Patterning technologies of quantum dots for color-conversion micro-LED display applications

 Yuhui Wang,^{†a} Yunshu Luo,^{†a} Xuemin Kong,^a Tingzhu Wu,^{ID a} Yue Lin,^{ID *a,b}
 Zhong Chen^{ID *a,b} and Shuli Wang^{ID *a}

Quantum dot (QD) materials and their patterning technologies play a pivotal role in the full colorization of next-generation Micro-LED display technology. This article reviews the latest development in QD materials, including II–VI group, III–V group, and perovskite QDs, along with the state of the art in optimizing QD performance through techniques such as ligand engineering, surface coating, and core–shell structure construction. Additionally, it comprehensively covers the progress in QD patterning methods, such as inkjet printing, photolithography, electrophoretic deposition, transfer printing, microfluidics, and micropore filling method, and emphasizes their crucial role in achieving high precision, density, and uniformity in QD deposition. This review delineates the impact of these technologies on the luminance of QD color-conversion layers and devices, providing a detailed understanding of their application in enhancing Micro-LED display technology. Finally, it explores future research directions, offering valuable insights and references for the continued innovation of full-color Micro-LED displays, thereby providing a comprehensive overview of the potential and scope of QD materials and patterning technologies in this field.

1. Introduction

Displays, one of the ideal interfaces for human–machine interaction, provide clear and accurate images and text, enabling

efficient and intuitive interaction with computers.^{1–3} High-resolution displays reveal more details, enhancing image realism and fidelity, which, in turn, improves user satisfaction with graphical interfaces and overall usability. With the rise of the “metaverse” concept, there has been growing interest in both academia and industry towards near-eye displays, particularly those suitable for virtual reality (VR), augmented reality (AR), and mixed reality.^{2,4,5} These application domains demand higher optical quality, resolution, color vividness, and contrast from modern displays.⁶ To meet these demands, the development of new display technologies with high resolution

Yuhui Wang

Yuhui Wang received his Bachelor of Engineering degree from Xiamen University in 2022. He is currently pursuing his Master of Engineering degree at the Department of Electronic Science, School of Electronic Science and Engineering, Xiamen University, under the direction of Professor Zhong Chen. His current research interest focuses on microfluidics-based patterning of quantum dots for color conversion full-color micro-LED displays.

Yunshu Luo

Yunshu Luo received her Bachelor of Engineering degree from the School of Electronic Science and Engineering, Xiamen University, in 2023. Now, she is a graduate student at Xiamen University, under the guidance of Professor Wang Shuli. Her research interests include inkjet printing of perovskite nanocrystal color-conversion layers for full-color micro-LED display technology.

and image quality is crucial for optimizing visual experience.⁷ Micro-LED display technology, which constructs self-emissive pixel units using Micro-LED chips smaller than 50 μm and assembles these pixels into high-density arrays, is regarded as the “ultimate display technology” in the realm of flat-panel displays.^{8,9} Owing to its outstanding performance in terms of brightness, contrast, viewing angles, energy consumption, response speed, resolution, lifespan, and color rendering, Micro-LED display technology shows promising applications in AR/VR, optical communication/optical interconnects, flexible transparent displays, and smart car lighting.^{10–12} Consequently, Micro-LED display technology has become a hot research topic in the fields of optoelectronic materials and display technologies in recent years.

To achieve superior visual experience, the construction of full-color Micro-LED displays requires the formation of micro-scale RGB pixel points. The realization of Micro-LED full-color displays mainly relies on two approaches: a three-primary-color chip scheme and color-conversion scheme.^{13,14} The three-primary-color chip scheme achieves full color by integrating arrays of RGB three-primary-color Micro-LED chips onto the display backplane.^{13–16} This scheme depends on high-precision massive transfer technology but suffers from lower transfer precision, lower product yield, and higher difficulty in repair, leading to higher costs for Micro-LED display products.¹⁵ Additionally, voltage differences between Micro-LEDs of different colors increase the complexity of the driver circuit design. By contrast, the color-conversion scheme uses fluorescent materials to emit fluorescence under the excitation of blue or UV Micro-LED chips to achieve full color.^{4,17,18} Currently, the fabrication technology of blue Micro-LED chips is relatively mature and can realize full-color display by exciting fluorescent materials that emit red

and green colors. Although this approach is simple and straightforward, it needs to address the issue of blue light leakage to avoid reducing the color purity and gamut of the display and to protect against potential harm to humans. In comparison, the color-conversion scheme for full colorization using UV Micro-LED chips requires the combination of RGB fluorescent materials. Generally, fluorescent materials exhibit good absorption properties for UV light, and technology for addressing the issue of UV light leakage is also relatively mature.

In color-conversion schemes, fluorescent materials must possess the following characteristics to ensure the color purity and color gamut of Micro-LED display devices: small size, high luminous intensity, narrow full width at half maximum (FWHM), and high quantum yields.^{5,19} Traditional phosphors such as calcium halophosphate phosphors and rare-earth tri-chromatic phosphors are not suitable for fabricating uniformly emitting micro-scale pixel points due to their larger particle sizes and slow response.^{13,17} In contrast, nanometer-scale quantum dot (QD) materials are ideal for achieving full-color Micro-LED displays *via* color conversion.^{5,20,21} QDs are semiconductor nanocrystals with quantum confinement effects, and their characteristic size is typically no larger than twice the Bohr radius of the exciton in the corresponding semiconductor material.²² QDs exhibit unique properties such as narrow emission spectra, high quantum yield, and tunable bandgaps, and they can emit light across a broad spectrum from visible to near-infrared.²³ Currently, the QD materials used in full-color Micro-LED displays primarily include II–VI group QDs, III–V group QDs, and perovskite QDs. However, the photoluminescence (PL) performance of QD materials may degrade under complex conditions such as exposure to light, heat, water, and oxygen. To make QD materials more suitable

Yue Lin is an associate professor in the Department of Electronic Science, Xiamen University. His research scope includes (a) micro-LED display technology, (b) electrohydrodynamic inkjet printing for quantum dot color conversion layers, (c) GaN- and AlGaIn-based semiconductor materials and devices and optoelectronic properties, and (d) all-inorganic and hybrid perovskite quantum dots and the optoelectronic properties. As the first

and/or corresponding author, he has published more than 30 papers in journals such as Advanced Materials, Advanced Optical Materials, Small, Journal of Materials Chemistry C, Photonics Research, and Applied Physics Letters. He has hosted fundings including NSF of China, NSF and Cooperation of Fujian Province.

Zhong Chen

Chen Zhong received his Ph.D. from Xiamen University, China, in 1993. Currently, he is Professor and Dean of the School of Electronic Science and Engineering at Xiamen University and Executive Director of the National Innovation Platform for the Fusion of Industry and Education in Integrated Circuits at Xiamen University. His research interests mainly focus on LED lighting and display,

magnetic resonance and medical imaging. To date, he has published more than 570 SCI papers in journals such as Nature Communications, Advanced Materials, Journal of the American Chemical Society, and Angewandte Chemie International Edition.

for color conversion in Micro-LED displays, performance optimization is often required. These optimization measures include ligand engineering, coating techniques, and the fabrication of core-shell structures to enhance the luminous intensity and stability of QDs, thereby improving the stability and longevity of micro-display devices. Additionally, QD materials should have high ultraviolet or blue light absorption coefficients to increase the light conversion efficiency.

In addition to high-quality QD materials, developing reliable QD patterning technologies is crucial for achieving high precision, high density, and high uniformity in QD deposition on target substrates. The patterning technology significantly impacts the resolution and luminous performance of Micro-LED full-color display devices. Currently, researchers have developed various QD patterning methods including inkjet printing,^{24–29} photolithography,^{30–33} electrophoretic deposition,^{34,35} microfluidic techniques,^{36–38} micro-transfer printing,³⁹ and micropore filling method.^{40–42} Each method has its own advantages and limitations. From the perspective of QD color conversion for Micro-LED displays, an ideal patterning technology should not only produce uniform and high-resolution pixel patterns but also be capable of creating QD films with the required thickness to efficiently absorb background blue or UV light. This enhancement in light conversion efficiency reduces background light leakage and improves color purity. According to Beer-Lambert's law, the optical absorbance of QD films is related to the QD absorption coefficient, film thickness, and QD concentration (including solid content and porosity). Given that QDs typically have high absorption coefficients, with molar extinction coefficients generally in the range of 10^5 – 10^6 M^{−1} cm^{−1}, achieving 99.9% UV or blue light absorption would require a QD film thickness of at least several micrometers, assuming the film is composed of pure QDs.^{43–45} QD patterning techniques involve specific

process conditions that may affect the performance of the QDs during patterning, thereby influencing the overall performance and stability of Micro-LED display devices. Therefore, an ideal QD patterning technology should minimize damage to the QDs to maintain the optimal performance of the prepared display devices.

In this review, we will comprehensively explore the latest advancements in QD materials and their patterning technologies for full-color Micro-LED displays (Fig. 1). First, we will provide an in-depth introduction to the commonly used QD materials in Micro-LED color-conversion full-color schemes including II–VI group QDs, III–V group QDs, and emerging perovskite QDs. We will also discuss various methods for optimizing QD performance such as ligand engineering, coating technologies, and core-shell structure fabrication. Next, we will systematically elaborate on the latest research findings in QD patterning technologies including inkjet printing, photolithography, electrophoretic deposition, microfluidic techniques, transfer printing, and micropore filling method. Our focus will be on how these techniques achieve high precision, high density, and high uniformity in QD deposition on target substrates, and we will delve into the luminous performance of QD color-conversion layers and devices fabricated using these technologies. Finally, based on a comprehensive summary of recent developments in this field, we will look ahead to future research directions, aiming to provide valuable references and insights for the further development and innovation of full-color Micro-LED display technology.

2. Quantum dots for color-conversion micro-LED displays

2.1. II–VI group quantum dots

Traditional II–VI group semiconductor QDs such as CdS, ZnS, CdSe, ZnO, and CdTe (Fig. 2A)⁴⁶ have found extensive applications in the optoelectronic field. The bandgap of II–VI group QDs can be precisely tuned through surface modification, size control, alloying, and ion doping, allowing their fluorescence emission wavelength to cover the entire visible spectrum. Fig. 2B presents the PL images and spectra of CdSe/CdS core-shell QDs with different emission wavelengths under UV excitation.⁴⁷ Fig. 2C displays the HRTEM image of CdSe/CdS/ZnS QDs.⁴⁸ Significant progress has been made in the synthesis and performance optimization of CdSe QDs. Leading international companies such as QD Vision, Nanosys, Nanoco, and Poly OptoElectronics Co. Ltd have achieved large-scale production of CdSe-based QDs, which are widely used in the back-light design for liquid crystal displays. Additionally, electroluminescent QLED display technology based on CdSe QDs is also rapidly advancing. With the rise of Micro-LED display technology, CdSe QDs, one of the most mature QD materials, are emerging as key luminescent materials for color-conversion full-color Micro-LED displays.

The synthesis of QDs involves nucleation and growth, which significantly influence the size, shape, structure, and

Shuli Wang

Shuli Wang received his B.S. degree in June 2013 and his Ph. D. in June 2018 from Jilin University, under the supervision of Professor Junhu Zhang. He then conducted postdoctoral research in Professor Xu Hou's group at Xiamen University from September 2018 to February 2022. In March 2022, he joined the School of Electronic Science and Engineering at Xiamen University as Assistant Professor. His current research interests

include perovskite nanocrystals, patterning technology, Micro-LED displays, and bioinspired materials. He has published over 50 papers in journals such as Nature, Science Advances, Advanced Materials, Accounts of Materials Research, Nano Letters, and Small.

Fig. 1 Commonly utilized QDs (inner cycle) and their patterning technologies (outer cycle) for constructing micrometer-scale color conversion pixel arrays for Micro-LED displays. properties of QDs. Murray *et al.* developed monodispersed CdSe, CdS, and CdTe QDs using high-temperature thermal injection at 300 °C, employing trioctylphosphine oxide (TOPO) as the solvent and trioctylphosphine (TOP) as the ligand.⁴⁹ This method allowed separate nucleation and growth, maintaining a size distribution within 5% and precise control over grain size. Peng Xiaogang's group replaced TOPO with the non-coordinating solvent 1-octadecene (ODE) to synthesize CdS and CdSe QDs, providing a "green chemistry" synthetic route for quantum dots, which is conducive to achieving a safer and more environmentally friendly synthesis process.^{50,51}

During the nucleation of QDs, the ligand significantly influences their growth dynamics. Ligand modification can reduce surface defects in QDs and improve the quantum yield, which is essential for efficient light-emitting devices. Talapin *et al.* added hexadecylamine (HDA) to the common trioctylphosphine/trioctylphosphine oxide (TOP/TOPO) system

to accurately control CdSe QD growth. Surface passivation with inorganic (ZnS) or organic alkyl amine layers improved the quantum efficiency of CdSe QDs to 40–60%.⁵² Further improvements were achieved by using environmentally friendly cadmium acetate instead of dimethylcadmium, which led to an increase in the photoluminescence quantum yield (PLQY) of CdSe QDs to 85%.⁵³

Coating a shell material on the core of QDs can effectively passivate the surface defects and reduce non-radiative recombination. Li *et al.* synthesized CdSe/CdS core-shell QDs using the successive ion layer adsorption and reaction (SILAR) technique.⁵⁴ After applying five monolayers of CdS coating on the CdSe core, the size distribution remained consistent, with PLQY between 20% and 40% and FWHM between 23 and 26 nm, showing better optical properties and stability than bare CdSe nanocrystals. Lv *et al.* developed a two-step synthesis strategy with non-coordinating solvents, first creating small-

sized CdSe QDs as seeds, then using chloride ligands to selectively grow cube-shaped dots with six {100} facets.⁵⁵ These CdSe dots displayed monodisperse sizes and a quantum yield of about 90%, with a narrow FWHM of 20 nm. Fig. 2D compares ligand passivation on the {100} facet with and without chloride ions, showing that smaller chloride ions are more effective than alkylamide ligands for Cd sites. Fig. 2E shows the HRTEM images of cubic CdSe QDs with clear {200} and {220} planes and the selected area electron diffraction (SAED) images revealing clear square-symmetrical spots, confirming parallel lattice fringes and six equivalent {100} facets. Zhang *et al.* controlled the surface ligand strain and CdSe/ZnSe lattice strain using a two-step epitaxial growth method and synthesized green CdSe/ZnSe/ZnS core/shell/shell QDs with a nearly uniform PLQY (Fig. 2F).⁵⁶ The TEM image in Fig. 2G shows the uniform size of the prepared QDs with 7 monolayers of the ZnSe shell. Fig. 2H shows the relationship between the

PLQY of QDs and the ZnS and ZnSe shell thickness, and the maximum PLQY of 92% was achieved when the ZnSe shell thickness is 7 monolayers.

2.2. Perovskite quantum dots

Perovskite QDs have demonstrated significant potential in the display industry due to their exceptional PL intensity, narrow emission peak, and facility of synthesis. The structure of perovskite QDs is typically represented as ABX_3 (Fig. 3A),⁵⁷ where A denotes a monovalent organic cation such as methylammonium ($CH_3NH_3^+$, MA^+), formamidinium ($CH(NH_2)_2^+$, FA^+), phenylethylammonium ($C_6H_5(CH_2)_2NH_3^+$, PEA^+), cesium (Cs^+), or rubidium (Rb^+); B represents a metal cation, such as lead (Pb^{2+}), tin (Sn^{2+}), zinc (Zn^{2+}), or copper (Cu^{2+}) ion; and X stands for a halide anion such as chloride (Cl^-), bromide (Br^-), or iodide (I^-).⁵⁸ Besides exploiting the quantum confinement effect by turning the size, directly shifting the intrinsic band-gap by changing the halide

component ratio provides a more convenient way to adjusting the PL peak wavelength. By adjusting the halide composition, the emission wavelength of perovskite QDs can span the entire visible spectrum. Fig. 3B shows the PL images (top) and spectra (bottom) of perovskite QDs with different emission wavelengths under ultraviolet excitation.⁵⁹ Fig. 3C shows the typical TEM image of CsPbCl₃, CsPbBr₃, and CsPbI₃ QDs, respectively.^{59–61} In practice, perovskite QDs are sensitive to external factors such as

oxygen, moisture, temperature, and radiation, which can cause dissociation or phase transitions, resulting in non-emissive structures and affecting their optical performance and stability.⁵⁸ Recent research has therefore aimed to enhance the stability and PLQY of perovskite QDs, employing strategies such as ion doping for lattice stabilization, ligand passivation to minimize surface defects, and coating with protective layers for surface preservation.^{62,63}

By carefully selecting the ion types and concentrations, the optical, electrical, and stability properties of perovskite QDs can be optimized. Li *et al.* developed a Na^+ ion doping method for CsPbBr_3 QDs, which enhances oxidation and reduction tolerance by increasing the Br^- vacancy diffusion barriers and reducing non-radiative recombination centers.⁶⁴ Na^+ -doped green CsPbBr_3 QDs show improved emission efficiency, color purity, PLQY, and stability against optical, thermal, and moisture effects. Liu *et al.* synthesized Ni^{2+} -doped red CsPbI_3 QDs by replacing Pb^{2+} with Ni^{2+} , which increased lattice formation energy and improved structural stability, radiative lifetime, and environmental stability (Fig. 3D).⁶⁵ TEM and HRTEM images (Fig. 3E) confirmed the cubic structure and lattice contraction of Ni^{2+} -doped CsPbI_3 . Fig. 3F shows that the PLQY of the QDs can be increased to 95%–100% by adjusting the Ni/Pb feed ratio.

Mir *et al.* used zwitterionic lecithin as a capping ligand for CsPbI_3 , which, compared to traditional ligands OA and OAm, causes less surface strain and significantly enhances the stability.⁶⁶ The modified CsPbI_3 QDs remain stable in air for over 6 months. Yang *et al.* reported the passivation of CsPbBr_3 QDs by dodecyl-dimethyl-ammonium bromide (DDAB)/ PbBr_2 and dispersed the QDs in non-polar solvent for preparing perovskite QD colloid inks with a PLQY of 94.06%.⁶⁷ Xie *et al.* treated CsPbI_3 QDs with hydrobromic acid and then replaced OA ligands with 1-dodecanethiol. This process reduced halide ion migration and increased the PLQY of the CsPbI_3 QDs from 48% to 82%.⁶⁸ Yang *et al.* proposed stabilizing strategy for dual ligands, 1-decanethiol (1-DT) and lecithin, to prepare mixed halide CsPbBrI_2 QD (Fig. 3G) colloid ink specialized for EHD inkjet printing of high-resolution red pixels.²⁴ The 1-DT and lecithin-passivated CsPbBrI_2 QDs show a smaller size than that of control sample OA- and OAm-passivated QDs (Fig. 3H). The dual-ligand treatment QD ink not only shows the highest PLQY of 94% (Fig. 3I), but also possesses significantly improved stability. Li *et al.* replaced CsPbI_3 long-chain ligands with 2-phenethylamine hydrochloride (TEAC), which reduced the defect density and achieved a PLQY of 92.5%.⁶⁹ Li *et al.* used 2-naphthalenesulfonic acid (NSA) to suppress Ostwald ripening and ammonium hexafluorophosphate (NH_4PF_6) to replace long-chain ligands, achieving pure red CsPbI_3 QDs with a quantum yield of 94% and maintaining over 80% quantum yield after 50 days.⁷⁰

Huang *et al.* coated SiO_2 shells on the perovskite QDs *via* a hydrolysis reaction of tetramethyl orthosilicate (TMOS). The synthesized $\text{CH}_3\text{NH}_3\text{PbBr}_3@\text{SiO}_2$ QDs showed a PLQY of 87% and maintained 94.10% of their initial luminescence after 7 hours of exposure to 470 nm blue light.⁷¹ Song *et al.* replaced the surface ligands of CsPbBr_3 QDs with 3-aminopropyltriethoxysilane (APTES) and created a SiO_2 shell *via* hydrolysis.⁷² These $\text{CsPbBr}_3@\text{SiO}_2$ QDs retained 35.8% of their luminescence after 48 hours in water, demonstrating excellent PL and water resistance. He *et al.* developed an *in situ* method to grow QDs within mesoporous silica nanospheres, resulting in silica-coated QDs with a PLQY of 87% and high stability.⁷³ Fan *et al.* proposed dual-component core-shell QDs with silica

coating (Fig. 3J).⁴² The QDs have red CsPbI_3 QDs as the shell and green CsPbBr_3 as the core. The TEM images in Fig. 3K show that CsPbI_3 surrounds the CsPbBr_3 core. The PL spectra show a luminescence peak of both bare $\gamma\text{-CsPbI}_3$ and bicomponent QDs at 688 nm, while the intensity of the bicomponent QDs is significantly enhanced. The highest PLQY of red-emissive dual-component perovskite QD reached 99.9% (Fig. 3L). Under continuous blue LED excitation, the silica coated bicomponent samples showed apparently improved stability (Fig. 3M), demonstrating the great potential of the prepared QDs as color-conversion layers with blue micro-LED excitation.

2.3. III–V group quantum dots

Due to the toxicity of Cd-based QDs and Pb-containing perovskite QDs, low-toxicity III–V group QDs, particularly InP QDs, are emerging as eco-friendly alternatives. InP QDs exhibit a larger exciton Bohr radius and a direct bandgap, leading to notable quantum confinement and high stability. They are theoretically capable of covering the entire visible and near-infrared spectrum. Typically synthesized *via* the hot-injection method, InP QDs face challenges like surface defects and size uniformity despite their high PLQY and narrow FWHM. Enhancements in their performance can be achieved through improved synthesis, surface modifications, and core-shell design. Fig. 4A shows the schematic of the structure of InP/ZnSe/ZnS core/shell/shell QDs.⁷⁴ Fig. 4B displays the PL image (top) and spectrum (bottom) of InP QD emission across the visible range under UV excitation.⁷⁵ Fig. 4C presents the TEM images of blue InP/ZnS/ZnS, green InP/ZnSe/ZnS, and red InP/ZnSe/ZnS QDs. Compared to CdSe QDs, InP QDs have narrower spectral linewidths, making them ideal for high color purity displays.

The synthesis methods for InP QDs primarily involve one-pot and two-step strategies, differing mainly in precursor types. The one-pot method uses a single precursor, while the two-step method employs two precursors to provide indium and phosphorus separately. Although simpler, the one-pot method lacks the compositional and size control of the two-step approach. Jo *et al.* utilized tri(dimethylamino)phosphine as a safer phosphorus source instead of the toxic trimethylsilane phosphine to create $\text{InP/ZnSe}_{1-x}\text{S}_x/\text{ZnS}$ green QDs *via* two-step synthesis.⁷⁶ Fig. 4D illustrates the synthesis flow, which involves a double-layer shell growth around InP cores. Initially, a $\text{ZnSe}_{1-x}\text{S}_x$ inner shell is formed with a compositional gradient, followed by a ZnS outer shell to enhance PL. As the ZnSe ratio in the inner shell increases, the QDs show improved uniformity. Fig. 4E displays the TEM image of InP/ZnSe_{0.18}S_{0.82}/ZnS QDs with an average diameter of about 9.1 nm. Fig. 4F presents the PL spectrum, showing a PL peak at 527 nm, an FWHM of 37 nm, and a PLQY of up to 87%. Kim *et al.* synthesized blue InGaP QDs *via* a cation exchange strategy, resulting in double-shell InGaP/ZnSeS/ZnS QDs with a blue shift from 475 to 465 nm and a high PLQY of 80–82%.⁷⁷ Yu *et al.* synthesized InP-based QDs using sodium phosphide (NaOCP), achieving a tunable PL wavelength peak at 620 nm

and a maximum PLQY of 97% by adjusting the precursor ratios and nucleation temperature.⁷⁵

Ligands greatly enhance the PL of InP QDs by passivating surface defects. Common ligands for passivating InP QDs include halide ions, thiols (*e.g.*, 1-octanethiol), phosphides, carboxylates, amines, and other organics. Calvin *et al.* employed metal halide salts (ZnCl₂, ZnBr₂, and InCl₃) to facilitate ligand exchange on the surface of InP quantum dots, where more electronegative halogen ions replaced the less electronegative carboxylate ligands. This substitution reduced electron trapping caused by surface defects or miscoordinated environments, thereby enhancing the quantum yield, with ZnCl₂ achieving a PLQY over 80%.⁷⁸

Zhang *et al.* synthesized blue InP QDs using bromide passivation with low-temperature nucleation and high-temperature coating methods (Fig. 4G).⁷⁹ The TEM images in Fig. 4H (left) show the InP core QDs with a ZnS shell, with a size of 3.8 ± 0.50 nm. Introducing 1-dodecanethiol (DDT) for a second ZnS shell resulted in InP/ZnS/ZnS QDs, with increased size of 6.2 ± 0.52 nm (Fig. 4H right). Fig. 4I displays the PL and UV-visible absorption spectra of these bromide-passivated blue InP QDs. The results indicate that the ZnBr₂ passivation significantly improved the PLQY of the QDs from 54% to 93%.

Wu *et al.* introduced a quasi-shell growth strategy (QS strategy) for synthesizing green InP/ZnSe/ZnS QDs (Fig. 4J).⁸⁰ In the

traditional strategy (TS), Se precursors form a ZnSe shell at high temperatures, while in QS, Se precursors form a quasi-ZnSe (Q-ZnSe) shell at a lower temperature, which gradually transforms into ZnSe. Fig. 4K shows that the QS strategy results in more uniform spherical QDs, as the Q-ZnSe shell reduces Ostwald ripening. Fig. 4L compares the absorption and PL spectra of QDs prepared using the two strategies. The results indicate that the InP QDs from the QS strategy show a higher absorption valley-to-depth ratio, a narrower FWHM of 36 nm, and a high PLQY of 91%. Li *et al.* prepared red-emitting InP/ZnSe core/shell quantum dots by adjusting the shell thickness, with an emission peak at 620 nm, an FWHM of 39 nm, and a maximum PLQY of 95%.⁸¹ Yu *et al.* synthesized green-emitting InP/ZnSe_xS_{1-x}/ZnS QDs with an inner ZnSe_xS_{1-x} layer, and the FWHM of the emission peak is 35 nm, and a maximum PLQY of 97% was obtained when the Se/S ratio was 0.7.⁸²

3. Patterning technologies of quantum dots

3.1. Inkjet printing technology

Inkjet printing technology is the precise spraying of QD ink onto a substrate through a nozzle, where QDs deposit at designated positions on the substrate to form an array of QD microstructures after the solvent evaporates. Optimizing the solvent system in the ink to match the physical and chemical properties of the substrate can significantly improve the morphology and dimensions of the printed QD microstructures. Inkjet printing technology has the advantages of simple process, low cost, maskless fabrication, non-contact operation, and high automation. According to the driving principle of ink droplet ejection, inkjet printing can be divided into three main types: piezoelectric inkjet printing, aerosol jet printing (AJP), and electrohydrodynamic (EHD) inkjet printing.

3.1.1. Piezoelectric inkjet printing. Piezoelectric inkjet printing is one of the most commonly used inkjet printing technologies. This technique controls the voltage applied to piezoelectric ceramics to adjust their deformation, thereby precisely regulating the volume of QD ink ejected from the nozzle and enabling accurate droplet deposition. Typically, the nozzle diameter is around 20 μm , and the viscosity of the QD ink is controlled within the range of 1–25 mPa s, with surface tension between 25 and 50 mN m⁻¹. Such precise control allows piezoelectric inkjet printing to effectively fabricate QD color-conversion arrays with diameters ranging from 10 μm to 220 μm .^{11,83}

Shi *et al.* used piezoelectric inkjet printing to deposit a perovskite precursor solution droplet onto a polymer-coated substrate, followed by heating to crystallize the precursor, resulting in a perovskite QD microdisk array (Fig. 5A).²⁵ This method is suitable for various polymer substrates such as polymethyl methacrylate (PMMA), polystyrene (PS), polyvinyl chloride (PVC), and polyacrylonitrile (PAN) (Fig. 5B). PAN-based perovskite QD films achieved the highest brightness with a PLQY

of up to 80% under 365 nm UV excitation. The heating temperature influences microstructure size, as the temperature increases from 30 °C to 90 °C, the contact angle of the precursor solution on PAN rises from 10.5° to 23.5°, while the average microdisk size decreases from 212 μm to 110 μm (Fig. 5C). By adjusting the halogen ratio in the perovskite precursor solution, researchers successfully fabricated tunable emission MAPbBr_xCl_{3-x} perovskite QD patterns ranging from blue to red (Fig. 5D).

Liu *et al.* used piezoelectric inkjet printing to deposit perovskite precursor inks with a photoinitiator onto a PDMS-modified ITO substrate.⁸⁴ UV light was used to form a polymer network, and the following heating induced perovskite crystallization in the network, forming 3D perovskite QD microarrays. This microarray showed excellent brightness and uniformity under UV light, with no coffee ring effect. PDMS modification reduced the surface energy of the substrate and increased the contact angle of the QD precursor ink to 90°. Further adjustment of the photoinitiator content increased the contact angle of the precursor ink to 100°. By adjusting parameters such as nozzle diameter, ink release time, and applied voltage, QD microstructures with a diameter of 30 μm and a height of 10 μm were fabricated, achieving a pixel density of 500 ppi. The produced RGB QD pixel arrays had peak wavelengths of 472 nm, 526 nm, and 654 nm, with PLQYs of 10%, 35%, and 20%, respectively, and a color gamut of 112% of the NTSC standard was achieved.

Wei *et al.* developed a ternary solvent system of naphthene, dodecane, and heptane for preparing CsPbX₃ perovskite QD inks.⁸⁵ This system significantly improved the printability and film-forming properties compared to the traditional binary solvent system. Heptane's low boiling point reduced QD aggregation and sped up solvent evaporation, minimizing the coffee ring effect. QD films made with the ternary solvent showed about 52.14% higher fluorescence intensity and a 17% increase in PLQY compared to those from binary systems. The research team successfully printed a QD matrix with a resolution of 250 ppi using the ternary solvent ink.

Wang *et al.* used a one-step thermal injection method at 120 °C to prepare CsPbX₃ QD inks with tunable colors and UV-curable properties.⁸⁶ They employed piezoelectric inkjet printing to form color-variable QD arrays. By adjusting QD precursor composition, they tuned the emission spectra from 410 nm to 710 nm. The perovskite QDs had narrow spectral linewidths, with the FWHM ranging from 21 to 39 nm. Ultimately, the researchers successfully fabricated uniform red and green QD array films with thicknesses of 13.7 μm and 14.7 μm , respectively.

Cai *et al.* used PDMS to encapsulate CsPbBr₃ QDs modified with dodecylbenzenesulfonic acid (DBSA) and applied piezoelectric inkjet printing to create color-conversion arrays (Fig. 5E).²⁶ The high flow resistance of the CsPbBr₃/PDMS ink minimizes the coffee ring effect, leading to more uniform printing. Using piezoelectric inkjet printing, the researchers created a QD microstructure with a diameter of 17 μm and a height of 20 μm (Fig. 5F). These microstructures can be used

as micro-LED color-conversion layers (Fig. 5G). Comparative tests showed that the $\text{CsPbBr}_3/\text{PDMS}$ pattern has reduced blue light component and improved stability, as evidenced by shifts in color coordinates and microscope images.

Lee *et al.* used piezoelectric inkjet printing to create InP QD arrays on surface-modified substrates.⁸⁷ CF_4 plasma treatment increased the contact angle of QD droplets on the substrate from 74.6° to 123.7°, which facilitated the formation of InP QD structures with a three-dimensional (3D) morphology. By adjusting the number of ink droplets, the QD thickness was controlled up to 10 μm , which reduced blue light leakage by 26.38% and improved color-conversion efficiency by 5.71%.

3.1.2. Aerosol jet printing. Traditional piezoelectric inkjet printing techniques impose strict requirements on ink viscosity.¹¹ In contrast, AJP offers a more versatile solution. In the AJP process, the QD ink is first atomized using either a pneumatic atomizer or an ultrasonic transducer. The atomized ink is then transported to a virtual impactor under the influence of a nitrogen gas flow and finally ejected through a nozzle. By adjusting the flow intensity of the nitrogen gas, the aerosol jet's ink mist flow can be precisely controlled. AJP accommodates a broader range of ink viscosities (0.5–1000 mPa s), enabling the fabrication of QD structures with dimensions less than 30 μm .⁸⁸

Han *et al.* applied AJP for depositing blue CdS QDs and red/green CdSe/ZnS colloidal QDs onto a UV-emitting GaN-based Micro-LED array, creating a full-color display device.⁸⁹ The QD color-conversion layer features $35\ \mu\text{m} \times 35\ \mu\text{m}$ pixel size and $40\ \mu\text{m}$ pixel pitch, reaching a resolution of 282 ppi. The average heights of blue, green, and red QDs are $2.879\ \mu\text{m}$, $5.581\ \mu\text{m}$, and $6.462\ \mu\text{m}$, respectively. To boost the UV photon use, a distributed Bragg reflector (DBR) was incorporated, significantly enhancing the light intensity by reflecting leaked UV photons back into the QD layer, with improvements in light intensity of 194%, 173%, and 183% for blue, green, and red subpixels, respectively. However, QD overflow during printing caused a significant optical crosstalk in the Micro-LED color-conversion layer, affecting display performance.

To tackle this issue, Lin *et al.* improved the process by adding a black photoresist matrix on the Micro-LED chip (Fig. 6A top), and then depositing CdSe QD ink within the matrix using AJP (Fig. 6A bottom).²⁷ The QD color-conversion

layer with the black matrix has clearer boundaries (Fig. 6B), reducing the optical crosstalk between pixels compared to that without the black matrix (Fig. 6C). Without the black matrix, the overlap between red and green QD pixels is about $13.4\ \mu\text{m}$, resulting in 32.8% optical crosstalk. With the barrier layer, optical crosstalk drops to nearly 0. Additionally, inkjet printing within the photolithography structure minimizes the coffee ring effect, leading to a more uniform thickness distribution.

Kim *et al.* passivated CsPbBr₃ and CsPb(BrI)₃ QDs with trioctylphosphine (TOPO) – zinc complexes and incorporated scattering metal oxide particles to create green and red perovskite QD inks.²⁸ These inks were deposited onto blue OLED films using AJP technology (Fig. 6D). The resulting QD color-conversion structures were well-ordered and uniform, with a thickness of up to $3\ \mu\text{m}$. The metal oxides Al₂O₃ and SiO₂ enhanced blue light propagation within the structure, leading to improved excitation absorption. Consequently, red and green luminescence increased by 37.4% and 42.4%, respect-

Fig. 6 (A) Schematic of the construction of black matrix on a Micro-LED chip and AJP of QDs in the black matrix. ively, with minimal blue light leakage. This method is also compatible with various patterning processes, enabling the fabrication of 30 μm diameter green and red QD patterns (Fig. 6E).

3.1.3. Electrohydrodynamic inkjet printing. EHD inkjet printing is a technique that utilizes an electric field to drive ink ejection. In this process, applying a pulsed voltage causes ions or polarized charges in the ink to relax at the liquid–air interface, forming a meniscus. When the induced electric field force overcomes the surface tension, droplets detach from the meniscus and move downward under gravity. During deposition, large droplets can break into multiple smaller droplets, which then continuously deposit onto the substrate. After solvent evaporation, a nanoparticle pattern is formed. Compared to piezoelectric inkjet printing and AJP, EHD inkjet printing accommodates a wider range of ink viscosities (1–10 000 mPa s).¹¹ Furthermore, the EHD inkjet printing enables the fabrication of QD structures at sub-micron scales, making it suitable for producing ultra-high-resolution pixel patterns.

Li *et al.* dispersed red CdSe/CdS/ZnS QDs in a cyclohexane–*n*-heptane mixture to prepare QD inks. Using the EHD inkjet printing, they created micrometer-scale QD microstructures. The results indicated that the coffee ring effect was fully suppressed with a cyclohexane-to-*n*-heptane ratio of 8/2. By optimizing EHD printing parameters, they controlled droplet volume precisely, achieving a Cd-based QD pixel microarray with 1 μm diameter and 306 ppi resolution.

Zhu *et al.* prepared perovskite precursor inks by dissolving cesium halides (CsCl, CsBr, and CsI), lead halides (PbCl₂, PbBr₂, and PbI₂), 2-phenylethylammonium bromide (PEABr), and crown ether in dimethyl sulfoxide (DMSO).⁹⁰ Using EHD inkjet printing, they created full-color QD microarrays with high luminescence and resolution (Fig. 7A). The PLQY of QD solutions ranged from 29% to 80%, with CsPbBr₃ exceeding 75%. The pulse frequency and amplitude of pulsed voltage influence the QD pixel size. It was observed that the droplet generation frequency of the QDs was almost synchronized with the pulse frequency, and the diameter of the QD pixels decreased with the increase in voltage frequency (Fig. 7B). By optimizing the printing parameters, the team produced uniform green QD arrays with a subpixel diameter of 1.5 μm , and RGB monochromatic and multicolored QD patterns (Fig. 7C).

Chen *et al.* used EHD inkjet printing to deposit QD color-conversion layers on nano-ring structured Micro-LED chips, creating full-color Micro-LED devices.⁹¹ They achieved a 1.65 μm minimum line width for the QD structures with excellent uniformity. Wang *et al.* used an eco-friendly high-viscosity ionic liquid as the solvent to prepare perovskite QD inks. With EHD inkjet printing, they produced high-resolution, flexible full-color devices with 1 μm diameter QD structures and a maximum resolution reaching approximately 5080 ppi.

EHD inkjet printing usually requires polar solvents, which can quench perovskite QDs and impair performance. Thus, developing non-polar solvent inks suitable for EHD inkjet

printing is of significant importance. Yang *et al.* developed non-polar inks by dispersing green perovskite QDs, passivated with DDAB/PbBr₂, in a 1:1 mixture of 1,3,5-triisopropylbenzene and *n*-tetradecane.⁶⁷ Through EHD printing, they produced high-resolution QD microstructures with uniform thickness and minimized the coffee ring effect, a linewidth of 2 μm and a resolution up to 22 718 ppi.

Red-perovskite QDs are less stable than green QDs, especially during EHD printing, where halide ions can migrate and affect luminescence. Yang *et al.* used lecithin and 1-DT as dual ligands to passivate mixed-halide CsPbBr₂ and disperse the QDs in xylene to prepare a non-polar ink.²⁴ The dual-ligand passivation significantly enhanced the stability of red-perovskite QDs and enabled high-resolution red QD color-conversion arrays *via* EHD inkjet printing. The lecithin reduces damage to CsPbBr₂ under the electric field, while 1-DT passivates halide vacancies. Compared to arrays printed by using an OA/m-CsPbBr₂ ink, the arrays from the dual-ligand passivated CsPbBr₂ ink show higher brightness and a less spectral blue shift. The dual-ligand passivated CsPbBr₂ microarrays also demonstrate excellent stability during storage and UV exposure. Ultimately, they achieved a resolution of up to 2540 dpi for CsPbBr₂ red QD arrays and successfully fabricated red, green, and blue color-conversion arrays.

Chen *et al.* dispersed CsPbX₃ QDs with polystyrene (PS) in xylene and used EHD inkjet printing to create 3D perovskite microstructure arrays.⁹² The PS-containing ink produced pronounced 3D structures with a height of 3 μm , while the height is only 100 nm for microstructures printed from QD ink without PS (Fig. 7E). The 3D structure morphology was controllable by adjusting the pulse width and voltage. Increasing the pulse width resulted in a change in microcolumn diameter from 2.8 μm to 7.6 μm and height from 7 μm to 24 μm (Fig. 7F). Fig. 7G shows the EHD-printed RGB monochromatic and multicolor 3D QD color-conversion arrays with high resolution and excellent uniformity.

3.2. Photolithography

Photolithography is a processing technique that transfers high-precision patterns from a mask to a substrate by selectively exposing photosensitive materials and developing them in the developer.^{93,94} This technology is indispensable in the field of semiconductor chip manufacturing. When applied to QD patterning, lithography enables the creation of small-sized, high-precision, and large-area QD arrays, offering a reliable approach for fabricating color-conversion Micro-LED full-color display devices. Based on the variations in lithography processes, QD patterning techniques can be categorized into four types: photoresist-assisted photolithography, QD photoresist (QDPR) lithography, QD direct lithography, and QD *in situ* lithography.

3.2.1. Photoresist-assisted lithography. Photoresist-assisted lithography can be achieved by two methods. The first method involves depositing a QD film on a substrate, followed by coating with a photoresist, exposing, and developing. This process removes the QDs not protected by the photoresist, thereby pat-

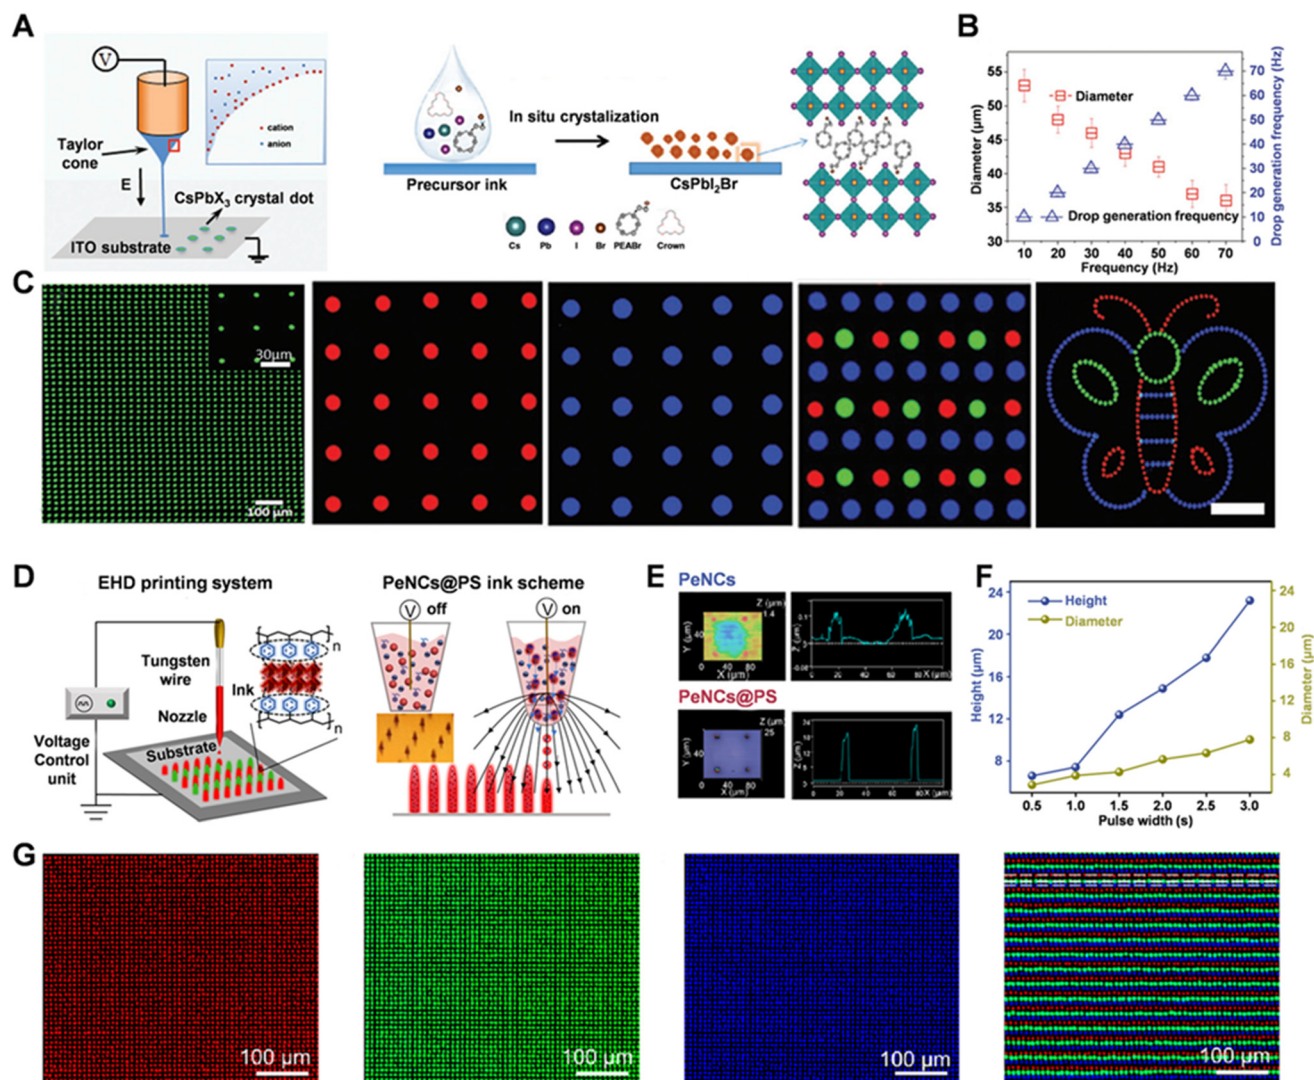

Fig. 7 (A) Schematic of the EHD printing of perovskite precursor inks with cesium halides, lead halides and PEA Br. turning the QD film. The second method involves spin-coating the substrate with photoresist, exposing and developing it under a mask to form the photoresist pattern, then spin-coating QDs on top of the photoresist. After depositing the QDs, the photoresist is removed to achieve the patterning of monochromatic QDs. During the photolithographic patterning processes, the utilization of chemicals such as photoresist and developer damages the optical properties of the QDs. Therefore, research studies were mainly focused on how to reduce the damage of the patterning processes on the QD performance.

The modification of QD surfaces was adopted to improve their resistance in chemicals. Bae *et al.* used the bifunctional ligand mercaptopropionic acid (MPA) to passivate CdSe/ZnS

core-shell QDs, minimizing QD damage during photolithography.⁹⁵ This approach was applied to fabricate square and circular QD microstructure arrays. Compared to untreated CdSe/ZnS QDs, MPA-treated QD films showed a higher PL intensity before and after development, with no significant change in fluorescence lifetime.

Kim *et al.* used multiple atomic layer deposition (ALD) processes to passivate QDs with ZnO, improving their solvent resistance.⁹⁶ The passivated QD inks were employed in photolithography to create color-conversion layers. This method achieved full-color QD arrays with a resolution of 3000 ppi and is versatile for fabricating microstructure arrays of perovskite QDs, Cd-based QDs, and InP QDs.

Lee *et al.* used coated a ZnO protective layer on InP QDs by an ALD technique and employed positive photoresist with a photoacid generator (PAG) to fabricate high-resolution, multi-color InP QD films by photolithography (Fig. 8A).³² Fig. 8B shows the changes in the PL spectra of red and green InP QDs during the patterning processes. ZnO-passivated QD films exhibited a higher PL intensity than bare QDs, though spin-coating and developing caused damage, reducing PL intensity by 19% for red and 22% for green QD films post-patterning. The height profile in Fig. 8C shows that the thickness of the prepared QD film is 4 μm . Fig. 8D shows the prepared red and green InP QD patterns and blue ZnSeTe QD patterns, with a maximum resolution of 2000 ppi.

Mei *et al.* combined a sacrificial layer-assisted patterning method with photolithography to fabricate QD color-conversion layers.⁹⁷ They used polyvinylpyrrolidone as the sacrificial layer material, employing negative photoresist and the sacrificial layer to define the QD pixel positions while protecting the QDs during the photolithography process. Using this approach, they achieved RGB full-color QD pixels with dimensions of $39\ \mu\text{m} \times 5\ \mu\text{m}$, a resolution of 500 ppi, and a color gamut reaching 114% of the NTSC standard.

3.2.2. Quantum dot photoresist lithography. The QDPR Lithography technique involves incorporating QDs into photoresist to prepare the QDPR and the formation of patterned QD arrays through a single-step lithography process. This method is straightforward, allows for large-area fabrication, and provides facile control over the thickness and morphology of the QD array films.

Myeong *et al.* prepared the QDPR by mixing CdSe/ZnS QDs with the negative photoresist AZ-5214E and used it to create QD color-conversion layers by photolithography (Fig. 9A).³³ To reduce the light crosstalk between the subpixels, Cr patterns were prepared on the substrate before lithography of the

QDPR. Repeat of the lithography of QDPRs with different colors can form multicolor patterns on the substrate. The team successfully fabricated red (Fig. 9B) and green pixel arrays with minimum linewidths down to 7 μm and a QD film thickness of approximately 5 μm . Fig. 9C shows the prepared RGB QD structures with different patterns and sizes, and the minimum linewidth of about 4–5 μm .

Chang *et al.* mixed SiO_2 -coated CdSe/ZnS QDs with the negative photoresist SU-8 3010 to create QDPR for a QD color-conversion layer.⁹⁸ The SiO_2 coating aids in mixing QDs with polar dispersants and photoresists while protecting the QDs. They fabricated a red-green dual-color QD array ($50\ \mu\text{m} \times 50\ \mu\text{m}$) and used it in a full-color display device with blue light micro-LED backlighting. A DBR reflective layer was added to reduce blue light leakage by 99.08%. The device showed excellent stability, with less than 15% brightness decay after 500 hours at 85 $^\circ\text{C}$ and 90% humidity.

Weng *et al.* prepared a high-performance QDPR by mixing CdSe/ZnS QDs, TiO_2 scattering particles, and negative photoresists, and used it to fabricate a full-color QD color-conversion layer by lithography.⁹⁹ The scattering effect of TiO_2 helps reduce the film's total internal reflection, enhancing blue light absorption and light conversion efficiency. Using this QDPR, the authors fabricated square red and green QD films with pixel sizes of $80\ \mu\text{m} \times 80\ \mu\text{m}$ (Fig. 9D), showing improved color-conversion efficiency (CCE) compared to unpatterned films. The microscopic images in Fig. 9E show the red and green two-color QD color-conversion arrays. The authors also studied the impact of black photoresist structures on color conversion, and the results showed that the black photoresist effectively reduces light crosstalk and enhances pattern clarity. The introduction of black photoresists led to a significant reduction in the intensity of red, green, and blue light, with CCE decreases of 3.93% and 5.97% for green and red light,

Copyright 2023, Elsevier.

respectively (Fig. 9F). Upon integrating two-color QD color-conversion layers with blue light Micro-LEDs, the full-color display devices achieved a color gamut of 120.53% of the NTSC standard (Fig. 9G).

Lee *et al.* used a low-temperature ALD technique for passivating patterned QDPR arrays with TiO_2 , which enhanced QD stability under high-temperature and natural conditions.¹⁰⁰ The prepared $7\ \mu\text{m} \times 7\ \mu\text{m}$ red and green pixel arrays show uniform light when excited by the bottom blue-UV mixed micro-LED. After adding a DBR layer, the CCEs of the red and green QD color-conversion layers reached 96.25% and 92.91%, respectively, with the full-color display device achieving a color gamut of 128.2% of the NTSC standard.

Huang *et al.* prepared a perovskite QDPR by mixing perovskite QDs with propylene glycol methyl ether acetate (PGMEA),

photoinitiators, and acrylic monomer resin.¹⁰¹ Original ligands, OA, were exchanged by 2-(4-chlorosulfonylphenyl) ethyltrimethoxysilane (CES) for the growth of homogenous perovskite QDs with small size and high stability. Using this perovskite QDPR, the authors achieved QD patterns with sizes smaller than $5\ \mu\text{m}$. By combining the as-prepared red and green QD color-conversion layers with a monolithic integrated micro-LED chip, the authors prepared a full-color Micro-LED display panel with a high-resolution of 3300 ppi, and a color gamut reaching 130.4% of the NTSC standard.

3.2.3. Quantum dot direct lithography. Traditional lithographic methods involving photoresists often entail multiple baking and developing steps, which increase the process complexity and may adversely affect the PL properties of QDs due to interactions with chemical substances. In contrast, QD

direct lithography leverages chemical reactions induced by light to change the solubility of QDs in specific solvents, thereby achieving patterning while mitigating the impact of chemical substances on the optical properties of QDs.

Ko *et al.* functionalized QD ligands with vinyltriphenylamine-random-azidestyrene and crosslinked QDs using PTPA-N₃-SH. UV irradiation of the azide groups produced nitrene radicals, creating a crosslinked QD network within the film.¹⁰² Using the direct lithography method, the authors fabricated microstructured arrays of red CdSe/ZnCdS, green InP/ZnSeS, and blue CdZnS/ZnS QDs with excellent uniformity. Yang *et al.* employed a ligand crosslinking agent, 4-azido-2,3,5,6-tetrafluorobenzoic acid esters, to react with adjacent QD ligands under UV light, resulting in robust QD films. They used this technique to create RGB QD color-conversion pixels, each 4 $\mu\text{m} \times 16 \mu\text{m}$, achieving a resolution of up to 1400 ppi.

Ko *et al.* replaced the original ligands (OA and OAm) of CsPbX₃ QDs with photo-crosslinkable cinnamoyl polymer ligands (PCEMA-NH₃X, where X = Cl, Br, and I).¹⁰³ This enabled UV-induced crosslinking and pattern formation after toluene development (Fig. 10A). They successfully created defect-free circular arrays with 10 μm diameter (Fig. 10B) and large-area patterned arrays (2 cm \times 8 cm) (Fig. 10C). The patterned structures remained stable after ethanol immersion (Fig. 10D). Tuning the terminal groups (-NH₃Cl, Br, and I) of PCEMA ligands adjusted the wavelength of QDs across the visible spectrum. The synthesized blue, green, and red QDs were used to produce patterned arrays of blue squares (10 μm), green squares (5 μm), and red circles (10 μm), achieving a resolution of up to 10 465 ppi (Fig. 10E).

Liu *et al.* added bis-azide compounds as light-sensitive additives to perovskite QD solutions.¹⁰⁴ UV exposure generated

Fig. 10 (A) Schematic of the replacement of the OA and OAm of CsPbX₃ QDs with photo-crosslinkable PCEMA-NH₃X for the patterning of QDs by direct photolithography. (B) Microscopic image of QD circular arrays and the corresponding photomask. (C) Large-area patterned QD arrays. (D) Immersion of the patterned structures in ethanol. nitrile radicals that formed covalent C–N bonds with long alkyl chains in natural ligands OAm and OA, creating a crosslinked network between QDs. They achieved patterning with structural widths as small as 5 μm , with consistent uniformity and surface roughness before and after lithography. The perovskite QDs retained their size and crystal structure, and the team demonstrated successful patterning on flexible substrates, indicating potential for flexible displays.

Hahm *et al.* designed and synthesized dual-ligand passivated $\text{InP/ZnSe}_x\text{S}_{1-x}$ QDs, comprising photo-crosslinkable ligands (PXLs) and dispersing ligands (DLs).¹⁰⁵ They used photoreactive benzoin derivatives as PXLs, which underwent crosslinking under light (365 nm, 35 mJ cm^{-2}). The authors achieved a resolution of up to 15 000 ppi for QD arrays using this QD direct lithography method.

Shin *et al.* employed thiol molecules as ligand crosslinkers for OA-capped QDs, utilizing thiol–ene click reactions to achieve direct lithographic patterning of InP QDs.¹⁰⁶ Through this method, the authors successfully produced patterns with a minimum size of 5 μm , and the ligand crosslinking process resulted in a 122.9% increase in the PLQY compared to the original QD films.

Ong *et al.* synthesized a bidentate photo-crosslinkable ligand, which contains a photosensitive acrylate group and a carboxylic acid binding group, for direct photolithographic patterning of perovskite QDs.¹⁰⁷ By optimizing the solvent system, concentration, and processing parameters, the authors achieved an optical density of 1.1 using a fully retained photo-crosslinked CsPbBr_3 nanocrystal film with a thickness of 1.4 μm . By using a mask-free direct laser writing technology, the authors fabricated pixel patterns with a size of 20 μm . By using direct laser writing, well-defined green and red perovskite nanocrystal arrays with feature sizes down to 20 μm were obtained.

3.2.4. Quantum dot *in situ* lithography. In conventional photolithography methods for QDs, the QDs are typically pre-fabricated and then patterned using the photolithography process. However, the chemicals used in photolithography, such as photoresists, developers, and photosensitive additives, can adversely affect the performance of pre-fabricated QDs. To address this issue, researchers have proposed a new approach where a patterned network structure is first created, confining the QD precursors within this network structure, and then the QDs are synthesized *in situ*. This method aims to avoid the impact of the patterning process on the performance of the QDs, potentially leading to high-performance QD color-conversion arrays.

Zhang *et al.* developed a direct *in situ* lithography technique for patterning perovskite QDs using lead bromide complex-catalyzed photopolymerization.³¹ As shown in Fig. 11A, UV light (365 nm) initiates the photopolymerization of perovskite precursors, creating high-resolution patterns. This method integrates lead bromide complex catalysis, eliminating the need for external initiators or catalysts and avoiding potential QD damage. The process includes a final annealing step to synthesize QDs within the polymer matrix. The authors suc-

cessfully created micrometer-sized patterns with uniform fluorescence intensity (Fig. 11B). The team also prepared red, green, and blue QD color-conversion patterns, achieving a minimum feature size of 5 μm , a maximum thickness of 10 μm , and a resolution up to 2450 ppi.

Wei *et al.* developed an enhanced photoresist benzoin-grafted allyl phenolic resin FROS-BP by grafting photosensitive benzoin (BP) onto a silicon-modified allyl phenolic resin FROS, which improves radical confinement and selectivity in photolithography (Fig. 11C).¹⁰⁸ For *in situ* photolithography, they prepared a resist using a solution of perovskite precursor, photosensitive monomer FROS-BP, and crosslinker in a polar solvent. Fig. 11D shows that the QD patterns created with FROS-BP exhibited sharp edges and precise 120° angles, compared to the less defined edges from FROS. The process enabled the fabrication of multi-color QD patterns with various sizes, shapes, and uniform thicknesses, with the smallest feature size being 20 μm , and the patterns were transferable to flexible PET substrates (Fig. 11E).

Li *et al.* replaced traditional DMF and DMSO solvents with the polymerizable monomer 4-acryloylmorpholine, which also served as a photopolymerization monomer.¹⁰⁹ This approach enabled direct *in situ* fabrication and patterning of perovskite QDs. Using this QD ink, the authors achieved color QD patterns with a high PLQY of 90%, a minimum feature size of 5 μm , a thickness over 3 μm , and excellent fluorescence uniformity. Li *et al.* developed an *in situ* photolithography technique based on light-induced halide removal. They blended perovskite QD precursors with PMMA to create PQD precursor/polymer films.¹¹⁰ These films were exposed to 254 nm UV light through a mask, inducing halide removal and generating high-resolution QD patterns without the need for development or etching. The team successfully created square dot matrices with a sub-pixel width of 2 μm , and the QD films remained stable after 6 months in water.

3.3. Transfer printing technology

Transfer printing technology is an advanced micro–nanofabrication method that uses patterned transfer stamps for transferring QDs onto substrates with high precision. This technique is cost-effective, efficient, and achieves exceptionally high resolution with minimal environmental control.^{111–113} Currently, the precision of transfer printing technology can reach up to 2 nanometers, demonstrating its significant potential for nanoscale pattern fabrication. Transfer printing technology enables the fabrication of QD patterns with extremely high resolutions (ranging from thousands to tens of thousands of ppi). However, the thickness of these QDs typically ranges from a few nanometers to tens of nanometers, making the technology particularly suitable for electroluminescent QLED devices. Yet, fabricating QD patterns with a micrometer-scale thickness using transfer printing methods presents great challenges. This difficulty arises from the need to precisely control the thickness and uniformity of the patterns during the transfer process, which imposes stringent technical demands on the transfer printing technique.

Zou *et al.* successfully fabricated high-resolution QD patterns with thicknesses exceeding 10 μm by combining plasma etching and transfer printing technologies.³⁹ The pixel resolution and thickness of the QDs can be tuned through the microstructure of the transfer printing template and the etching process (Fig. 12A). In this method, due to the expansion of the PDMS stamp upon contact with the QD solvent (toluene), patterned recessive silicon was used as the master template, and a temporary substrate coated with an adhesive layer was employed to transfer the QDs from the recessive mold. The temporary substrate was then subjected to plasma etching to remove residual QDs, and the patterned QD film was finally transferred to the target substrate. The authors used this transfer printing technique to create QD arrays with varying sizes (less than 40 μm) and thicknesses (greater than 10 μm). Fig. 12B shows the fluorescence intensity distribution of 169 subpixels with a diameter of 40 μm and the fluorescence intensity distribution of individual subpixels, indicating good uniformity in both pixel arrays and individual pixels. As shown in the statistical plot, the fluorescence intensity distribution of 85% of the pixels is between 140 and 150.

In this study, the authors incorporated a polystyrene-*block*-polyisoprene-*block*-polystyrene (SPS) polymer into the QD ink.

The polyisoprene block in SPS increases the main chain length and reduces the proportion of phenyl side chains, making SPS potentially more flexible than PS. Under the same conditions, the QD@SPS ink achieved a uniform pillar structure with a thickness of 12.97 μm, while the columnar structures from the QD@SPS ink after transfer exhibited irregularities and fractures. The authors successfully prepared QD patterns with a pixel resolution of 669 ppi and a maximum thickness of 19.74 μm, and high-resolution red-green CdSe/ZnS QD patterns on flexible substrates (Fig. 12C). QD films with thicknesses over 10 μm integrated onto blue Micro-LED chips displayed good color-conversion performance (Fig. 12D), revealing the potential of the transfer printing technology for full-color Micro-LED displays.

3.4. Electrophoretic deposition

Electrophoretic deposition is an emerging technique for fabricating QD color-conversion layers. This method leverages the ionizability of QD ligands in solutions, enabling the directed migration of QD particles under the influence of an electric field. Specifically, the electric field applied by the electrodes drives the QD particles toward electrodes with opposite charges, leading to their deposition and formation of high-

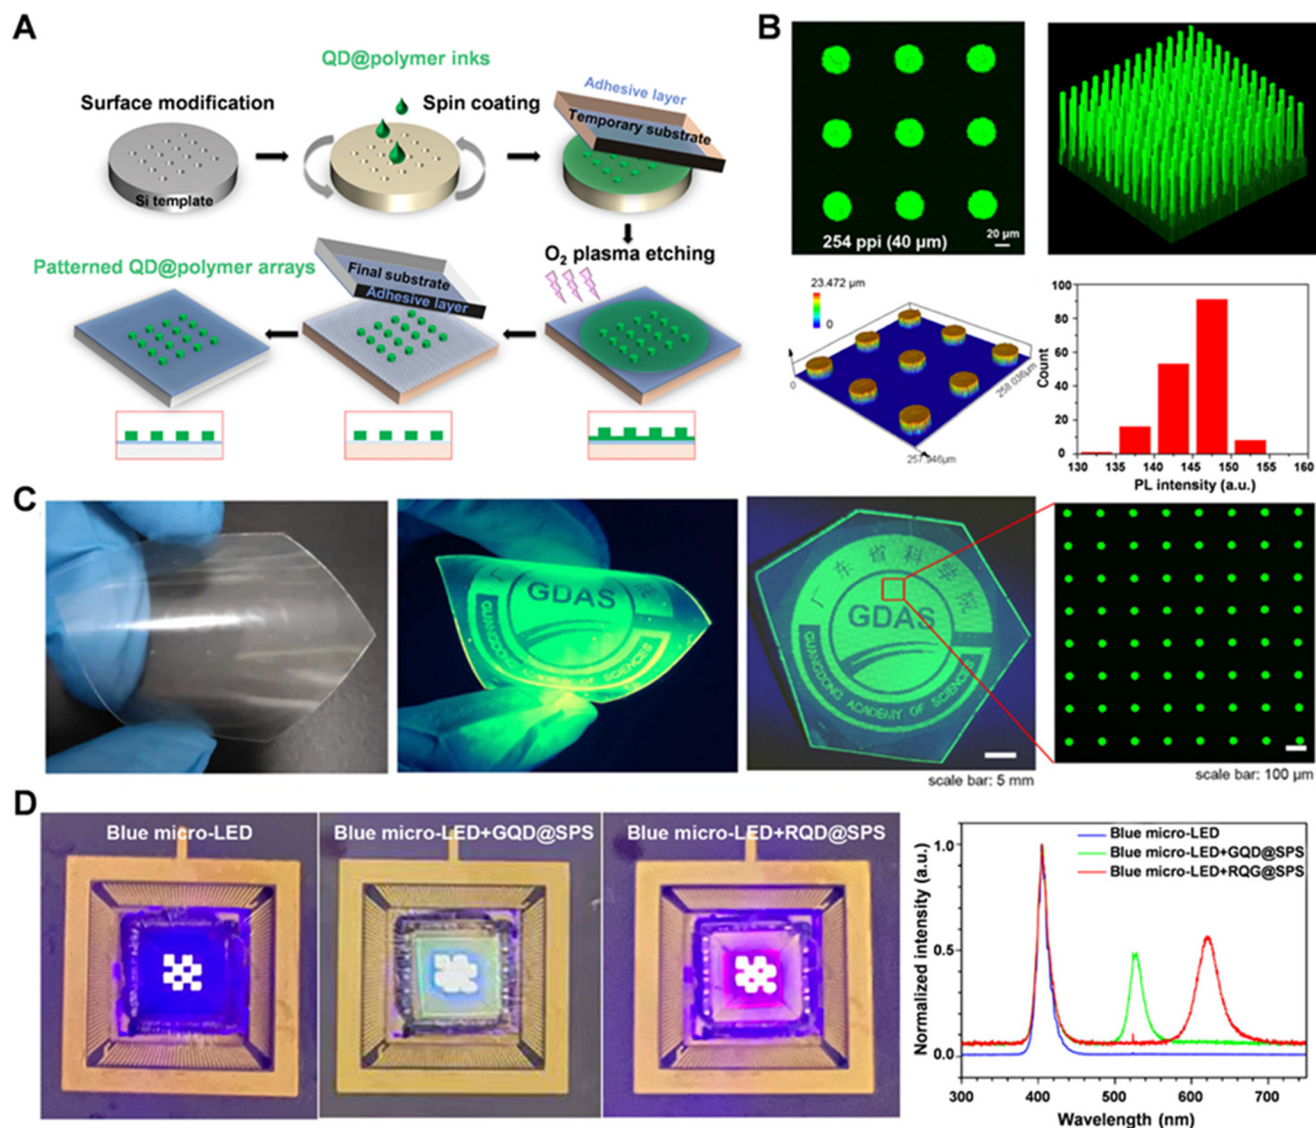

Fig. 12 (A) Schematic of the transfer printing of high-resolution QD patterns combining with plasma etching technique. quality color-conversion layers on these electrodes. This technique offers excellent controllability and precise patterning capabilities, providing an efficient and reproducible method for manufacturing QD color-conversion layers.

Zhao *et al.* combined photolithography with electrophoretic deposition to produce large-area, full-color QD pattern arrays (Fig. 13A).³⁴ The process involved immersing patterned electrodes sequentially in solutions of red, green, and blue CdSe/ZnS QDs in PGMEA. An electric field drove the QDs to oppositely charged electrodes, creating an RGB array. PEG-COOH-coated CdSe/ZnS QDs were used, and increasing the PEG-COOH concentration raised the zeta potential (Fig. 13B), indicating that the QD charges come from ligand ionization and can be adjusted by the ligand concentration. By varying the applied

voltage and deposition time, the thickness of the patterned QDs can be precisely controlled. As the SEM images shown in Fig. 13C, the QD deposition is very uniform with no noticeable surface defects. The authors also created QD pixel arrays of various shapes, sizes, and colors by modifying electrode patterns (Fig. 13D). Using multiple deposition steps, they achieved RGB QD pixel arrays measuring $14\ \mu\text{m} \times 14\ \mu\text{m}$ with a resolution of 1075 ppi.

Li *et al.* developed a multi-particle electrophoretic deposition (EPD) technique, combining CdSe/ZnS QDs with SiO₂ and TiO₂.³⁵ SiO₂ acts as a dispersion matrix, while TiO₂ provides scattering effects (Fig. 13E). Prior to deposition, SiO₂ was modified with silane-PEG-COOH to match the QD electrical properties. Higher PEG-COOH grafting rates on SiO₂ increased both zeta potential

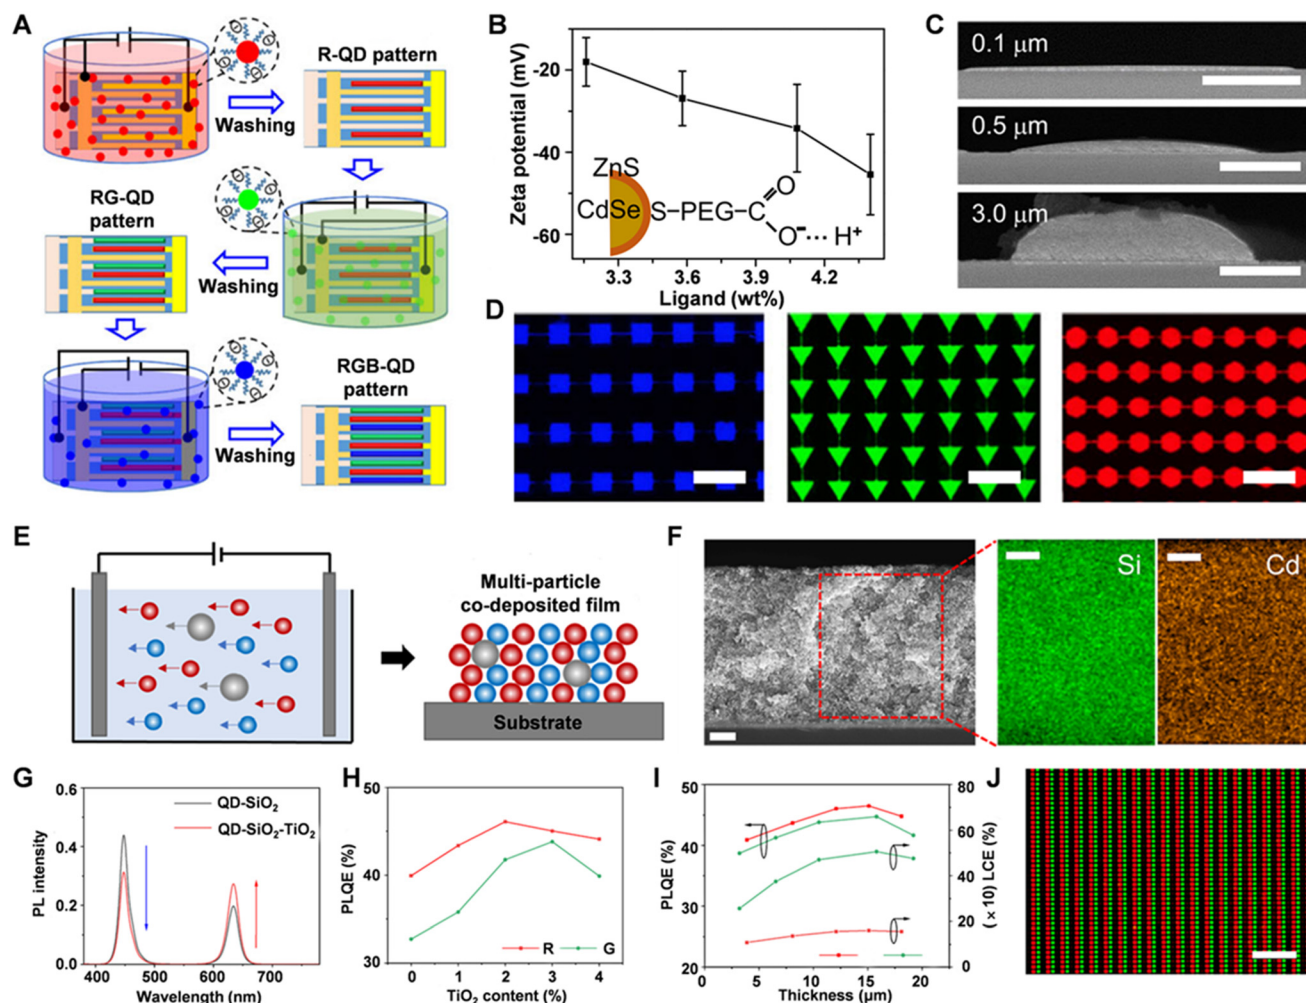

Fig. 13 (A) Schematic of the electrophoretic deposition to full-color QD pattern arrays. (B) Relationship between the zeta potential of the PEG-COOH-coated CdSe/ZnS QDs with the concentration of ligand PEG-COOH. (C) SEM images of the deposited QDs with different thickness. and electrophoretic mobility, improving the multi-particle assembly. Co-deposited QD-SiO₂ films were created with varying mobilities and analyzed through SEM, energy-dispersive spectroscopy, and Si/Cd ratio calculations, showing that 10% grafting resulted in uniform films (Fig. 13F). However, blue light leakage was observed due to incomplete excitation absorption. Introducing TiO₂ enhanced blue light absorption by increasing the optical path length and scattering (Fig. 13G), and improving the PLQE and LCE. The optimal TiO₂ concentrations led to PLQE values of 46% for red QD films and 43.8% for green QD films (Fig. 13H). Furthermore, the thickness of the multi-particle films was optimized to achieve better luminous performance (Fig. 13I). The technique enabled the creation of red-green two-color arrays with resolutions of 149 ppi, 568 ppi, and 1017 ppi (Fig. 13J), achieving a theoretical color gamut of 118% of the NTSC standard.

3.5. Microfluidic technology

Microfluidic technology involves the precise manipulation of fluids within micro- and nanoscale channels and their applications. This technology has found widespread use in fields such as chemistry, biology, and medicine.¹¹⁴ The notable advantages of microfluidic technology include minimal sample volume, high precision, low cost, and rapid fabrication, making microfluidic-based QD patterning a viable and practical solution. By utilizing microfluidic technology, researchers can precisely control fluid flow on a small scale, achieving high-precision QD patterning and providing a more efficient and economical solution for related applications.

Li *et al.* used microfluidic technology to create QD color-conversion layers for Micro-LED displays.³⁶ They introduced

red CsPbBr_2 and green CsPbBr_3 perovskite QDs into microchannels *via* syringe. A volatile solvent, *n*-hexane, was utilized to form solid QD films, and the channels were sealed after evaporation to protect the quantum dots from air and moisture. The resulting QDs emitted at wavelengths of 514 nm and 625 nm have narrow linewidths and high PLQE. The size of the QD arrays was measured to be $140\ \mu\text{m} \times 50\ \mu\text{m}$ and the full-color display device achieved a color gamut of 131% of the NTSC standard.

In another work, Li *et al.* fabricated flexible QD color-conversion layers using microfluidic technology. The sealing layer and microchannels were both fabricated from PDMS. After treating with oxygen plasma, the microchannels are aligned and bonded with the sealing layer to enhance the success rate of the color-conversion layer fabrication. Subsequently, red and green perovskite QDs are dispersed in *n*-hexane and introduced into the microchannels to complete the fabrication of the color-conversion layer. Further studies investigated the impact of bending radius on the performance of the microfluidic flexible color-conversion layer. At a bending radius of 15 mm, the emission intensity of red and green pixels changed by 26% and 3%, respectively. After 1000 bending cycles, the emission intensity changes were 29% and 5% for red and green pixels, respectively, with color gamut variations of less than 4%.

Weng *et al.* used a microfluidic technology to create patterned QD color-conversion films.¹¹⁵ Vacuum suction guides resin into the microchannel to form the pattern after photo-

chemical or thermal curing. The addition of polymers to the QD solution demonstrated to reduce the defect of patterned QD films after drying. Using this technology, the authors produced red and green QD patterned films with a linewidth of $8\ \mu\text{m}$ and a thickness of $5\ \mu\text{m}$.

Due to the lack of complete isolation between the pixels, the prepared pixels suffered from color crosstalk between the adjacent subpixels. To solve this, Zhu *et al.* developed a static droplet array (SDA) microfluidic technology for creating separate color-conversion QD arrays (Fig. 14A).³⁸ In this approach, red and green CdSe/ZnS QD solutions are introduced separately into SDA microchannels. Capillary forces guide the QDs into circular pixel areas through bridge structures. Transparent silicone oil, immiscible with the QD solution, is then injected to remove the QDs, creating a uniformly sized and separated two-color QD array. The entire process takes only 257 seconds (Fig. 14B). Using the SDA microfluidic technology, the authors produced droplets from 1 to $100\ \mu\text{m}$. As shown in Fig. 14C, the $20\ \mu\text{m}$ red-green monochrome and two-color QD arrays demonstrate high optical uniformity and minimal crosstalk. The uniformity of $20\ \mu\text{m}$ QD pixels is 98.58% and 98.72% for red and green, respectively.

3.6. Micropore filling method

The micropore filling method involves the creation of patterned arrays with micrometer-scale thickness and filling of QDs into these patterned arrays. This method allows for the

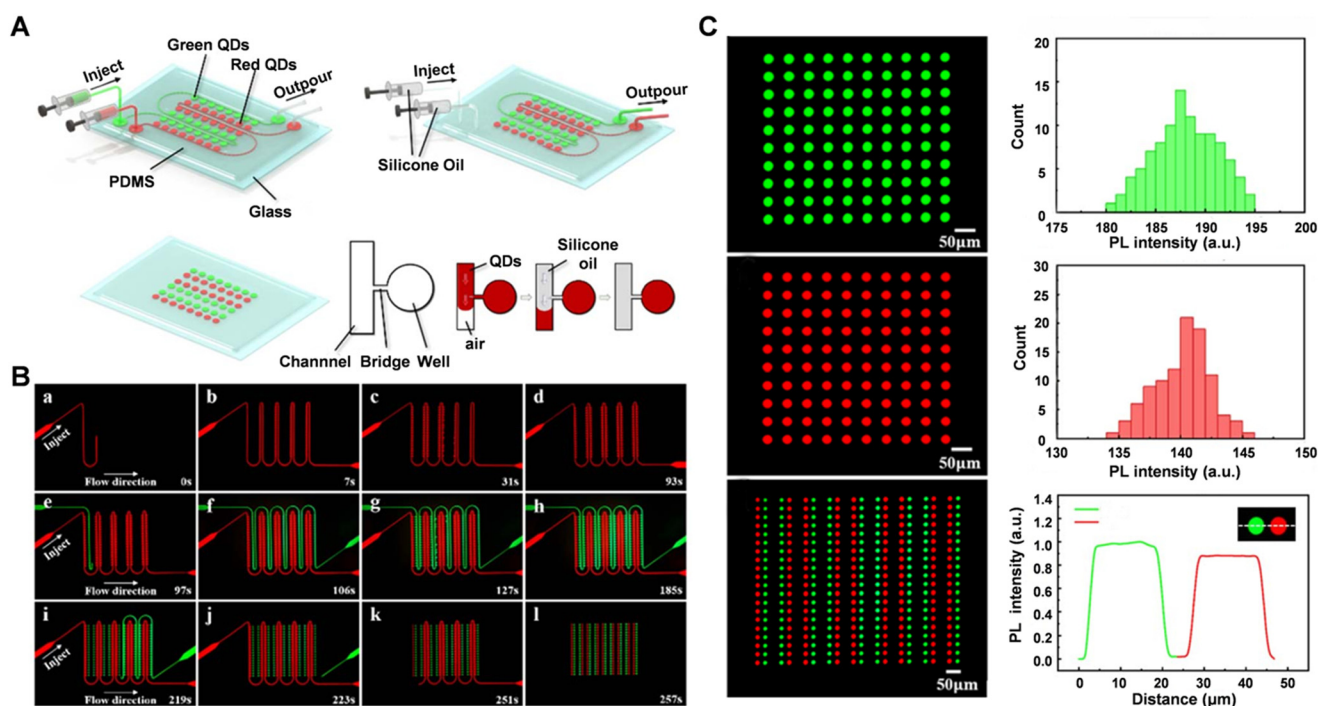

Fig. 14 (A) Schematic of the SDA system for creating color conversion layers by using microfluidic technology. (B) Processes of the injection of red QD solution, green QD solution, and silicone oil for generating separate two-color QD arrays. (C) Green and red monochrome and two-color QD arrays and the corresponding PL intensity. Reprinted with permission from ref. 37. Copyright 2023, Royal Society of Chemistry.

construction of color-conversion arrays of a single color with a single filling step. To fabricate multicolor QD color-conversion layers, this filling process can be repeated. Notably, the micropore filling method causes minimal damage to the QDs, which helps to maintain their excellent photoluminescence properties, making it a valuable approach for preserving the QD performance.

Huang *et al.* used the micropore filling method to fabricate QD color-conversion layers.⁴⁰ They created a patterned micropore array on a substrate *via* photolithography and then spin-coated CdSe QDs and removed excess materials to complete the layer. Additionally, the QDs can be further protected by SiO₂ or Si₃N₄ dielectric layers. The team produced rectangular QD arrays with widths of 5 μm , 10 μm , 15 μm , and 20 μm . Long-term stability tests showed that the CCE of arrays decreased by only 14.9% over 5980 hours, suggesting a device lifetime of approximately 12 830 hours.

Sun *et al.* employed the micropore filling method to deposit perovskite QDs with pixel sizes from 2 μm to 100 μm .⁴¹ They created a micropore array on an SU-8 film *via* photolithography, filled it with QDs using spin-coating and polished away excess QDs (Fig. 15A). This method supports diverse perovskite QD patterns and adjustable pixel thicknesses by altering the SU-8 mold. The authors achieved green pixel arrays with up to 849 ppi resolution on a 2-inch glass substrate (Fig. 15B), with the smallest pixel size of 2 μm . Fluorescence analysis of 3136 pixels showed a uniformity of $3.22 \pm 0.61\%$, indicating excellent optical consistency (Fig. 15C). Finally, the authors created red-green dual-color QD layers, with pixel sizes of 10 $\mu\text{m} \times 10 \mu\text{m}$ and 10 $\mu\text{m} \times 30 \mu\text{m}$ (Fig. 15D).

Fan *et al.* combined dual-component red perovskite QDs with the micropore filling method to fabricate QD color-conversion layers (Fig. 15E).⁴² The team deposited CsPbBr₃ QDs

and dual-component red QDs into a glass micropore array with a pixel size of 10 μm , and used a corresponding-sized Micro-LEDs as the excitation source. Fig. 15E shows the microscopy images of the color-conversion layer and the blue Micro-LED arrays. The color theoretical gamut of the Micro-LED device made from the blue LED, green perovskite QD, and dual-component red QDs reached 135.90% of the NTSC standard (Fig. 15F).

4. Conclusions and perspective

In this article, we comprehensively reviewed the latest achievements in QD materials and their patterning technologies for full-color Micro-LED displays. First, we talked the commonly used II–VI group QD, III–V group QD, and perovskite QD materials in Micro-LED display applications, and generally utilized ligand engineering, coating technologies, and construction of core–shell structures for improving the luminescence intensity and stability of these QDs. Then, we systematically elaborated on the latest research in QD patterning technologies including inkjet printing, photolithography, electrophoretic deposition, microfluidic techniques, transfer printing, and micropore filling method. These patterning methods all possess their advantages and limitations. With the advancement of QD color-conversion Micro-LED technology, future research will focus on enhancing the display quality, reducing costs, and improving the production efficiency. The following is our outlook upon the future development of the QD patterning technique specialized at color-conversion Micro-LED displays.

(1) Inkjet printing provides a high-resolution and high-material-utilization technique for patterning QDs. In particular, the EHD printing technique can be used to prepare QD pixels with a resolution over 20 000 dpi. However, the QD arrays are prepared by inkjet printing usually with a height of hundreds of nanometres, which lead to relatively low CCE and severe excitation light leakage. Therefore, the optimization of QD inks specialized for inkjet printing and printing parameters is essential to prepare high-resolution and 3-dimensional QD pixels with a height of several micrometers and enough QD concentration. For the construction of high-resolution patterned black matrix, accurate and continuous inkjet printing of QD is helpful to reduce the excitation light leakage and color crosstalk between the pixels.

(2) Photolithography can be used to prepare high-resolution QD color-conversion structures in large areas in a high-throughput manner. The direct photolithography can reduce the damage of lithographic patterning processes on the QDs, which is vital in practical applications. However, the mass utilization of the QDs in lithographic patterning is low, which increases the display production costs. Combining with other patterning techniques such as inkjet printing to pre-deposit the QDs on the substrate and further patterning them with lithography may provide alternative solutions for increasing the QD utilization ratio.

(3) Electrophoretic deposition provides a fast deposition technique for QD patterns with controllable thickness. This technique requires the construction of electrodes on the substrate through photolithography and metal or metal oxide deposition. Although the microscopy images of the QDs show regular shapes, the neighbor pixels with the same color were connected by QDs with narrow linewidth due to the existence of underlying electrode. Therefore, a more rational design of the electrodes is required for depositing absolutely separated QD pixels for decreasing the potential color-crosstalk.

(4) Microfluidic technology shows its potential for constructing QD color-conversion arrays with a high material utilization efficiency. However, this technique needs to prepare mold and microfluidic chips, which makes this method beneficial if the microfluidic chips can be utilized repeatedly to reduce the cost. In addition, this method needs to prove its potential in patterning QDs in a large area, which requires the optimization of the physicochemical properties of the microfluidic chips and rheological properties of the QD inks.

(5) Transfer printing has shown its potential in the patterning of single-color and multi-color QDs with a micrometer thickness. To date, the highest resolution of the transfer printed QD arrays with high thickness is limited to several hundred ppi. With the aim to apply Micro-LED displays in AR, VR, *etc.*, the resolution of the transfer printed QD arrays needs to be further increased.

(6) Micropore filling method provides a straightforward and simple method to prepare large-area QD patterns. The damage of this patterning technique for QDs is low, but only color-conversion structures were demonstrated. In the future, the accurate alignment and bonding of the large-area multi-color QD color-conversion layer and Micro-LED chip are required to prove the commercial potential of the micropore filling method.

Besides the high PL intensity, PLQY, and the stability of QDs, the patterning techniques require the QDs to possess some specific properties such as the rheological properties for inkjet printing, photoactivity of the ligands for lithography, and charge of the QDs for electrophoretic deposition. Therefore, the preparation of high-quality QDs and patterning techniques are highly correlated. Through continuous technological innovation and improvement in QD synthesis and patterning techniques, QD-based color-conversion Micro-LED displays are expected to play a more significant role in the future display technology.
