)		
			20 °C	30 °C	35 °C
50	6.206	0.0397	-5.255	-5.759	-6.078
100	2.856	0.0358	-7.660	-7.934	-8.221
200	9.799	0.0645	-9.071	-9.808	-10.038

the plot of $\ln K$ versus $1/T$. A comprehensive summary of all calculated thermodynamic properties is provided in Table 1.

$$K = \frac{q_e}{C_e} \quad (2)$$

$$\Delta G = -RT \ln(K) \quad (3)$$

$$\ln(K) = \frac{\Delta S}{R} - \frac{\Delta H}{RT} \quad (4)$$

where T is the temperature in kelvin, R is the gas constant (8.314 J mol⁻¹ K⁻¹). ΔG , ΔH , and ΔS are the Gibbs free energy (kJ mol⁻¹), enthalpy (kJ mol⁻¹), and entropy (kJ mol⁻¹ K⁻¹). K represents the equilibrium constant, determined by the ratio of q_e (adsorption capacity in mg g⁻¹) to C_e (equilibrium concentration in mg L⁻¹).³⁶

The negative values of ΔG for the adsorption of tetracycline onto CF indicate that the adsorption process is thermodynamically favorable and spontaneous across the studied temperature range. As the temperature increases, ΔG becomes more negative, suggesting that higher temperatures enhance the adsorption of tetracycline. The calculated ΔG values ranged from -20 to 0 kJ mol⁻¹, suggesting that physical adsorption is the predominant mechanism.³⁷

The positive ΔH value indicates that the adsorption process is endothermic, meaning higher temperatures favor greater adsorption of tetracycline. The relatively low ΔH value (less than 40 kJ mol⁻¹) is consistent with physisorption as the dominant mechanism.⁷ This behavior confirms that the adsorption process is enhanced with increasing temperature. Additionally, the positive ΔS value suggests an increase in randomness at the solid-solution interface during adsorption, likely due to the displacement of structured water molecules or ions. This entropy increase contributes to the favorability of the adsorption process when accompanied by a sufficiently negative ΔH to ensure an overall negative ΔG . The positive ΔS also implies the stability and irreversibility of the adsorption process.³⁸

3.1.9. Adsorption kinetics. The kinetics of tetracycline adsorption on to CF plays a vital role to gain insights into the adsorption mechanism and understand the effect of contact time on the adsorption capacity. The kinetic data was obtained by recording tetracycline concentration at fixed time intervals with varied initial feed concentrations and was modeled using the pseudo-first-order, pseudo-second order and intra-particle diffusion model equations as shown in eqn (5) to eqn (7) respectively.

The pseudo-first order kinetic model (PFOM):

$$\ln(q_e - q_t) = \ln(q_e) - k_1 t \quad (5)$$

where k_1 is the pseudo first-order adsorption rate constant (min^{-1}), q_t is adsorption capacity (mg g^{-1}) at time (t) and q_e is the adsorption capacity at equilibrium (mg g^{-1}).

The pseudo-second-order kinetic model (PSOM):

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^2} + \frac{1}{q_e} (t) \quad (6)$$

where q_e is adsorption capacity (mg g^{-1}) at equilibrium and k_2 is the equilibrium rate constant (min^{-1}) for second-order kinetics.

The intraparticle diffusion model (IPDM), introduced by Weber and Morris.³⁹

$$q_t = k_i t^{1/2} + C \quad (7)$$

where q_t is the adsorption capacity (mg g^{-1}) at time t (min), k_i ($\text{mg g}^{-1} \text{h}^{-1/2}$) is the intraparticle diffusion rate constant and C is associated with the boundary layer thickness.

The results of the model fitting for the adsorption kinetics are illustrated in Fig. 8, and the corresponding kinetic parameters are presented in Table 2. In comparison to the PFOM with R^2 value of 0.9443–0.9597, the PSOM illustrated a better fit to describe the adsorption process of tetracycline over the CF. Additionally, the fitted kinetic parameter values for adsorption capacity (q_e) determined from PFOM differed from the experimental values (q_{cal}) at equilibrium.⁴⁰ The high R^2 values of 0.99–1.00 for PSOM reflects that this model effectively describes the adsorption kinetics at varied feed concentrations. The q_e values determined using PSOM fitting agrees well with the experimental values for various feed concentrations (100, 200, and 500 mg L^{-1}) in this study. This indicates that the adsorption process is primarily driven by chemisorption of tetracycline onto the CF, where the rate of adsorption is dependent on the availability of active sites on the solid surface.^{40,41} Furthermore, the mass transfer resistances in the adsorption process were evaluated by modelling the kinetic data using the IPD kinetic model. According to this model, the adsorption process is solely controlled by intra-particle diffusion if the data forms a straight line through the origin, implying a C value of zero. However, the process may involve multiple phases if the fit requires several linear segments.⁴² Fig. 8 showed that the adsorption process occurs in two distinct steps. The initial rapid adsorption in the first step is attributed to the diffusion on the external surface due to the boundary layer, followed by a slower rate in the second stage, representing intra-particle diffusion of tetracycline.

The PSOM model appears to have the best fit across all the concentrations, with R^2 values close to 1, indicating that the adsorption kinetics followed a pseudo-second-order process. Although the PFOM model provides a reasonable fit, it is less accurate than the PSOM. The IPDM model further indicates the presence of multiple stages in the adsorption process, as evidenced by the different slopes in the plots. A pseudo-second order adsorption kinetics mechanism was reported²⁴ to be a better fit to describe the Rhodamine-B dye adsorption on a phenolic foam-derived magnetic CF with an adsorption capacity of 258 mg g^{-1} . Similarly, pseudo-second order was

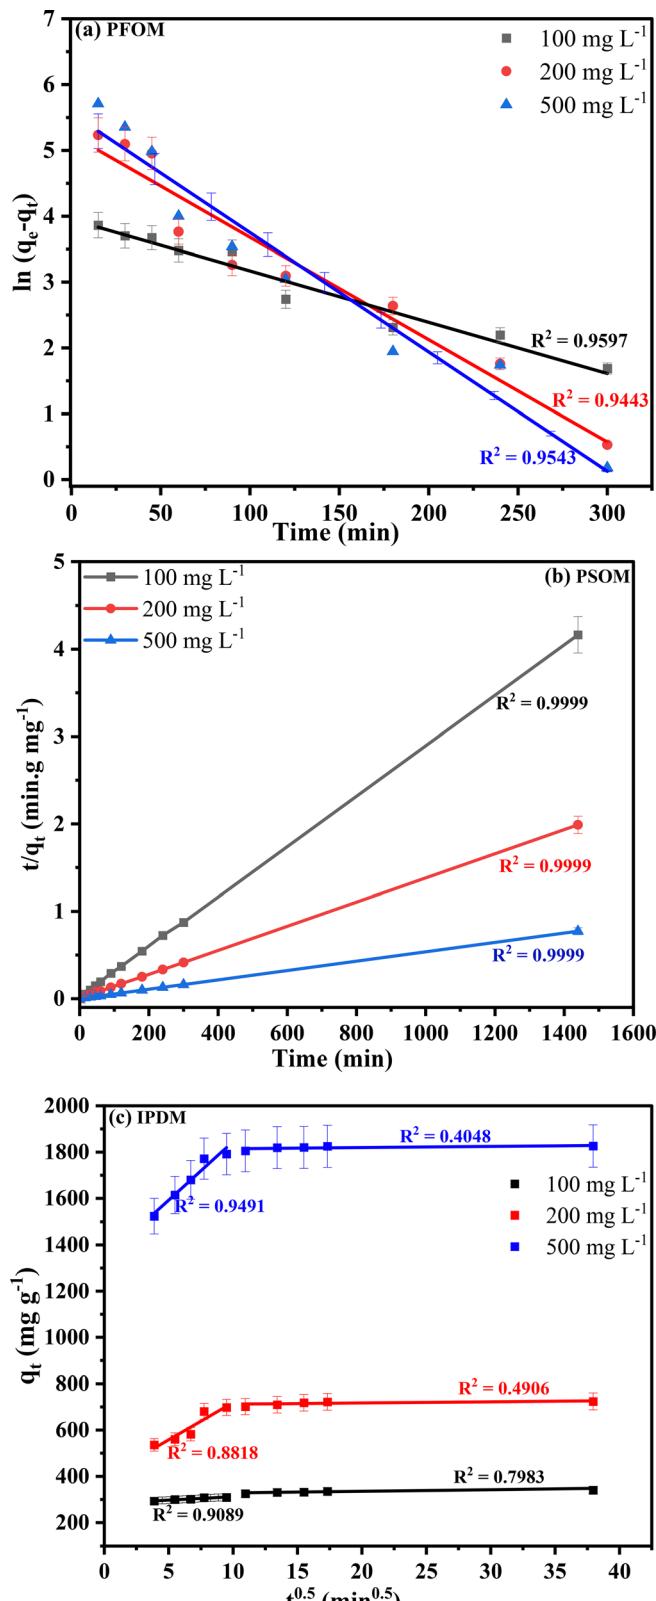

Fig. 8 Kinetic modelling studies for the adsorption of tetracycline over CF using (a) pseudo first-order, (b) pseudo second order, and (c) IPDM models.

shown to be a best fit for various dyes (crystal violet, malachite green and Congo red) adsorption on to starch derived zinc

based CF that was reported³⁰ to exhibit ultra-high adsorption capacity towards crystal violet (25 000 mg g⁻¹), malachite green (1200 mg g⁻¹) and Congo red (1429 mg g⁻¹).

3.1.10. Adsorption isotherms. Adsorption isotherms are crucial for understanding the distribution of molecules (adsorbate) between a liquid phase and a solid surface (adsorbent) at equilibrium. This study evaluates the applicability of three classical adsorption models: the Langmuir, Freundlich, and Temkin models in characterizing the adsorption of tetracycline on CF. The results of the adsorption isotherm fittings and the estimated model parameters are presented in Fig. 9 and Table 3. The Langmuir, Freundlich, and Temkin model equations are given below in eqn (8), eqn (9) and eqn (10) respectively.

$$\frac{1}{q_e} = \frac{1}{q_m} + \frac{1}{q_e K_L C_e} \quad (8)$$

$$\ln(q_e) = \ln(K_f) + \frac{1}{n} \ln(C_e) \quad (9)$$

$$q_e = B \ln(K_t) + B \ln(C_e) \quad (10)$$

where C_e is the equilibrium concentration (mg L⁻¹), q_m is the maximum adsorption capacity (mg g⁻¹), q_e is the adsorption capacity (mg g⁻¹) at equilibrium and K_L is the Langmuir adsorption rate constant. K_f and n are Freundlich constants, where K_f is related to the adsorption capacity, and $1/n$ indicates the adsorption intensity. B is a constant related to the heat of adsorption, which can be calculated as: $B = RT/b_T$, R is the universal gas constant (8.314 J mol⁻¹ K⁻¹) and T is the absolute temperature in Kelvin (K). b_T is the Temkin constant related to the heat of adsorption (J mol⁻¹).⁴¹

The Langmuir model is regarded as an ideal representation of adsorption, as it assumes a uniform adsorbent surface and that adsorbate molecules form a monolayer without interacting with one another. In this study, the model yielded an R^2 value of 0.966. Notably, the experimental maximal adsorption capacity exceeds the q_m value predicted by the Langmuir model. This discrepancy indicates that the Langmuir model underestimates the actual adsorption capability of the adsorbent.⁴³ The Freundlich isotherm accounts for non-ideal adsorption behavior, allowing the multilayer adsorption on the surface. This model is particularly useful for describing heterogeneous systems

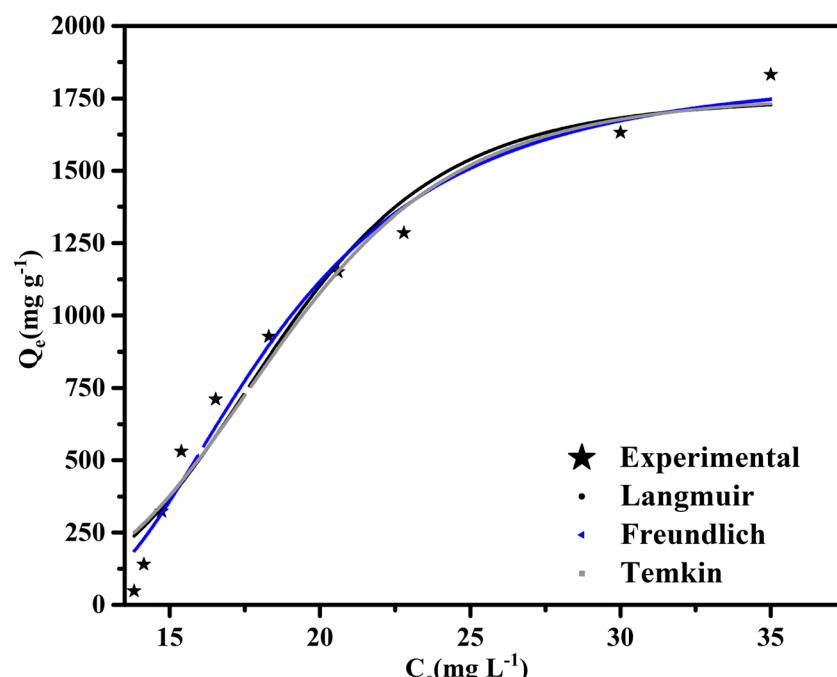

Fig. 9 Adsorption isotherm fitting for tetracycline removal over CFs.

Table 3 Isotherm's equations and constants for tetracycline adsorption on carbon foam

Isotherms	Parameters	Values
Langmuir	q_m (mg g ⁻¹)	1756
	K_l (L mg ⁻¹)	7.47
	R^2	0.966
Freundlich	K_F (mg g ⁻¹) (L mg ⁻¹) ^{1/n}	1831
	n	4.5
	R^2	0.98
Temkin	K_R (L g ⁻¹)	0.086
	b_T (J mol ⁻¹)	1.26
	R^2	0.946

characterized by varying energy sites and differing adsorption strengths. In this study, the Freundlich model demonstrated a high R^2 value of 0.980, indicating an excellent fit to the experimental data. The calculated n^{-1} value of 0.22 suggests that the adsorption process is favored and reflects the heterogeneous nature of the adsorbent surface, where variations in site energies significantly influence overall adsorption behavior.⁴⁴ Our results were found to be in line with the literature studies that used corn straw based porous carbon for tetracycline adsorption.⁴⁵

The Temkin isotherm model is particularly effective for describing chemical adsorption processes, especially in cases where there is a significant electrostatic attraction between oppositely charged species. This model accounts for the interaction of energy between adsorbed molecules, which can influence the adsorption process. In this study, the Temkin model provided a reasonable fit, with an R^2 value of 0.947. A key parameter in the Temkin isotherm, the constant b_T , reflects the variation in adsorption energy as the process progresses. This constant is instrumental in understanding the thermodynamic nature of adsorption, specifically indicating whether the process is exothermic or endothermic. If the b_T value falls within a range of 1–10, the adsorption is generally considered exothermic, while a b_T value close to 0 indicates an endothermic process. In this study, the obtained b_T value of 1.26, being close to 1, signifies a mildly exothermic process with moderate energy release, reflecting favorable adsorbent-adsorbate interactions.^{39,46}

The comparison in Table 4 highlights the remarkable performance of carbon-based adsorbents for the removal of

tetracycline, with a clear ranking of adsorption capacities (q_e). The CF derived from agar in this study shows the highest adsorption capacity at 1831 mg g⁻¹, outperforming a variety of other carbon-based materials. The significant difference in adsorption capacities demonstrates the superior surface properties and adsorption efficiency of the synthesized CF compared to other materials. The agar-derived CF's exceptional capacity positions it as a promising candidate for efficient pharmaceutical pollutant removal in water treatment applications.

3.1.11. Reusability. Batch adsorption studies were conducted to evaluate the reusability of the CF adsorbent. After each adsorption cycle, the used adsorbent was separated and thoroughly rinsed with double-distilled water to remove any residual contaminants. To regenerate the adsorbent, it was subjected to a desorption step involving washing with an appropriate desorbing agent, such as ethanol, to facilitate the release of the adsorbed tetracycline. The adsorbent was then rinsed again with double-distilled water and dried at 40 °C in a hot air oven. The adsorption performance of the regenerated adsorbent was evaluated over three consecutive cycles, each with an initial tetracycline concentration of 200 mg L⁻¹. The maximum removal efficiencies were found to be 96.2%, 95.6%, and 94.0% for the first, second, and third cycles, respectively, as shown in Fig. 10. The slight decline in adsorption capacity over successive cycles can be primarily attributed to the incomplete desorption of tetracycline, particularly within the micropores of the adsorbent, leading to potential pore blockage and residual chemisorbed species. Indeed, more studies are ongoing to demonstrate the long term stability of the adsorbent as well as in evaluating the structural integrity of these materials.

3.1.12. Adsorption mechanism. The adsorption of tetracycline on ZnO carbon foam occurs through a combination of physical and chemical interactions that work together to achieve high removal efficiency. The CF has a hierarchical porous network, which means there are many accessible pores of different sizes and a high number of available active sites. This structure allows tetracycline molecules to quickly diffuse into the adsorbent and come into close contact with its surface.⁵⁵ In the initial stage, tetracycline molecules are

Table 4 Literature comparison of tetracycline adsorption capacity with different carbon-based adsorbents

attracted to the CF surface through physical adsorption. This is mainly driven by van der Waals forces, which are weak intermolecular attractions that help bring tetracycline molecules close to the surface. Depending on the pH of the solution, this attraction is enhanced by electrostatic forces between the ionized tetracycline molecules and oppositely charged sites on the CF surface.^{56,57} When tetracycline molecules are close to the surface, stronger chemical interactions take place. The carbon domains within CF have delocalized π -electrons that can interact with the aromatic rings of tetracycline through π - π stacking. This type of interaction is common between aromatic compounds and carbon materials. The oxygen-containing functional groups on CF, such as hydroxyl ($-\text{OH}$) and carboxyl ($-\text{COOH}$) groups, can form hydrogen bonds with functional groups in tetracycline, such as its hydroxyl and amide groups. FTIR analysis confirms the presence of these functional groups on CF and shows changes after tetracycline adsorption, indicating hydrogen bonding is involved.⁵⁸ Adsorption isotherm and kinetic studies indicate that the overall adsorption mechanism involves a multilayer heterogeneous adsorption, as suggested by the good fit of Freundlich models alongside pseudo-second-order kinetics.

An additional and important mechanism in this system comes from the ZnO nanoparticles embedded in the CF matrix. These ZnO particles act as Lewis's acid sites, meaning they can accept electron pairs from TC's electron-rich groups, such as phenolic and amide functionalities. This forms coordination bonds that further strengthen the adsorption.^{59,60} Overall, the main active sites for TC adsorption are the oxygen-containing functional groups on the carbon, the π -electron-rich graphitic

domains, and the ZnO nanoparticle surfaces. These work together to give CF its high adsorption capacity.

3.2. Material characterization results

3.2.1. FTIR analysis. The choice of biomass precursor and the metal catalyst significantly influences the structure and functional group content of the resulting CF which impacts its applicability. Therefore, FTIR analysis was carried out to determine the presence of different functional groups on the CF. The FTIR spectra of various CFs synthesized using (a) zinc nitrate catalyzed CF derived from different biomass carbon precursors and (b) CF derived from agar using different metal nitrate catalysts and the comparison of both fresh and spent zinc-agar based CF adsorbent are shown in Fig. 11(a–c). It is evident from Fig. 11a that the FTIR spectra of CF derived from different biomass precursors indicates the presence of broad and strong absorption bands in the range of $3600\text{--}3800 \text{ cm}^{-1}$ which typically correspond to the stretching vibrations of hydroxyl groups. This peak which is noticed in almost all biomass derived CF is mainly due to the incomplete dehydration reaction.⁶¹ The $\text{C}=\text{O}$ stretching peak noticed at 1639 cm^{-1} is an indicative of carboxyl, ester or ketone functional groups in CF that are formed due to incomplete carbonization. The $\text{C}=\text{C}$ stretching peak corresponding at 1547 cm^{-1} corresponds to the presence of aromatic compounds formed during the foaming process. The peak around 1409 cm^{-1} originates from the $\text{O}-\text{H}$ in-plane bending vibration.²⁷ The absorption peak at 1050 cm^{-1} is due to $\text{C}-\text{O}$ stretching vibration from alcohols, ethers, or ester groups that are common in partially carbonized biomass. The differences in peak intensities and positions among the biomass

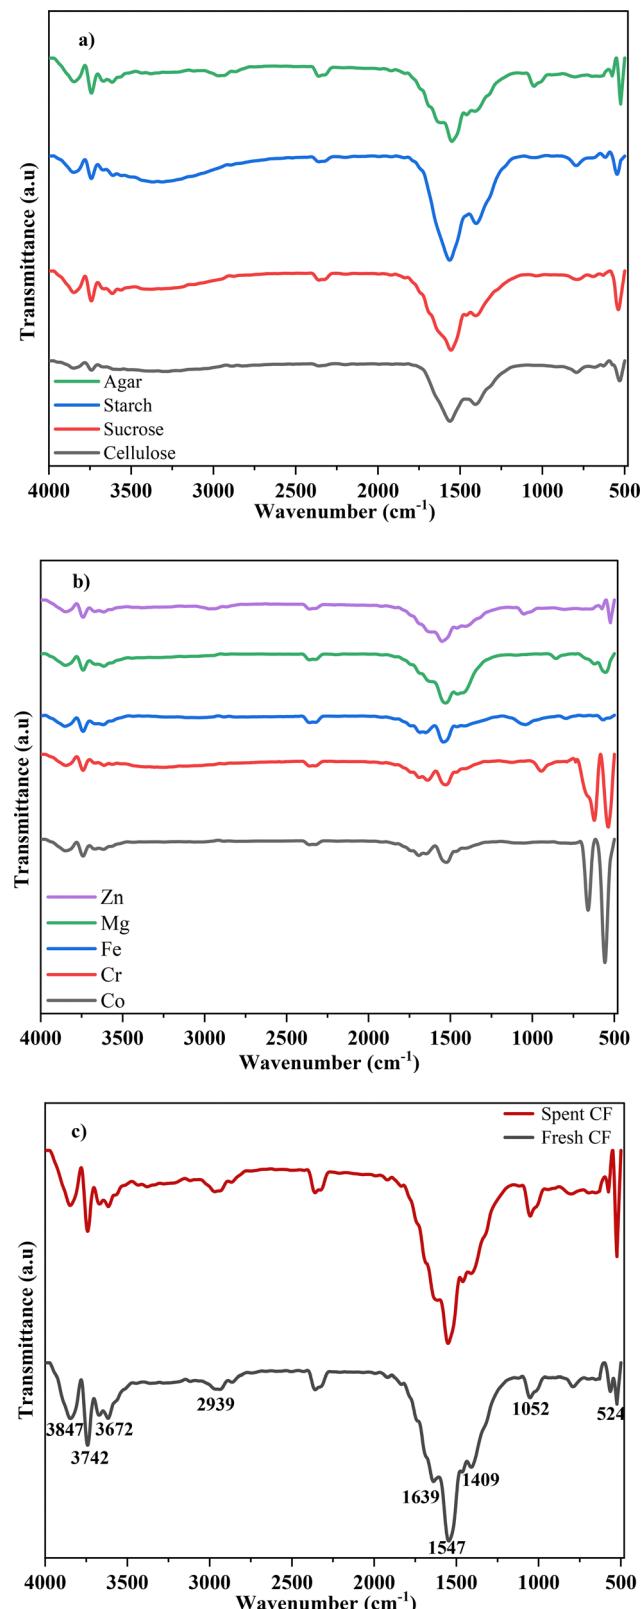

Fig. 11 FTIR spectra of (a) zinc nitrate catalyzed CF derived from various biomass streams, (b) agar based CF catalyzed with different metal nitrates, and (c) fresh and spent adsorbent of agar based CF catalyzed with zinc.

precursors reflect variations in their chemical compositions. Cellulose and starch show stronger O-H and C-H stretches due to their polysaccharide structures. The weaker C=C peaks in sucrose compared to cellulose may suggest less efficient conversion to aromatic carbon structures.

Each metal nitrate catalyst seems to influence the carbonization pathway differently (Fig. 11b). For example, Fe and Cr likely promote more significant graphitization, as seen by the stronger C=C peaks, while Zn and Mg might lead to less efficient carbon structure formation due to weaker aromatic bands. Metal–oxygen peaks in the range of 500 – 600 cm⁻¹ are associated with the formation of metal residues or oxides incorporated during the carbonization process. Tetracycline that has been adsorbed onto CF is mostly responsible for the minor peak alterations that were seen in the fingerprint area of 500–1500 cm⁻¹ with the spent adsorbent (Fig. 11c).

3.2.2. XRD analysis. The XRD spectra of fresh and spent CF are depicted in Fig. 12. The primary diffraction peaks have been indexed at specific 2θ values: 31.80° , 34.6° , 36.25° , 47.49° , 56.65° , 62.90° , and 68.19° corresponding to the crystallographic planes (100), (002), (101), (102), (110), (103) and (112) of the wurtzite phase of ZnO particles.³⁰ A weaker signal, attributable to the carbon particles, suggests the amorphous nature of the carbon material. This interpretation is supported by the lack of distinct crystalline peaks in the XRD pattern, indicating that the CF is predominantly amorphous. These crystallite size measurements provide insight into the material's microstructural properties, suggesting a consistent and well-defined crystalline morphology for CF.^{47,62} Following the adsorption, the XRD pattern reveals a reduction in the intensity of specific peaks and slight shifts in peak positions. The observed decrease in peak intensity may be due to the adsorption of tetracycline molecules on the surface or within the pores of the CF, leading to partial obstruction of the crystallographic planes and reducing the corresponding diffraction intensity. Potential shifts in peak positions may indicate structural changes or strain introduced by the interaction between ZnO and the adsorbate.

3.2.3. Surface characteristics. The surface morphology of both fresh and spent zinc catalyzed CF is shown in Fig. 13a and b. The CF exhibits a porous structure, beneficial for adsorption due to the increased number of active sites. The variation in pore sizes is attributed to gas release from metal nitrate catalysts during biomass carbonization at elevated temperatures, which contributes to the foaming process and results in larger pores. Similar observations were reported³⁰ during CF synthesis from starch, leading to larger pore formation. While it is clear that the spent adsorbent is not as porous in nature as the fresh adsorbent indicating the pore blocking due to the deposition of the organics after adsorption.

Energy-dispersive X-ray spectroscopy (EDX) analysis confirmed the presence of zinc, oxygen, and carbon in the samples (Fig. 13c and d). The fresh CF adsorbent contained approximately 60% zinc, 19% carbon, and 21% oxygen. After tetracycline adsorption, the carbon content increased to 40%, indicating the presence of adsorbed organics, while the zinc content decreased

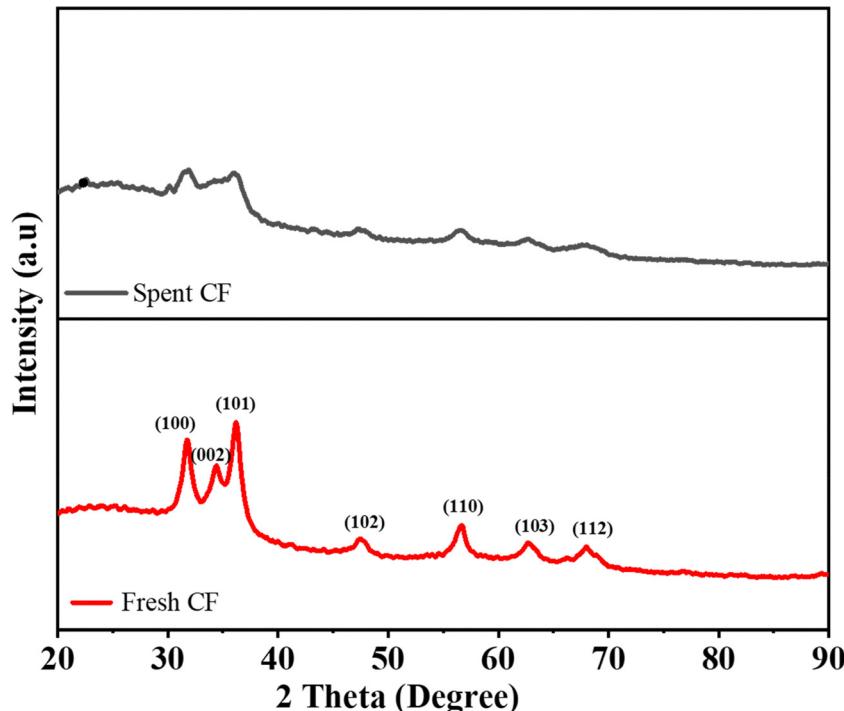

Fig. 12 XRD spectra of fresh and spent zinc catalyzed agar-based CF.

to 30%, and oxygen increased to 30%, signifying successful adsorption onto the zinc catalyzed CF.⁶³

3.3.3. BET analysis. The porous structure of the modified carbon foam was systematically investigated using nitrogen adsorption–desorption isotherms. The Brunauer–Emmett–

Teller (BET) analysis revealed a specific surface area of $38.09 \text{ m}^2 \text{ g}^{-1}$, representing the total accessible external surface area for adsorption. Further analysis using the Barrett–Joyner–Halenda (BJH) method indicated a mesopore surface area of $74.10 \text{ m}^2 \text{ g}^{-1}$, along with a total pore volume of $0.058 \text{ cm}^3 \text{ g}^{-1}$

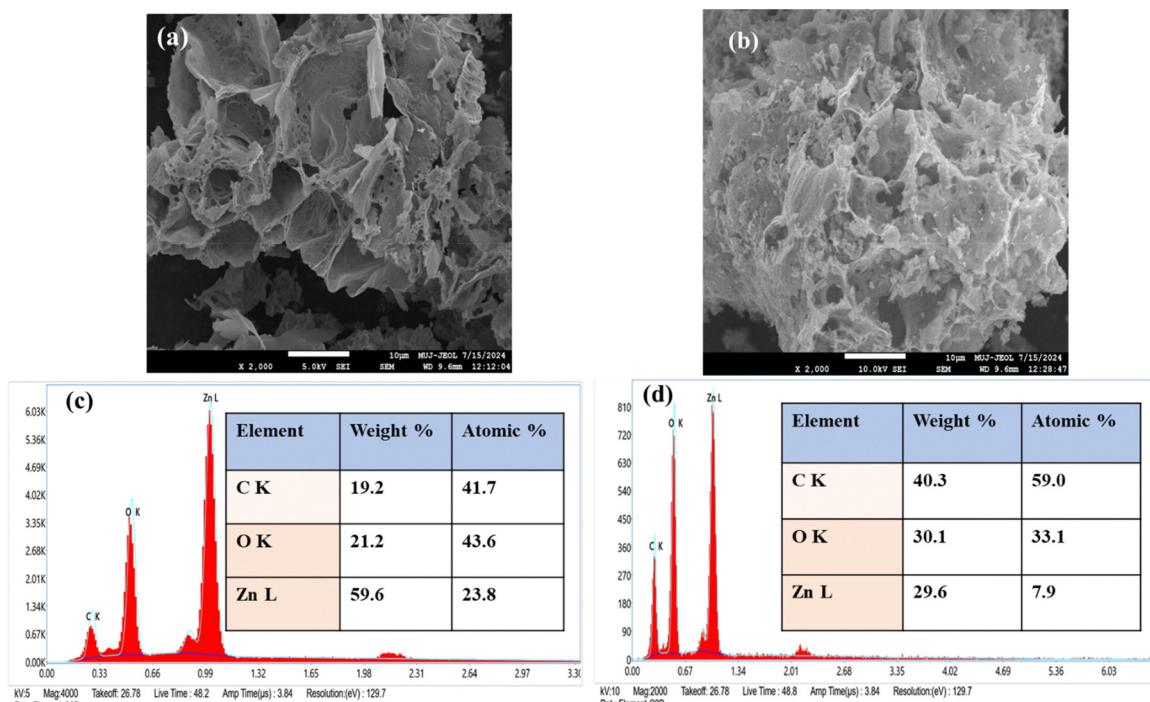

Fig. 13 FESEM and EDX analysis of fresh (a) and (c) and spent adsorbent (b) and (d) with elemental composition tabulated.

and an average pore diameter of 1.69 nm. Although this pore width falls at the lower boundary of the mesoporous regime (2–50 nm), it also suggests a significant contribution from micropores. To confirm this, the Horváth–Kawazoe (HK) method was employed, which yielded a micropore volume of $0.024\text{ cm}^3\text{ g}^{-1}$, thereby substantiating the coexistence of both micro- and mesopores within the foam. This kind of hierarchical pore structure, combining micropores (which provide high adsorption potential due to strong adsorbate–adsorbent interactions) and mesopores (which facilitate molecular diffusion and accessibility), is advantageous for adsorption processes. The relatively modest BET surface area compared to commercial activated carbons is compensated by the presence of interconnected pores and high adsorption affinity, which together explain the exceptionally high adsorption capacity observed for the synthesized carbon foam.^{64,65}

4. Conclusion

This study successfully demonstrates the synthesis of CF from various biomass-derived precursors, showing high adsorption capacity for pharmaceutical effluent removal. Despite the use of different biomass precursors—agar, cellulose, sucrose, and starch—the adsorption efficiency for tetracycline remained consistent, indicating that the carbon precursor plays a limited role in adsorption performance. However, the catalytic influence of different metal nitrates was significant. In particular, zinc-catalyzed CF derived from agar exhibited complete removal of a range of pharmaceutical contaminants, highlighting its superior adsorption potential. Tetracycline adsorption followed the Freundlich isotherm, suggesting that the CFs have heterogeneous surfaces with multiple adsorption sites, leading to non-uniform adsorbate distribution. The kinetics of the adsorption process adhered to a pseudo-second-order model, confirming chemisorption as the dominant mechanism. Thermodynamic analyses further revealed that the adsorption is spontaneous and endothermic, driven by entropy increase, making the process favorable under the tested conditions. A key finding of this work is the excellent reusability of the zinc-catalyzed CF, which retained its high adsorption capacity across multiple cycles without significant loss of efficiency. This highlights its potential as a cost-effective and sustainable solution for water treatment applications, offering both environmental and economic benefits in the management of pharmaceutical pollutants.
