Self-patterning of liquid Field's metal for enhanced performance of two-dimensional semiconductors†

Kwanghee Han, ^{‡,a,b} Heeyeon Lee, ^{‡,a} Minseong Kwon, ^{a,c} Vinod Menon, ^b Chaun Jang ^c and Young Duck Kim ^{*,a,d}

Two-dimensional (2D) van der Waals semiconductors show promise for atomically thin, flexible, and transparent optoelectronic devices in future technologies. However, developing high-performance field-effect transistors (FETs) based on 2D materials is impeded by two key challenges, namely, the high contact resistance at the 2D semiconductor–metal interface and limited effective doping strategies. Here, we present a novel approach to overcome these challenges using self-propagating liquid Field's metal, a eutectic alloy with a low melting point of approximately 62 °C. By modifying pre-patterned electrodes on WSe₂ FETs through the deposition of Field's metal onto contact pad edges followed by vacuum annealing, we create new semimetal electrodes that seamlessly incorporate the liquid metal into 2D semiconductors. This integration preserves the original electrode architecture while transforming to semimetal compositions of Field's metal, such as Bi, In, and Sn, modifies the work functions to 2D semiconductors, resulting in reduced contact resistance without inducing Fermi-level pinning, and improves charge carrier mobilities. Our method enhances the electrical performance of 2D devices and opens new avenues for designing high-resolution liquid metal circuits suitable for stretchable, flexible, and wearable 2D semiconductor applications.

1. Introduction

One of the breakthroughs for future electrical devices is developing integrated circuits based on the 2-dimensional (2D) semiconductor. However, creating a reliable contact between the metal electrodes and 2D transition metal dichalcogenides (TMD) has been challenging. Due to metal-induced gap states (MIGS),^{1–5} Schottky barriers lead to increased contact resistance and reduced on-current density.^{6,7} Meanwhile, recent work has demonstrated breakthroughs for low contact resistance in 2D TMD devices using bismuth (Bi),⁸ indium (In),⁹ and their alloys as electrodes.^{10,11} Here, we propose a new strategy to reduce the contact resistance of 2D semiconductors by using self-propagation of Field's metal. Previously, Field's metal has been used to make ohmic contact with graphene devices using the micro-soldering method.¹² In addition, it has been used to investigate van Hove singularities in the local

density of states for magic-angle-twisted bilayer graphene.¹³ This work demonstrated extremely precise electrodes using liquid Field's metals on pre-patterned structures. Since the Field's metal alloy contains Bi, In, and Sn,^{14,15} our strategy can be utilized to enhance the performance of 2D semiconductor-based electronics.

2. Results

2.1. Self-propagation of liquid Field's metal by vacuum annealing

Metals or conductors that become liquid near room temperature offer several advantages. First, they can be utilized in stretchable, soft electrical devices,¹⁶ which have great potential for clothing, medical implants, or wearable materials for key applications.¹⁷ Second, liquid-metal patterning is a significantly simpler process compared to physical vapor deposition (PVD) techniques, which require high temperatures and vacuum conditions to melt metals ($T > 1000$ °C).¹⁸ Finally, liquid metals are highly reconfigurable, allowing precise control of their shape and position once heated to their melting point ($T < 100$ °C).^{19–23} Consequently, various approaches have been developed to print liquid metal circuits, including techniques such as direct writing^{24,25} and the voltage-induced self-healing effect.²⁶

Despite the great potential of liquid metal for flexible electronic applications, conventional fabrication methods for liquid metal electrodes face several challenges. Liquid metal electrode fabrication methods are constrained by limited fabrication resolution,¹⁸ with reported resolutions of $\sim 2\text{ }\mu\text{m}$ for imprint techniques,¹⁹ $\sim 10\text{ }\mu\text{m}$ for injection methods,¹⁸ and $\sim 100\text{ }\mu\text{m}$ for direct wire methods.^{25,27} Another challenge is reduced electrical contact with semiconductors due to formation of native oxide layers. For instance, liquid gallium forms a gallium oxide layer when exposed to ambient conditions,²⁸ and such native oxide layers make it more difficult to use liquid metals in fabricating semiconductor devices with low-contact resistance.¹⁸

Recent studies have shown that precise liquid metal electrodes can be made using intermetallic bond-assisted patterning.^{29–32} Since liquid metal alloys are mixed with other metals, the liquid metal can be deposited on the pre-patterned substrate and spread by jetting or rolling. In addition, etching solutions are used to remove surface oxide and liquid metal residues, resulting in liquid metal electrodes with resolution

larger than $50\text{ }\mu\text{m}$.³² A further issue is the use of mechanical force to remove metal alloys from the mold and placing the assembly in chemical solutions for cleaning, which could damage the patterned electrodes. In our work, however, self-propagation of the liquid metal along the pre-patterned electrodes does not require any mechanical or chemical post-processing, and our method offers significantly higher resolution ($\sim 200\text{ nm}$) than conventional liquid metal fabrication techniques.

Self-propagation is a new physical property of liquid metals which can facilitate formation of new alloys with metal surfaces *via* heating. It is a different technique from other methods used in previous research such as rolling²⁹ and applying voltage.^{23,33} Furthermore, unlike these previous techniques, self-propagation occurs even under ambient pressure conditions, indicating that the processing of the Field's metal is driven by intrinsic material properties rather than external pressure differences (ESI Note 3†).

As shown in Fig. 1a, the liquid Field's metal self-propagates along the pre-patterned electrodes during vacuum annealing

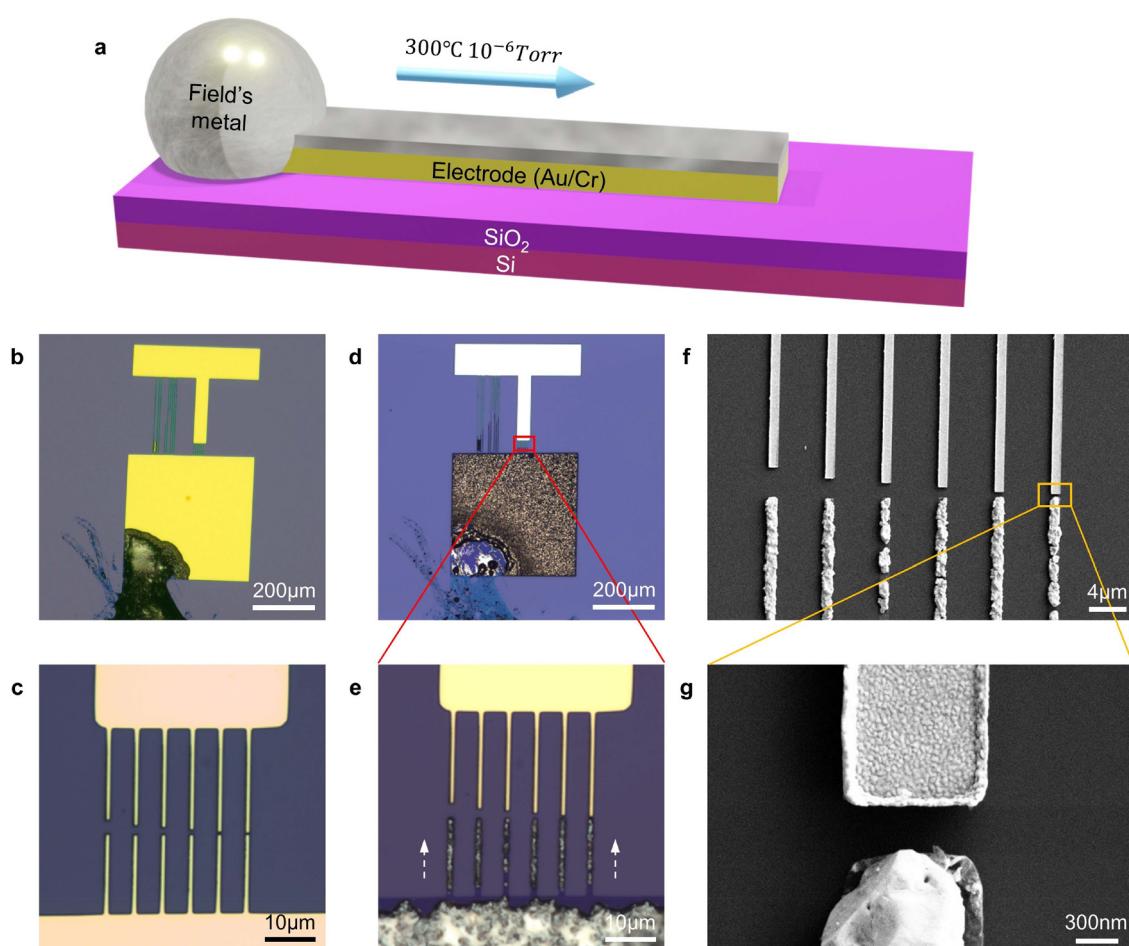

Fig. 1 Self-propagation of Field's metal by vacuum annealing. (a) Schematic diagram of the self-propagation effect of liquid metal. (b and c) Optical images of pre-patterned Au/Cr electrodes after placing Field's metal on top of the surface. (d and e) Optical images after vacuum annealing. The Field's metal propagated through the electrodes. (f and g) SEM images of Field's metal electrodes. Accurate electrodes with dimensions of a few hundred nanometers can be produced by this method.

above the melting point ($T > 62$ °C) and accurately forms the semimetal electrode composite (including Bi, In, and Sn) with the same shape as the original pre-patterned electrodes (Au/Cr). To investigate this process, we prepared pre-patterned electrodes separated by two electrode gaps of 0.2–5 μm distance (Fig. 1b and c). After vacuum thermal annealing ($T \sim 300$ °C, 2 h), we observed the self-propagation of liquid Field's metal through the pre-patterned electrodes without significant spread of the metal through the SiO_2 substrate and its hopping of the 200 nm gap as shown in the optical images (Fig. 1d and e) and the scanning electron microscopy (SEM) images (Fig. 1f and g). Thus, our electrode formation techniques using self-propagating liquid Field's metal show a higher resolution than conventional methods when fabricating precise nanoscale liquid metal electrodes.^{18,19,25,27} According to resolution tests for this method, we could realize Field's metal electrodes with \sim 200 nm width (ESI Note 4†). In addition, the accuracy of self-patterned liquid Field's metal electrodes is the same as the resolution of electrodes obtained from e-beam lithography.

By applying the self-propagation liquid metal technique, devices that feature 2D semiconductor FETs can be readily fabricated with Field's metal electrodes. Fig. 2a is a schematic illustration of a multilayer WSe₂ device assembled *via* the self-propagation of liquid Field's metal. After placing Field's metal on the edge of each gold electrode and subjecting it to vacuum annealing, the electrodes can be reformed with the same design as pre-patterned electrodes using the semimetal alloys

of the Field's metal. To determine the contact resistance value of the WSe₂ device, we use the transfer-length method (TLM). The pre-patterned Cr/Au electrodes are fabricated using multi-layer WSe₂ flake (61 nm) with different values of channel length ($L_{\text{CH}} = 1$ μm , 2 μm , 3 μm , 4 μm) but having the same metal contact length (L_c) of 1 μm . All channels have width (W) values of 7 μm . As shown in the optical images of Fig. 2b and c, we can confirm that Field's metal electrodes successfully reform after self-propagation under vacuum annealing.

2.2. Electrical properties of a WSe₂ FET device with Field's metal electrodes

To compare the pre-patterned (Au/Cr) and liquid Field's metal alloy composite (Bi/In/Sn) electrical contacts with the WSe₂, we measured their transfer characteristics ($I_{\text{DS}}-V_{\text{G}}$) under constant $V_{\text{SD}} = 1$ V at room temperature. As shown in Fig. 3a, the on-current at a high gate voltage ($V_{\text{G}} = 60$ V) increased from 1.18 μA to 6.12 μA (~5.2 times) after forming the Field's metal electrodes. Furthermore, the output characteristics ($I_{\text{DS}}-V_{\text{DS}}$) show a significant increase in current flow up to \sim 14.6 times under a lower gate voltage ($V_{\text{G}} = 40$ V) and higher saturation currents after the self-propagation process, as shown in Fig. 3d and e. This is attributed to the reformation of pre-patterned electrodes by liquid Field's semimetal alloy composites (Bi, In, Sn), significantly lowering the contact resistance between 2D semiconductors and metal electrodes.

Au/Cr is a common material used to make electrodes in 2D material-based devices, but its Schottky barrier results in high

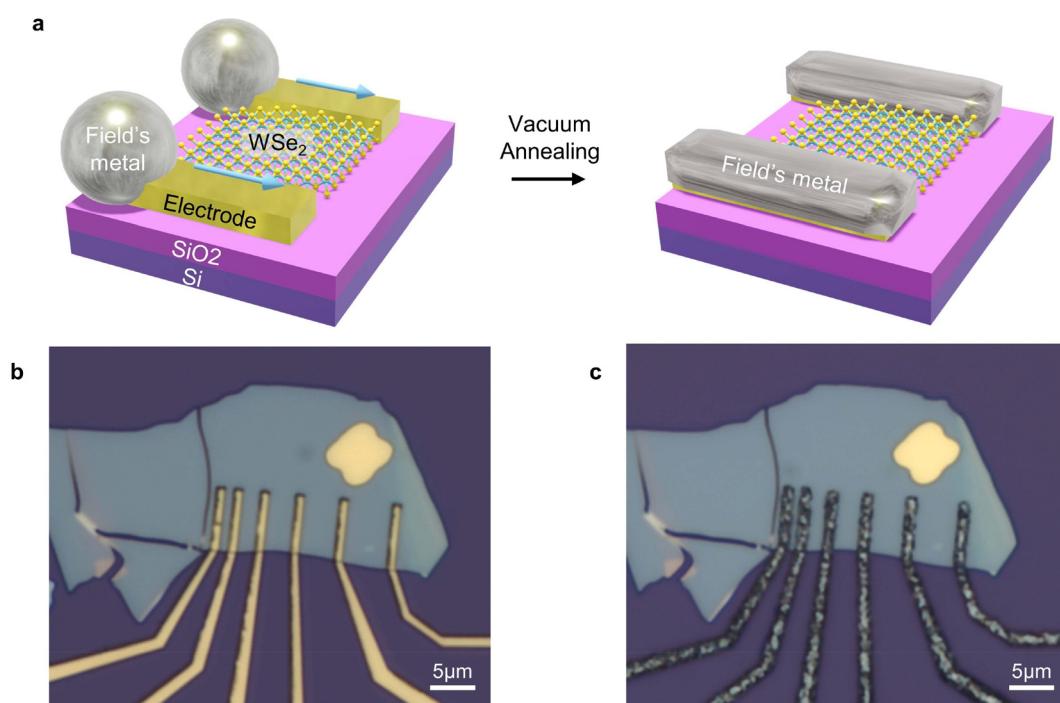

Fig. 2 A WSe₂ FET device with Field's metal electrodes obtained using self-propagation. (a) Schematic illustration of the assembly of a WSe₂ field-effect transistor by using the self-propagation method. (b) Optical image of the device before annealing. (c) Optical image of the device after annealing. The Field's metal was formed accurately with the same structure as the Au/Cr electrodes.

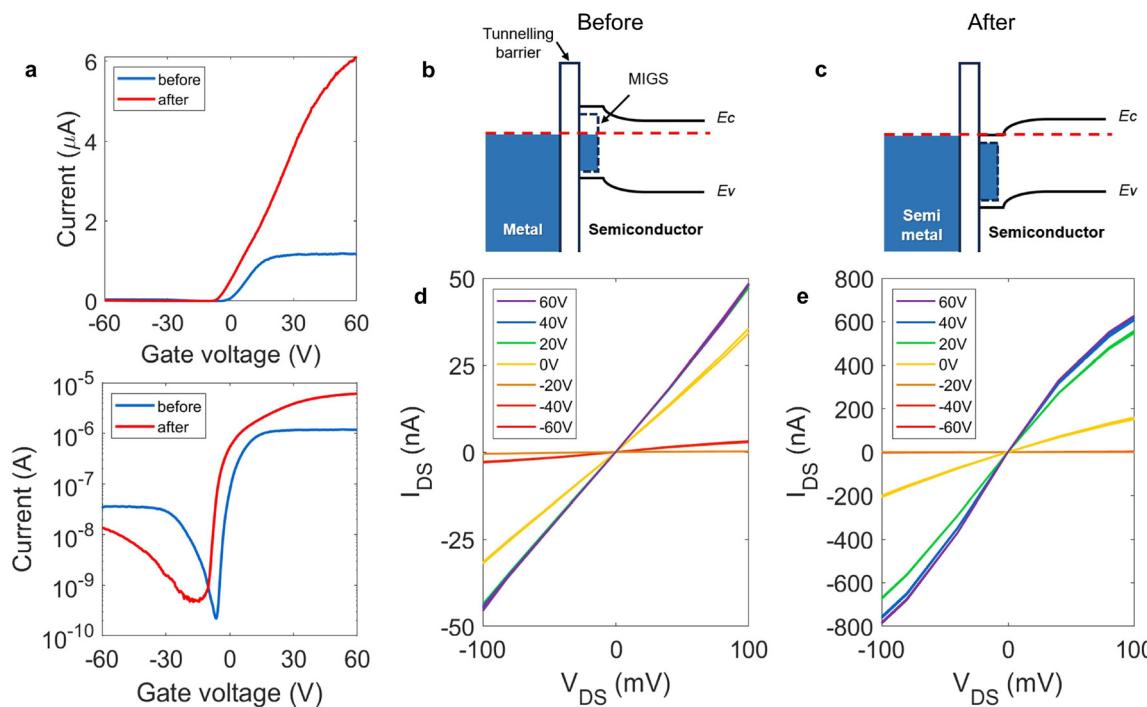

Fig. 3 Comparison between electrical characteristics of contact of Au/Cr and Field's metal electrodes with WSe₂. (a) Room-temperature transfer characteristics (I_{DS} – V_G) before and after self-propagation of Field's metal. The on-current is increased by ~5.2 times after the process. (b) The band structures of metal–semiconductor contact showing a Schottky barrier by metal-induced gap states (MIGS). (c) The band structures of semimetal–semiconductor interaction that exhibits ohmic contact by preventing gap-state pinning. (d and e) Output characteristics (I_{DS} – V_{DS}) at room temperature of the WSe₂ FET device before and after forming Field's metal electrodes.

contact resistance. For instance, a recent report indicated that WSe₂ with Cr contacts exhibits a mobility of $1.838 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and a contact resistance of $496 \text{ k}\Omega \mu\text{m}^{-1}$.³⁴ Also, Cr (~4.5 eV) and Au (~5.1 eV) do not align well with the valence band of WSe₂ (~5.3–5.4 eV), resulting in a large Schottky barrier for p-type injection.³⁵ Furthermore, chromium can chemically react with the WSe₂ surface, potentially forming defects at the interface, which may degrade device performance.^{36,37} However, our results show that the n-type contact can be improved by this method. Although achieving good n-type contact with WSe₂ is challenging, our results demonstrate a clear improvement in contact performance.

Fig. 3b shows the band structure of the contact between metal and semiconductor, which explains the high contact resistance with gold electrodes and WSe₂. Because of the energy difference between metal and semiconductor and MIGS via Fermi-level pinning, the Schottky barrier is created and this results in higher contact resistance.⁷ However, as Fig. 3c reveals, the contact resistance is reduced by using semimetal materials as electrodes. Because the semimetal, bismuth and indium, can facilitate ohmic contact with TMDC,^{8,9} the Field's metal electrodes can lower the Schottky barrier height with the same mechanism. The self-propagation of liquid Field's metal enables the modification of the work function of pre-patterned metal electrodes through the formation of semi-metallic alloys, demonstrating its potential for tuning band alignment

to enhance the electrical performance of 2D semiconductor devices.

As shown in Fig. 4, we also estimated the field-effect mobility (μ_{FE}) of each channel and the contact resistance (R_C) from the transfer characteristics (I_{DS} – V_G). The log-scale transfer characteristics by channel length show a significant difference in the electrical properties before (Fig. 4a) and after (Fig. 4b) self-propagation of the liquid Field's metal contact. Fig. 4c shows the relationship between the threshold voltage and the channel length of the WSe₂ FET device. The threshold voltages of the fabricated WSe₂ FET channels are initially around $V_{th} = 0 \text{ V}$, but there is a significant negative shift of threshold voltage after the transformation of the Field's metal electrodes. This is attributed to the formation of transparent contacts with semimetal alloys and the reduction of Fermi-level pinning caused by metal-induced gap states.

Fig. 4d shows that the mobility is increased by the Field's metal contact. The field effect mobilities are calculated by using the equation, $\mu_{FE} = \left[\frac{dI_d}{dV_G} \right] \times \left[\frac{L}{WC_i V_{DS}} \right]$, where W is the channel width, L is the channel length, and C_i is the capacitance between the channel and back gate per unit area. Before forming the Field's metal electrodes, the electron mobility values, indicated by blue dots, range from ~0.7684 $\text{cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ($L_{CH} = 1 \mu\text{m}$) to ~3.2814 $\text{cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ($L_{CH} = 4 \mu\text{m}$). On the other hand, after the transformation process with self-propa-

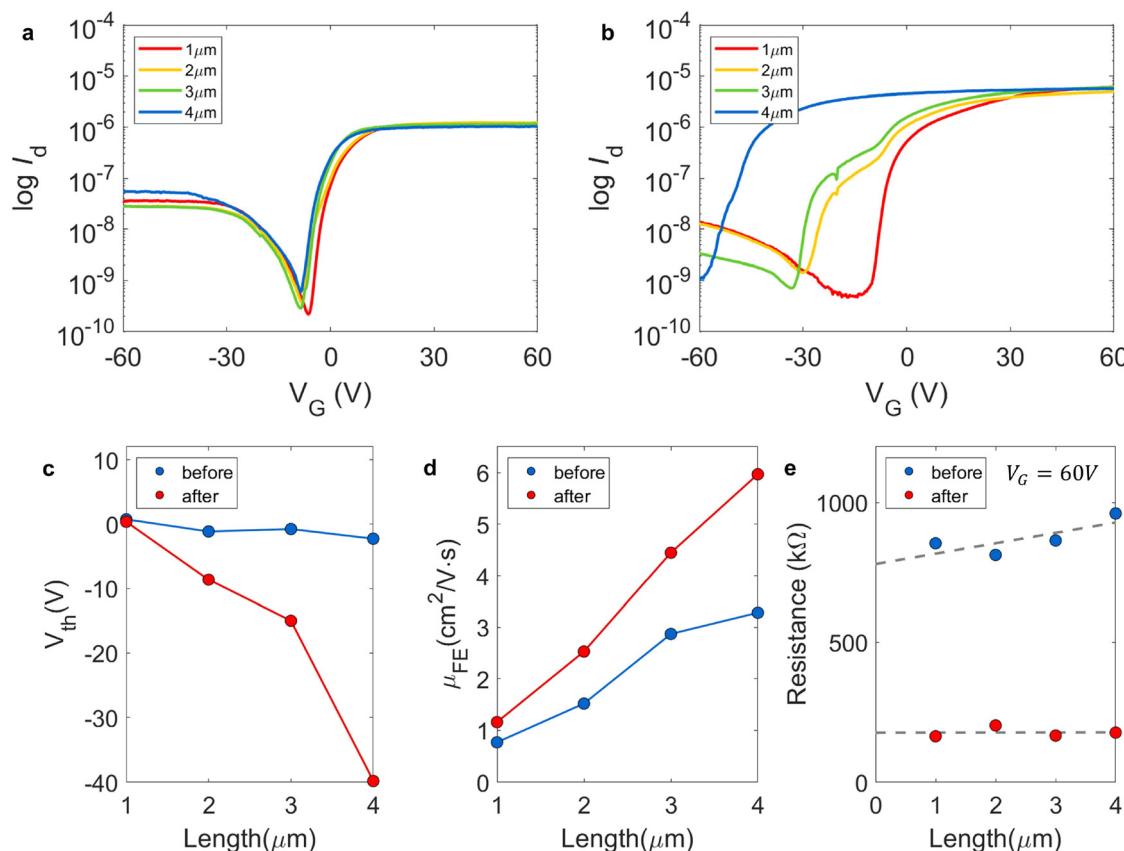

Fig. 4 Contact resistance reduced by self-propagation of Field's metal. (a and b) Log-scale transfer characteristics (I_{DS} – V_G) as a function of the channel length (a) before and (b) after self-propagation. (c) Threshold voltage (V_{th}) by channel length is changed after forming the Field's metal electrode. (d) Comparison of electron mobilities from the WSe₂ FET device before and after fabricating the Field's metal contact. (e) Contact resistance (R_C) measured by using the transfer-length method (TLM).

gation of liquid Field's metal, the mobility values are increased, as shown by the red dots in Fig. 4d, from $\sim 1.1602 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ($L_{CH} = 1 \mu\text{m}$) to $\sim 5.969 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ($L_{CH} = 4 \mu\text{m}$). By comparing these results, μ_{FE} has increased by about 1.51–1.82 times after formation of the Field's metal contact.

To investigate the reduction in contact resistance (R_c) by using liquid Field's metal, we measured the two-probe resistance (R_T) as follows:^{8,38}

$$R_T = 2R_c + R_{ch} = 2R_c + R_{sh}L_{ch}$$

where R_{ch} is the channel resistance, and R_{sh} is the sheet resistance of the semiconductor channel. Thus, from the graph of R_T as a function of L_{ch} , we can deduce the resistance at $L_{ch} = 0$, which corresponds to $R_T = 2R_c$. Fig. 4d shows the resistance by channel length when $V_G = 60 \text{ V}$. The blue (red) dots represent the data before (after) the self-propagation of the liquid Field's metal. So, the contact resistance with 2D semiconductor FETs is reduced by 22.6% (390 k Ω to 88 k Ω) after self-propagating liquid Field's metal. This integration preserves the original electrode architecture while the semimetal composition of Field's metal, including elements such as Bi, In, and Sn, reduces contact resistance without inducing Fermi-level pinning. Our method enhances the electrical performance of

2D devices and opens new avenues for designing high-resolution liquid metal circuits suitable for stretchable, flexible, and wearable 2D semiconductor applications.

3. Conclusion

In summary, we demonstrate the realization of high-resolution self-patterned liquid Field's metal to achieve transparent contact with 2D semiconductor devices. Simply placing the Field's metal on the pre-patterned electrodes and applying vacuum annealing enhances the electrical performance, as evidenced by increased mobility and reduced contact resistance. This occurs due to the transformation of Cr/Au electrodes into a semimetal alloy of Bi, In, and Sn, which reduces the Fermi level pinning effect caused by metal-induced gap states (MIGS) in WSe₂.⁸ Additionally, liquid metals composed of materials with varying work functions can be utilized, enabling more efficient interfacial charge transfer and lower contact resistance in 2D semiconductor FETs.⁹ Since this technique facilitates the fabrication of high-resolution liquid metal electrodes, it paves the way to developing nano-scale liquid metal electrodes for stretchable, flexible, and highly reconfigurable 2D integrated circuits.

4. Methods

4.1. Sample preparation

WSe₂ flakes were mechanically exfoliated onto 285 nm-thick SiO₂ using the Scotch tape technique. Pre-patterned electrical contacts were defined using electron-beam lithography (Zeiss Sigma 300 with NPGS) conducted at the Multidimensional Materials Research Center at Kyung Hee University (2021R1A6C101A437). PMMA A6 was used as the e-beam resist after spin coating at 2000 rpm for 60 s. It was baked at 180 °C for 5 min. After e-beam lithography, the samples were developed under IPA:DI water = 3:1 for 1 min. All the electrodes were deposited using a thermal evaporator (3 nm Cr, 60 nm Au). After deposition, we placed the samples in acetone overnight for the lift-off process. To make the Field's metal electrodes, we positioned a piece of Field's metal on the electrodes and annealed it under vacuum (200–300 °C, $\sim 10^{-6}$ Torr) for 2 hours.

4.2. Device characterization

All electrical measurements were conducted under vacuum ($\sim 10^{-6}$ Torr) on a probe station (MS TECH) using a parameter analyzer (HP 4155A Semiconductor Parameter Analyzer). The thickness of the WSe₂ samples was determined using AFM (Park Systems XE-100, Bruker Multimode 8). SEM images were obtained with a field emission scanning electron microscope (Zeiss Sigma 300, FEI Helios Nanolab 660).

Author contributions

K. H. and Y. D. K. designed the research project and supervised the experiment. K. H. fabricated the Field's metal samples. K. H. and H. L. performed the electrical measurements. K. H. and H. L. obtained the SEM images. M. K. and K. H. used an e-beam evaporator for making the Au/Cr electrodes. The fabrication process was supervised by C. J. and V. M. K. H. and Y. D. K. analysed the data and wrote the paper. All authors contributed to the scientific planning and discussions and commented on the manuscript.
