## Self-supporting poly(3,4-ethylenedioxythiophene) and Fe<sub>3</sub>C Co-decorated electrospun carbon nanofibers as Li<sub>2</sub>S supporters for lithium–sulfur batteries†

 Na Yang,<sup>‡</sup> Jiarui Xue,<sup>‡</sup> Yuanxiao Ji, Jiyuan Zhang, Weiye Zhang, Xuexia He, Qi Li,<sup>id</sup> Zhibin Lei,<sup>id</sup>\* Zonghuai Liu<sup>id</sup> and Jie Sun<sup>id</sup>\*

Lithium–sulfur (Li–S) batteries have attracted significant attention in recent years owing to their high theoretical energy density (2600 W h kg<sup>-1</sup>) and specific capacity (1675 mA h g<sup>-1</sup>), abundant reserves and environmental friendliness. However, the well-known poor electrical conductivity of sulfur/Li<sub>2</sub>S, shuttle effect of lithium polysulfides (LiPSs) and *in situ* formation of lithium dendrites during the cycling process extremely hinder the large-scale application of Li–S batteries. In this work, we designed and prepared poly(3,4-ethylenedioxythiophene) (PEDOT) and Fe<sub>3</sub>C nanoparticle co-decorated carbon nanofiber (CNF) membranes as self-supporting Li<sub>2</sub>S hosts to improve the electrochemical performance of Li–S batteries. The PEDOT coating layer firmly connected the Fe<sub>3</sub>C nanoparticles with the CNFs to form a conductive network, significantly enhancing the conductivity of the cathode. Simultaneously, the strong chemical adsorption of PEDOT and the catalytic effect of Fe<sub>3</sub>C effectively accelerated the conversion kinetics of LiPSs, thereby improving the battery performance. As a result, the optimized PEDOT@CNFs@Fe<sub>3</sub>C-16wt%/Li<sub>2</sub>S composite cathode achieved a high initial specific capacity of 816 mA h g<sup>-1</sup> at a current density of 0.1 C. Furthermore, the cathode exhibited only 0.033% capacity decay per cycle at 0.5 C after 1000 cycles, showing its potential as a high-performance self-supporting flexible Li–S composite cathode.

## 1 Introduction

With the continuous development and progress of the global economy and technology, the problem of energy shortage is becoming increasingly prominent. Developing new high-performance energy storage devices is an important means to solve the energy problems. Lithium–sulfur (Li–S) batteries are a new type of electrochemical energy storage device with high theoretical specific capacity (1675 mA h g<sup>-1</sup>) and energy density (2600 W h kg<sup>-1</sup>), abundant sulfur storage and environmental friendliness.<sup>1–4</sup> Based on the electrochemical reaction mechanism between sulfur and metallic lithium, the charging and discharging processes of Li–S batteries involve a multi-step redox reaction process, which

leads to a series of problems, resulting in a decrease in specific capacity and stability.<sup>5,6</sup> These problems include the serious volume change during the transformation between sulfur and Li<sub>2</sub>S, poor electrical conductivity of both discharge and charge products, shuttling of lithium polysulfides (LiPSs) during the cycling process, and the safety problems caused by lithium dendrites.<sup>7–12</sup> Plenty of efforts have been made to overcome these shortcomings, including cathode design,<sup>13,14</sup> separator functionalization,<sup>15</sup> electrolyte additive<sup>16</sup> and anode protection.<sup>17</sup>

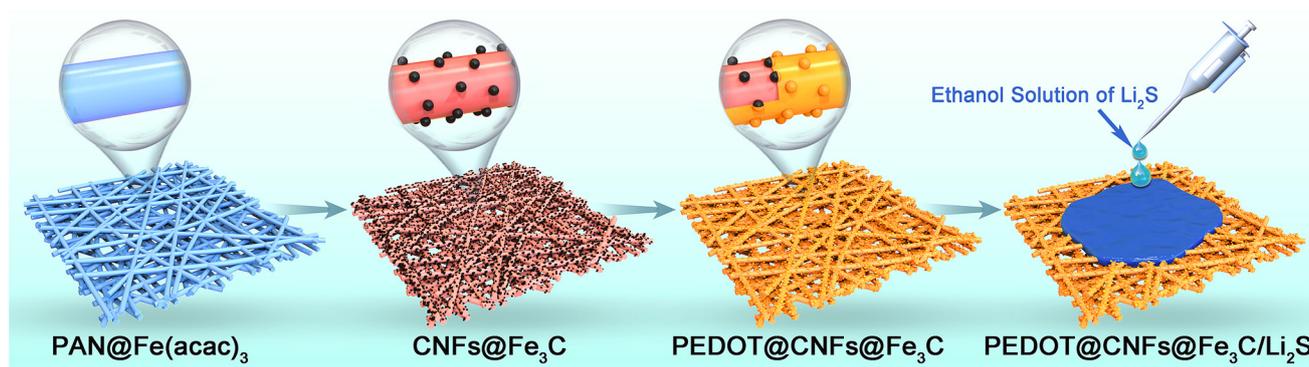

Compared with traditional sulfur cathode, the use of fully pre-lithiated Li<sub>2</sub>S as a cathode can effectively solve some of the above problems. As the final discharge product in Li–S batteries, Li<sub>2</sub>S possesses a low density (1.66 g cm<sup>-3</sup>) and high melting point (938 °C), which can also completely avoid volume expansion during the cycling process.<sup>18–21</sup> Moreover, the use of Li<sub>2</sub>S as a cathode is helpful for the assembly of lithium anode-free Li–S batteries.<sup>22–24</sup> However, the extremely low electronic conductivity of Li<sub>2</sub>S (10<sup>-14</sup> S cm<sup>-1</sup>) makes it difficult to achieve high efficiency charge transfer during the cycling process, leading to high interface impedance.<sup>19</sup> Moreover, the complex redox reactions with slow solid/liquid phase transition kinetics<sup>25</sup> lead to significant obstacles in the commercialization of Li<sub>2</sub>S cathodes.

**Scheme 1** Preparation route of the PEDOT@CNFs@Fe<sub>3</sub>C/Li<sub>2</sub>S composite cathode for Li–S batteries.

Conductive polymers have been widely used in the field of energy storage owing to their excellent reversibility during redox process, high conductivity in doped states, low cost, and superior mechanical properties.<sup>26–28</sup> Commonly used conductive polymers include polyaniline (PANI), polypyrrole (PPy), poly(3,4-ethylenedioxythiophene) (PEDOT) and their derivatives. Among them, PEDOT has relatively high conductivity, which is related to the delocalization of  $\pi$  electrons in its conjugated molecules. The longer conjugated chains of PEDOT ( $N > 15$ ) can form effective  $\pi$ – $\pi$  electron delocalization, enabling efficient charge transfer along the polymer chain.<sup>29,30</sup> The commercial PEDOT currently available for sale is mainly poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS), which is a micelle system composed of polycations and polyanions, whose electrical conductivity is relatively poor when compared with that of pure PEDOT. The pure PEDOT can be directly prepared by using solution polymerization, electrodeposition, and gas-phase oxidation polymerization methods.<sup>31–33</sup> During the polymerization process, the added surfactant or oxidant determines the final form of PEDOT. By adjusting the concentration of EDOT monomers and the type of surfactant, the

morphology of PEDOT can also be controlled.<sup>34</sup> For Li–S batteries, PEDOT can be used as functionalized sulfur host and separator modification materials simultaneously.<sup>35–37</sup> The unique dendritic network structure of PEDOT can effectively accelerate the electron transfer efficiency and improve the wettability of the electrodes. Simultaneously, sulfur functional groups have an excellent affinity to LiPSs, which is helpful in the acceleration of redox reaction kinetics.<sup>38</sup> In addition, the excellent flexibility of PEDOT has broad application prospects and research values in the preparation and application of flexible self-supporting cathodes.<sup>39,40</sup>

Transition metal carbides have been widely utilized in the fields of energy storage and catalysis,<sup>41–44</sup> of which Fe<sub>3</sub>C with an orthorhombic structure possesses high hardness and melting point, together with excellent electrical conductivity, that has been utilized as electrocatalysts,<sup>45</sup> electrodes<sup>46</sup> and photocatalysts.<sup>47</sup> In the field of Li–S batteries, Fe<sub>3</sub>C has been found to possess strong adsorption and catalytic abilities towards LiPSs.<sup>48–50</sup> In practical use, Fe<sub>3</sub>C is often composite with carbon materials because not only its preparation method is mainly based on carbothermal reduction reaction, but also the composite structure can significantly avoid adverse reactions between Fe<sub>3</sub>C particles and electrolytes, and prevent particle aggregation during the battery cycling process simultaneously.<sup>51</sup>

In this work, we design and prepare a PEDOT-coated Fe<sub>3</sub>C nanoparticle-decorated electrospun carbon nanofibers (CNFs) as a self-supported host to load Li<sub>2</sub>S as the composite cathode for Li–S batteries. The Fe<sub>3</sub>C nanoparticles in the prepared composites possess excellent catalytic activity towards LiPSs, while the PEDOT coating can effectively connect the dispersed Fe<sub>3</sub>C nanoparticles together to obtain a highly flexible conductive network. In addition, PEDOT can fully utilize its chemical adsorption capacity on LiPSs. After the loading of Li<sub>2</sub>S, the self-supporting PEDOT@CNFs@Fe<sub>3</sub>C/Li<sub>2</sub>S composite cathode can be obtained. The synthesis route of the composites is illustrated in Scheme 1. The PEDOT coating amount can be precisely adjusted through the regulation of the EDOT monomer addition amount. Further LiPSs catalytic and electrochemical performance of the assembled cells are also investigated in detail.

## 2 Experimental

### 2.1 Chemicals and materials

The 3,4-ethoxylene dioxy thiophene (97%), Ferric acetylacetonate (98%) and lithium sulfide were purchased from Shanghai Aladdin Co., Ltd. Anhydrous ethanol (AR) and hydrochloric acid (AR) were purchased from Sinopharm Chemical Reagent Co., Ltd. Polyacrylonitrile (97%) was purchased from Shanghai Macklin Biochemical Technology Co., Ltd. Acetylene black (AC) was purchased from Jiang Su XFANO Co., Ltd. *N*-Methyl-2-pyrrolidone (AR) and *N,N*-dimethylformamide (AR) were purchased from Tianjin Kemio Chemical Reagent Co., Ltd. The polyvinylidene difluoride, Celgard 2400 separator, electrolyte for Li-S batteries and lithium metal were all purchased from Dodo Chem Co., Ltd. All the chemicals were directly used without further purification.

### 2.2 Fabrication of CNFs@Fe<sub>3</sub>C composite fibrous membrane

The PAN/Fe(acac)<sub>3</sub> composite nanofibers were first prepared by applying the electrospinning method. Specifically, 0.5 g polyacrylonitrile (PAN) and 0.5 g Ferric acetylacetonate (Fe(acac)<sub>3</sub>) were dissolved in 5 mL of *N,N*-dimethylformamide (DMF) and stirred at room temperature for 10 hours to obtain an orange red viscous spinning solution. The above spinning solution was transferred into a 10 mL syringe, followed by the performing of electrospin process. The spin rate, receiving electrode distance and receiving rate were set as 100 rpm, 16 cm and 0.12 mm min<sup>-1</sup> respectively. Moreover, the positive and negative voltages were set to be +20 kV and -1.5 kV, respectively. After the electrospin process, the PAN@Fe(acac)<sub>3</sub> fibrous film with orange colour could be obtained. The fibrous film was then calcinated at 200 °C for 2 hours to stabilize the structure. A further calcination process under 700 °C was carried out in a tube furnace for 1 hour under Ar atmosphere. The final CNFs@Fe<sub>3</sub>C composite fibrous membrane could then be obtained.

### 2.3 Fabrication of PEDOT@CNFs@Fe<sub>3</sub>C composite fibrous membrane

A closed glass jar with a total volume of 500 mL was employed as the reaction vessel to prepare PEDOT@CNFs@Fe<sub>3</sub>C composite fibrous membrane. Specifically, 15 μL, 20 μL and 25 μL of EDOT monomer and 1 : 1 concentrated hydrochloric acid were added to the beaker placed in the glass jar. The whole glass jar was then heated to 100 °C to promote the vapor polymerization of EDOT onto the surface of the CNFs@Fe<sub>3</sub>C composite membrane. After a 30 min reaction, the PEDOT@CNFs@Fe<sub>3</sub>C composite membrane can be obtained. The products were then cut into circular electrode slices with a diameter of 1 cm. The amount of PEDOT polymerization can be determined by calculating the mass difference before and after the polymerization process. For example, 15 μL EDOT monomer reacted with 50 mg of CNFs@Fe<sub>3</sub>C to obtain a final product with a total mass of 56.45 mg. The polymerized PEDOT amount was 6.45 mg with a mass ratio of 6.45 mg/56.45 mg = 11%. Such composites were named as PEDOT@CNFs@Fe<sub>3</sub>C-11wt% (P@CNFs@Fe<sub>3</sub>C-11wt%). With different EDOT monomer

addition amounts, the P@CNFs@Fe<sub>3</sub>C-16wt% and P@CNFs@Fe<sub>3</sub>C-21wt% composites could also be obtained.

### 2.4 Preparation of PEDOT@CNFs@Fe<sub>3</sub>C/Li<sub>2</sub>S composite cathode

The ethanol solution of Li<sub>2</sub>S was first prepared in an Ar-filled glove box (water pressure <0.01 ppm, oxygen partial pressure <1 ppm) by dissolving 120 mg Li<sub>2</sub>S (99.5% purity) into 5 mL ethanol, followed by stirring sufficiently to form a saturated solution with a Li<sub>2</sub>S concentration of 24 mg mL<sup>-1</sup>. During the loading process of Li<sub>2</sub>S, 40 μL of the prepared Li<sub>2</sub>S ethanol solution was dropped onto the surface of the P@CNFs@Fe<sub>3</sub>C supporter, followed by pumping in the small transition bin of the glove box to volatilize all ethanol. The P@CNFs@Fe<sub>3</sub>C/Li<sub>2</sub>S composite cathode could then be obtained. Under this experimental condition, the areal loading amount of Li<sub>2</sub>S was calculated as 1.2 mg cm<sup>-2</sup>.

### 2.5 Material characterization

A Rigaku Miniflex 600 powder X-ray Diffractometer was employed to determine the phase compositions of different P@CNFs@Fe<sub>3</sub>C composites. The radiation source was selected as Cu K<sub>α</sub> with a characteristic wavelength of λ = 1.54056 Å. The scan range was set from 5° to 80° at a scan speed of 10° min<sup>-1</sup>. The surface morphology, microstructure and corresponding elemental distribution of different composites were characterized by using a SU8020 Field Emission Scanning Electron Microscope (FE-SEM) and a JEM-2800 Field Emission Transmission Electron Microscope (TEM) operated at 200 kV. Raman spectroscopy was collected by using a Renishaw inVia Reflex Raman spectrometer to evaluate the graphitization degree of carbon materials. The wavelength of the laser light source and scan range were set to 532 nm and 800–2000 cm<sup>-1</sup>, respectively. The AXIS ULTRA X-ray Photoelectron Spectroscopy (XPS) was employed to investigate the surface valence of elements before and after Li<sub>2</sub>S<sub>6</sub> adsorption. The X-ray source was an Al K<sub>α</sub> source with an energy of 1486.71 eV. Owing to the extreme sensitivity of Li<sub>2</sub>S<sub>6</sub> to the air, all the tested samples were sealed in a glove box before testing. All the peaks were first calibrated using the standard peak of C 1s at 284.8 eV before the testing process. The obtained results were all fitted using the Casa XPS software.

### 2.6 Li<sub>2</sub>S<sub>6</sub> visible adsorption experiment

The elemental sulfur and lithium sulfide (Li<sub>2</sub>S) were first mixed with a molar ratio of 5 : 1, followed by adding the bis (trifluoromethane sulfonyl) imide (LiTFSI) in a solvent mixture of 1,2-dimethoxyethane (DME) and 1,3-dioxolane (DOL) (1 : 1 in volume) solution with 2.0% LiNO<sub>3</sub> as an additive solution as the electrolyte. The suspension was stirred in a glove box for 24 hours to finally obtain a 7.5 mM Li<sub>2</sub>S<sub>6</sub> solution. The CNFs@Fe<sub>3</sub>C and P@CNFs@Fe<sub>3</sub>C composites with different PEDOT coating amounts were placed in different glass bottles. Then, 2 mL of the prepared Li<sub>2</sub>S<sub>6</sub> solution was added to each bottle separately. The color change in the solution after 30 min was recorded. Moreover, the UV-visible spectra of the LiPSs solution after adsorption were collected using a PerkinElmer Lambda 950 UV-VIS-NIR Spectrophotometer.

### 2.7 $\text{Li}_2\text{S}_6$ symmetrical cell assembly and electrochemical performance evaluation

The CNFs@ $\text{Fe}_3\text{C}$  and P@CNFs@ $\text{Fe}_3\text{C}$  composites with different PEDOT coating amounts were employed as both cathode and anode to assemble the  $\text{Li}_2\text{S}_6$  symmetrical cells. Specifically, the cathode, Celgard 2400 membrane separator, 40  $\mu\text{L}$  prepared  $\text{Li}_2\text{S}_6$  solution and anode were placed successively, followed by a sealing process to obtain the symmetrical coin cell. The Cyclic Voltammetry (CV) test was performed on a Multi Autolab M204 electrochemical workstation at a scanning speed of 1  $\text{mV s}^{-1}$  and a potential ranging from  $-1.0$  V to 1.0 V.

### 2.8 $\text{Li}_2\text{S}$ precipitation and dissolution experiment

The elemental sulfur and lithium sulfide ( $\text{Li}_2\text{S}$ ) with a molar ratio of 7 : 1 were weighed and added to the electrolyte. After stirring in a glove box for 24 hours, a 0.2 M  $\text{Li}_2\text{S}_8$  solution could be obtained. The CNFs@ $\text{Fe}_3\text{C}$  and P@CNFs@ $\text{Fe}_3\text{C}$ -16%wt composites were employed as the cathode, with lithium metal foil as the anode and Celgard 2400 as the separator to assemble the coin cells. The prepared  $\text{Li}_2\text{S}_8$  solution (20  $\mu\text{L}$ ) was dropped between the cathode and the separator, followed by adding another 20  $\mu\text{L}$  electrolyte to the anode side. For the  $\text{Li}_2\text{S}$  precipitation experiment, the assembled cells were first discharged galvanostatically at 0.112 mA until the potential dropped to 2.11 V. Then, the mode is switched to potentiostatically discharge at 2.10 V until the current density drops below  $10^{-5}$  A. The current-time curves during the whole process were collected and fitted using exponential functions to obtain the deposition capacity and nucleation time of  $\text{Li}_2\text{S}$  on different electrode surfaces. For the  $\text{Li}_2\text{S}$  dissolution experiment, the cells are first discharged galvanostatically to 1.7 V at 0.112 mA and then charged at a voltage of 2.4 V until the current drops below  $10^{-5}$  A. The current-time curves during the process were also collected accordingly.

### 2.9 Li-S battery assembly and electrochemical performance evaluation

For both regular and high loading amounts of  $\text{Li}_2\text{S}$ , the assembly method of the Li-S coin cells was completely the same. By placing the cathode shell, self-assembly cathode, separator, lithium anode and anode shell in an Ar-filled glove box successively, the 15  $\mu\text{L}$  electrolyte (the same as that used in the  $\text{Li}_2\text{S}_6$  visible adsorption experiment) was added to the cathode side and anode side. The lithium anode foil used in this work possesses a thickness of 0.6 mm and a diameter of 16 mm. After sealing carefully, the assembled cells were left in the glove box for 10 hours before electrochemical performance testing.

The Cyclic Voltammetry (CV) and Electrochemical Impedance Spectroscopy (EIS) curves of the assembled cells were collected on a MUL AUTOLAB M204 electrochemical workstation. During the CV testing, the voltage window was selected as 1.6 V–2.8 V at a scan speed of 0.1  $\text{mV s}^{-1}$ . In addition, the EIS was collected under the frequency range of 10 mHz–100 kHz and an amplitude of 5 mV. The Galvanostatic Charge–Discharge (GCD) curves for all the cathodes were collected on a LAND battery performance testing system under current densities ranging from 0.1 C to 2 C.

## 3 Results and discussion

### 3.1 Structural and morphology characterization of PAN/Fe(acac)<sub>3</sub> and CNFs@Fe<sub>3</sub>C composite nanofiber membranes

Fig. S1† shows the structural and morphological characterization results of PAN/Fe(acac)<sub>3</sub> and CNFs@ $\text{Fe}_3\text{C}$  composite nanofiber membranes. It is noticed that the prepared PAN/Fe(acac)<sub>3</sub> membranes exhibit a three-dimensional network structure with smooth surfaces and a diameter of approximately 200 nm, as shown in Fig. S1a and b.† After calcinating under the Ar atmosphere, the Fe(acac)<sub>3</sub> can be successfully reduced to  $\text{Fe}_3\text{C}$  with PAN transforming to CNFs simultaneously.<sup>52</sup> A large number of nanoparticles also appear at the surface of CNFs@ $\text{Fe}_3\text{C}$  after calcination, as shown in Fig. S1d and e.† The three-dimensional cross-linked network structure is still well maintained with relatively the same fiber diameter, providing a guarantee for a highly conductive self-supporting cathode in the future. X-ray Diffraction (XRD) and Raman spectroscopy characterization are further carried out to investigate the phase structure of PAN/Fe(acac)<sub>3</sub> and CNFs@ $\text{Fe}_3\text{C}$  composite nanofiber membranes. As observed from the XRD patterns in Fig. S1c,† there is a wide bulge in the patterns of PAN/Fe(acac)<sub>3</sub> composites at around  $2\theta = 26^\circ$ , corresponding to the PAN. Meanwhile, several diffraction peaks representing Fe(acac)<sub>3</sub> can also be observed at around  $2\theta = 10^\circ$ – $20^\circ$ . After the calcination process, the characteristic peaks representing the  $\text{Fe}_3\text{C}$  (JCPDS # 06-0670) phase can be observed clearly from the XRD patterns of CNFs@ $\text{Fe}_3\text{C}$  composites, suggesting the successful formation of  $\text{Fe}_3\text{C}$ . Moreover, the broadening peak at around  $2\theta = 26^\circ$  is still visible, which can now be attributed to amorphous CNFs. The Raman spectroscopy of the PAN/Fe(acac)<sub>3</sub> and CNFs@ $\text{Fe}_3\text{C}$  composite nanofiber membranes are also collected accordingly, as shown in Fig. S1f.† It is found that the PAN/Fe(acac)<sub>3</sub> composites do not exhibit any vibration bands in the range of 800–2000  $\text{cm}^{-1}$ . In comparison, the CNFs@ $\text{Fe}_3\text{C}$  composites show obvious D and G bands of carbon at around 1340  $\text{cm}^{-1}$  and 1580  $\text{cm}^{-1}$ , respectively.

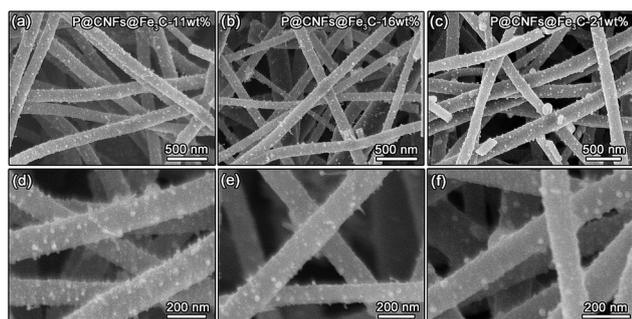

Transmission Electron Microscopy (TEM) is further employed to characterize the microstructure of CNFs@ $\text{Fe}_3\text{C}$  composites, as shown in Fig. S2.† As observed from the Bright Field (BF) image in Fig. S2a,† the interconnected network nature of the membrane with  $\text{Fe}_3\text{C}$  nanoparticles decorated intensively on the surface can also be confirmed. From the High-Resolution Transmission Electron Microscopy (HRTEM) image illustrated in Fig. S2b,† it is found that the  $\text{Fe}_3\text{C}$  nanoparticles with a size of approximately 15 nm are fully wrapped up by the graphite carbon. The corresponding Fast Fourier Transformation (FFT) figure taken from the red square region illustrates both diffraction spots of  $\text{Fe}_3\text{C}$  and diffraction rings of graphite, as shown in Fig. S2c.† Here, subscripts “G” and “F” represent graphite and  $\text{Fe}_3\text{C}$ , respectively. Using all the diffraction spots to construct the Inverse Fast Fourier Transformation (IFFT) figure, the 0.24 nm and 0.34 nm lattice spacing can be observed clearly, corres-

ponding to the (120) plane of  $\text{Fe}_3\text{C}$  and (002) plane of graphite, respectively, as shown in Fig. S2d.† The Scanning Transmission Electron Microscopy Dark-Field (STEM-DF) image and corresponding Energy Dispersive X-ray Spectroscopy (EDX) mapping scan results also clearly illustrate the successful uniform decoration of  $\text{Fe}_3\text{C}$  nanoparticles on the CNFs, as shown in Fig. S2(e–h).†

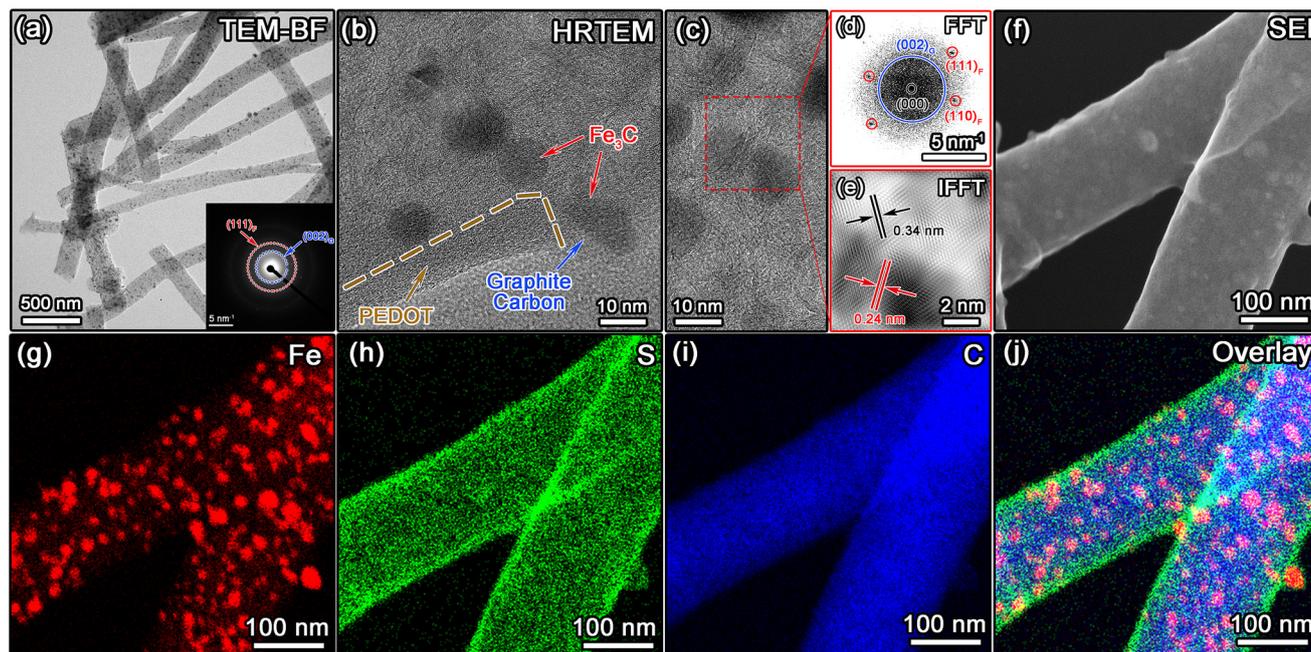

### 3.2 Structural and morphology characterization of PEDOT@CNFs@ $\text{Fe}_3\text{C}$ composite fibrous membranes

By employing CNFs@ $\text{Fe}_3\text{C}$  composites as the substrate, PEDOT can be coated successfully using a gas-phase polymerization method to prepare P@CNFs@ $\text{Fe}_3\text{C}$  composites. Fig. 1 shows the SEM images of the composites with different PEDOT polymerization amounts. As mentioned in the Experimental section, the use of 15  $\mu\text{L}$ , 20  $\mu\text{L}$  and 25  $\mu\text{L}$  EDOT monomer correspond to the PEDOT coating amounts of 11 wt%, 16 wt% and 21 wt%, respectively. As seen from the figure, it is found that the P@CNFs@ $\text{Fe}_3\text{C}$ -11wt% composite membranes exhibit quite similar morphology when compared with that of CNFs@ $\text{Fe}_3\text{C}$ , corresponding to the small amount of PEDOT coating, as shown in Fig. 1a and d. With the increase in the PEDOT coating amount,  $\text{Fe}_3\text{C}$  nanoparticles are gradually covered (Fig. 1b and e). When the PEDOT coating amount reaches 21 wt%, the surface exposed  $\text{Fe}_3\text{C}$  nanoparticles are significantly reduced, as shown in Fig. 1c and f. Under this condition, the coating of PEDOT can connect the isolated  $\text{Fe}_3\text{C}$  nanoparticles to form a continuous conductive network, thereby improving the electrical conductivity of the composite material. However, the excessive thickness of the PEDOT polymer layer may also affect  $\text{Li}^+$  transport efficiency during the charge–discharge process of the cells, which has been proved by our previous research works.<sup>53</sup>

Further structure analysis has also been carried out on the P@CNFs@ $\text{Fe}_3\text{C}$ -16wt% composites, as shown in Fig. 2. From

**Fig. 1** SEM images of P@CNFs@ $\text{Fe}_3\text{C}$  composite fibrous membranes with 11 wt% (a), 16 wt% (b) and 21 wt% (c) PEDOT polymerization amounts suggest the linear relationship between coating amount of PEDOT and coverage of  $\text{Fe}_3\text{C}$  nanoparticles. The corresponding enlarged SEM images (d–f) clearly illustrate the different surface exposure of  $\text{Fe}_3\text{C}$  nanoparticles on the surface of CNFs.

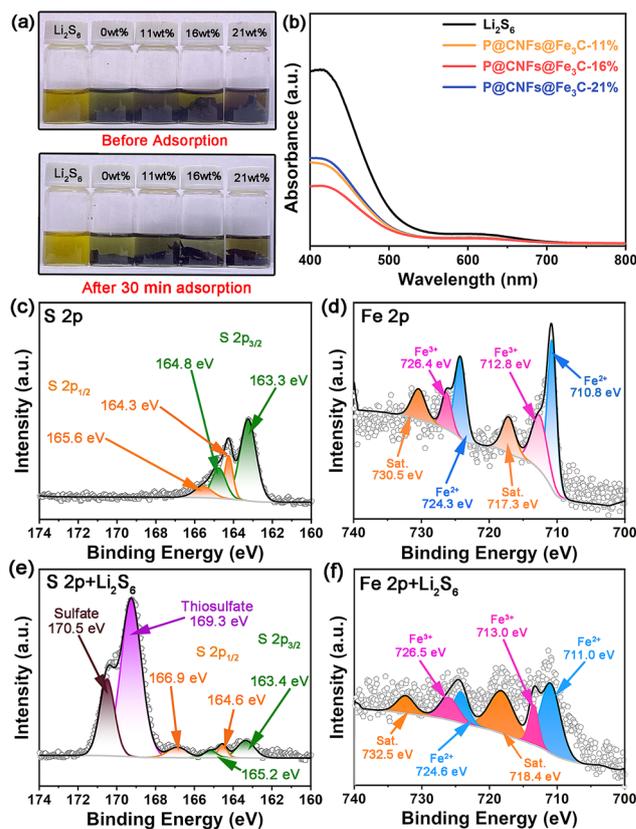

**Fig. 2** TEM BF image of P@CNFs@ $\text{Fe}_3\text{C}$ -16wt% nanocomposites and the corresponding SAED patterns (a) suggest the cross-linked fibrous morphology of the CNFs with  $\text{Fe}_3\text{C}$  nanoparticles decorated. The corresponding HRTEM image (b) confirms the amorphous nature of the PEDOT coating layer, which is fully covered on the surface of CNFs. The enlarged HRTEM image (c) and the corresponding FFT (d) and IFFT (e) figures further confirm the existence and distribution of graphite carbon and  $\text{Fe}_3\text{C}$  nanoparticles. The high resolution SEI (f) confirms the uniform coverage of the PEDOT layer at the surface of CNFs@ $\text{Fe}_3\text{C}$  composites. The corresponding EDX mappings (g–j) clearly illustrate the uniform distribution of Fe, S and C elements.

the BF image in Fig. 2a, there is no significant difference in the microstructure before and after PEDOT polymerization, which is consistent with the relatively lower polymerization amount. The corresponding Selected Area Electron Diffraction (SAED) patterns show two obvious polycrystalline diffraction rings, corresponding to the (002) crystal plane of graphite and the (111) crystal plane of  $\text{Fe}_3\text{C}$ , respectively. From the HRTEM image shown in Fig. 2b, an obvious amorphous layer can be observed at the edge of the CNFs, which refers to the PEDOT coating layer. In addition,  $\text{Fe}_3\text{C}$  nanoparticles are found to be fully wrapped by graphite carbon and the PEDOT coating. The FFT figure constructed from the enlarged HRTEM image (Fig. 2c) also illustrates the diffraction ring of graphite and several diffraction spots from  $\text{Fe}_3\text{C}$ , as shown in Fig. 2d. The corresponding IFFT figure further marks the 0.24 nm lattice spacing of (110) in  $\text{Fe}_3\text{C}$  and the 0.34 nm lattice spacing of graphite carbon, which exhibit similar features to those of  $\text{CNFs@Fe}_3\text{C}$  composites. The high-resolution Secondary Electron Image (SEI) collected in TEM (Fig. 2f) shows a more detailed surface morphology of  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  composites. Specifically, the  $\text{Fe}_3\text{C}$  nanoparticles are proved to be fully covered by the PEDOT conductive layer, which enables all the isolated  $\text{Fe}_3\text{C}$  nanoparticles to be linked into a continuous conductive network. Finally, the corresponding EDX mapping scan results (Fig. 2g-j) indicate the distribution of Fe on the particles, while S mainly covers the surface of the fibers. Such results further demonstrate the successful fabrication of  $\text{P@CNFs@Fe}_3\text{C}$  composite fibrous membranes.

### 3.3 Lithium polysulfide adsorption and catalytic behavior of PEDOT@CNFs@ $\text{Fe}_3\text{C}$ composite fibrous membranes

A visualized adsorption experiment was carried out on the  $\text{P@CNFs@Fe}_3\text{C}$  composites to investigate the adsorption performance of Lithium Polysulfides (LiPSs), as shown in Fig. 3. As observed from the optical photograph in Fig. 3a, it is noticed that different  $\text{P@CNFs@Fe}_3\text{C}$  composites exhibit varying degrees of color fading after standing for 30 min. Among the 4 different composites, the  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  shows the most obvious adsorption effect, suggesting its best adsorption performance on LiPSs. Moreover, the UV-visible spectra of the LiPS solutions after adsorption are also collected, as shown in Fig. 3b. It is easy to find that the  $\text{Li}_2\text{S}_6$  solution containing  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  composites exhibit the lowest adsorption peak among all the electrodes, demonstrating their best adsorption capacity. To further investigate the chemical interaction among PEDOT,  $\text{Fe}_3\text{C}$  and LiPSs, the XPS is employed to investigate the surface chemical states of the samples before and after  $\text{Li}_2\text{S}_6$  adsorption. Fig. 3c shows the S 2p core level spectra of  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  before adsorption. It is found that the experimental data can be fitted to 4 independent peaks, in which the binding energies at 164.3 eV and 165.6 eV belong to S 2p<sub>1/2</sub> spin splitting peaks, while the binding energies at 164.8 eV and 163.3 eV belong to those of S 2p<sub>3/2</sub>. After adsorption, the peaks representing sulfate and thiosulfate appear at 170.5 eV and 169.3 eV, respectively, which may be due to the partial oxidation of LiPSs. In addition, the relative peak intensities of S

**Fig. 3** Visible adsorption experimental results (a) and corresponding UV-visible spectra (b) of different electrodes suggest the best LiPSs adsorption performance of  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  composites. The XPS S 2p core level spectra before (c) and after adsorption (e) show an obvious peak shift toward a high binding energy direction and the appearance of the characterization peaks representing sulfate and thio-sulfate, suggesting the strong interaction between PEDOT and LiPSs. The XPS Fe 2p core level spectra before (d) and after adsorption (f) also reveal the peak shift toward a high energy direction together with a decrease in peak intensity, demonstrating the chemical interaction between  $\text{Fe}_3\text{C}$  and LiPSs.

2p<sub>1/2</sub> and S 2p<sub>3/2</sub> decrease significantly with the binding energy shifted toward a higher energy direction at the same time, as shown in Fig. 3e. Owing to the presence of sulfur in PEDOT, this binding energy shift indicates a strong chemical interaction between PEDOT and polysulfide ions, demonstrating its excellent anchoring effect on LiPSs. Fig. 3d shows the Fe 2p core energy level spectra before the adsorption process, in which 6 characteristic peaks can be observed, including two satellite peaks (730.5 eV and 717.3 eV), two characteristic peaks representing  $\text{Fe}^{3+}$  (726.4 eV and 712.8 eV) and two characteristic peaks representing  $\text{Fe}^{2+}$  (724.3 eV and 710.8 eV). After adsorption, the peak intensities of the 6 characteristic peaks also weakened, together with a binding energy shift toward a higher energy direction, as shown in Fig. 3f. This further proves the enhancement of Fe–S bonding, which originated from the chemical interaction between  $\text{Fe}_3\text{C}$  and LiPSs.

By assembling  $\text{Li}_2\text{S}_6$  symmetrical cells using  $\text{CNFs@Fe}_3\text{C}$  and different  $\text{P@CNFs@Fe}_3\text{C}$  composites for both cathode and

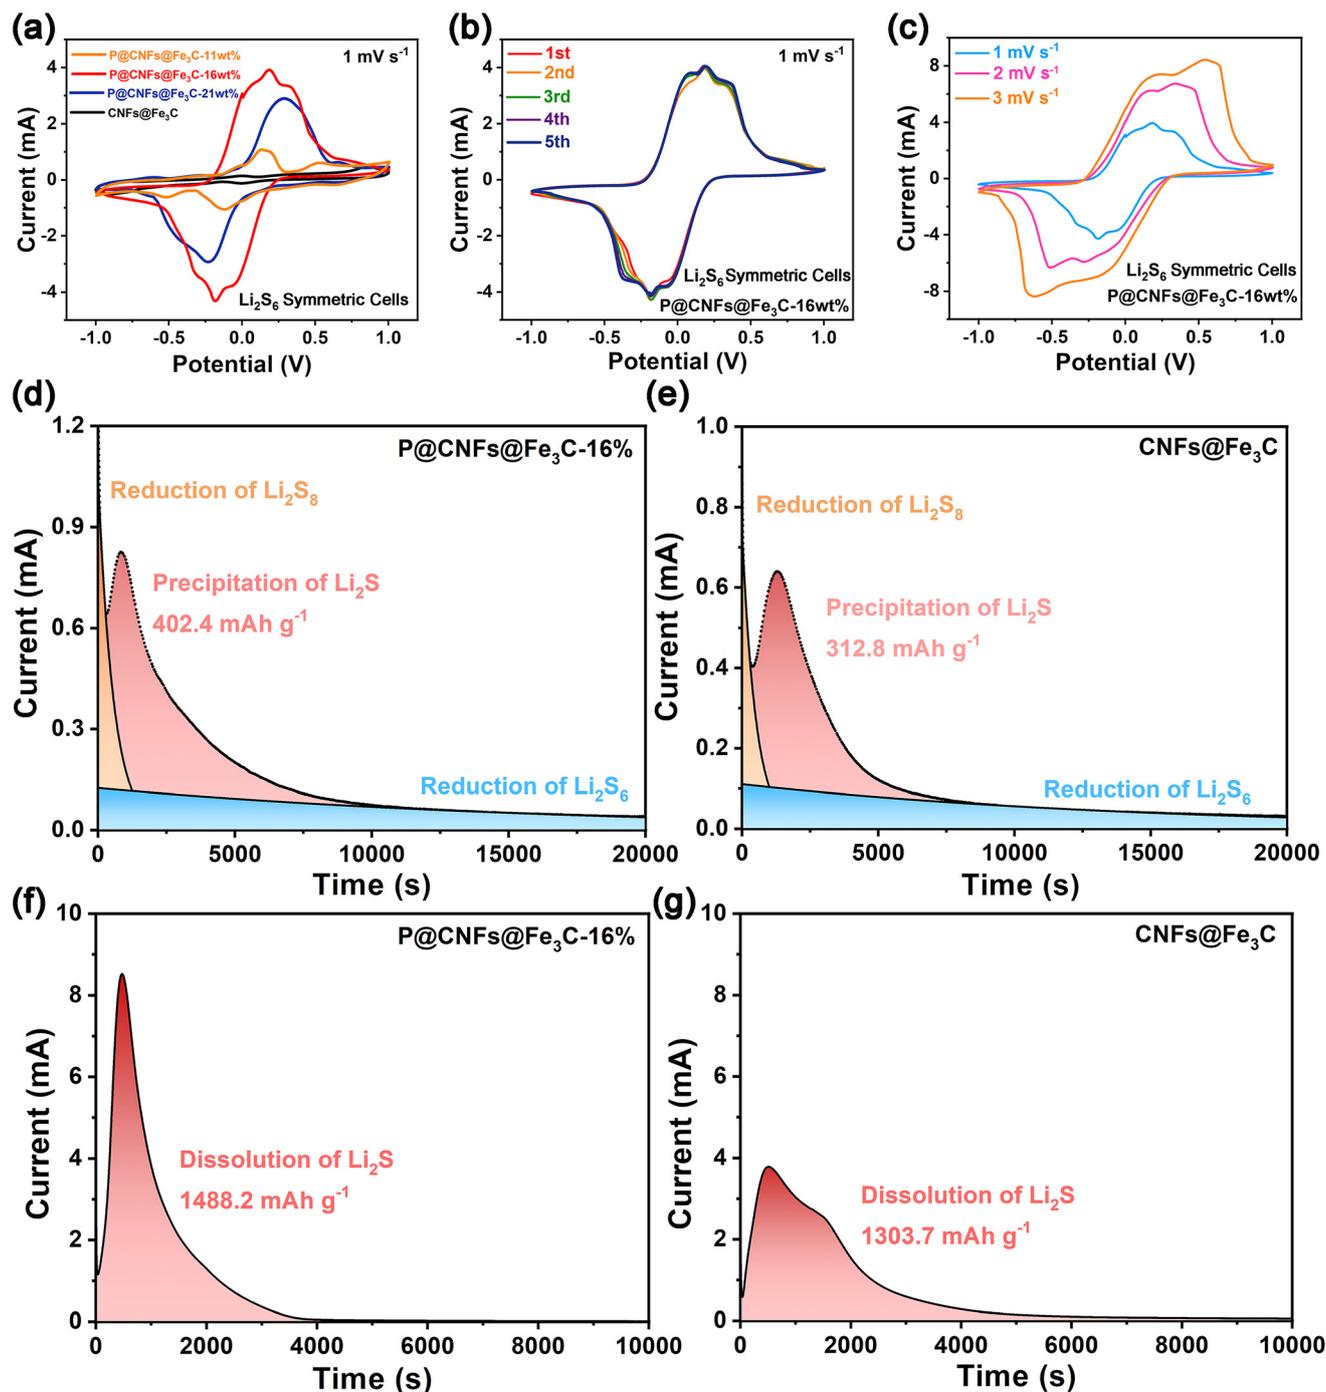

Fig. 4 CV curves of the  $\text{Li}_2\text{S}_6$  symmetric cells of different electrodes (a) exhibit the best electrochemical activity of the  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  electrode. The first 5 cycles of the CV curves of  $\text{Li}_2\text{S}_6$  symmetric cells under a scan rate of  $1 \text{ mV s}^{-1}$  (b) suggest the excellent cyclic stability of the  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  electrode. CV curves collected under different scan rates (c) also reveal the superior catalytic stability of the  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  electrode. The potentiostatic  $i-t$  curves (d–g) of the two electrodes further demonstrate the largest  $\text{Li}_2\text{S}$  nucleation and dissolution capacity of the  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  electrode.

anode, the LiPS catalytic performance can be evaluated through CV test, as shown in Fig. 4a–c. As depicted in Fig. 4a, it is noticed that all the 3 different  $\text{P@CNFs@Fe}_3\text{C}$  composites exhibit significant oxidation–reduction peaks within the selected voltage range except  $\text{CNFs@Fe}_3\text{C}$  composites, further suggesting the obvious

LiPS catalytic performance of the PEDOT coating layer. Among them, the  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  electrode exhibits the maximum response current and peak area, indicating the best catalytic activity. From the CV curves of the first 5 cycles of  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  electrode under a scan rate of  $1 \text{ mV s}^{-1}$ , it

is found that there is no significant change in the oxidation–reduction peak during cycling, demonstrating its optimized electrochemical stability, as shown in Fig. 4b. By changing the scan rates from  $1 \text{ mV s}^{-1}$  to  $3 \text{ mV s}^{-1}$ , the oxidation–reduction peaks can always be observed, further proving its excellent catalytic stability on LiPSs, as shown in Fig. 4c.

The  $\text{Li}_2\text{S}$  precipitation and dissolution experiments are carried out to further evaluate the catalytic effect of different electrodes on the solid–liquid and liquid–solid conversion processes of LiPSs, as shown in Fig. 4d–g. For the precipitation experiment, it is found that the  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  composites exhibit a higher precipitation peak current and larger  $\text{Li}_2\text{S}$  nucleation capacity ( $402.4 \text{ mA h g}^{-1}$ ) when compared with those of  $\text{CNFs@Fe}_3\text{C}$  composites ( $312.8 \text{ mA h g}^{-1}$ ). Moreover, the  $\text{Li}_2\text{S}$  nucleation time is shorter for  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  (850 s) than that of  $\text{CNFs@Fe}_3\text{C}$  electrode (1300 s), further demonstrating the catalytic activity of the PEDOT coating on the conversion from LiPSs to  $\text{Li}_2\text{S}$ . Furthermore, the  $\text{Li}_2\text{S}$  dissolution experiment results confirm the short dissolution time

(470 s) and larger dissolution amount ( $1488.2 \text{ mA h g}^{-1}$ ) of  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  electrode, as shown in Fig. 4f and g.

### 3.4 Electrochemical performance evaluation on $\text{P@CNFs@Fe}_3\text{C/Li}_2\text{S}$ composite cathode

After the loading of  $\text{Li}_2\text{S}$  onto the surface of different  $\text{P@CNFs@Fe}_3\text{C}$  composites, the coin cells are further assembled to evaluate the electrochemical performance of different composite cathodes, as shown in Fig. 5. Fig. 5a shows the CV curves of the battery assembled with 4 different composite cathodes at a scan rate of  $0.1 \text{ mV s}^{-1}$ . It should be mentioned that  $\text{Li}_2\text{S}$  can only achieve complete conversion to LiPSs when initially charged above 3.26 V.<sup>54</sup> In this case, the potential range during the CV test is selected to be 1.5–3.5 V. As observed from the figure, it is found that  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  electrode exhibits 3 reduction peaks located at 2.49 V, 2.28 V, and 1.97 V, corresponding to the reduction process from  $\text{S}_8$  to long chain LiPSs and the following reduction to  $\text{Li}_2\text{S}_2/\text{Li}_2\text{S}$ .<sup>55</sup> In addition, one obvious oxi-

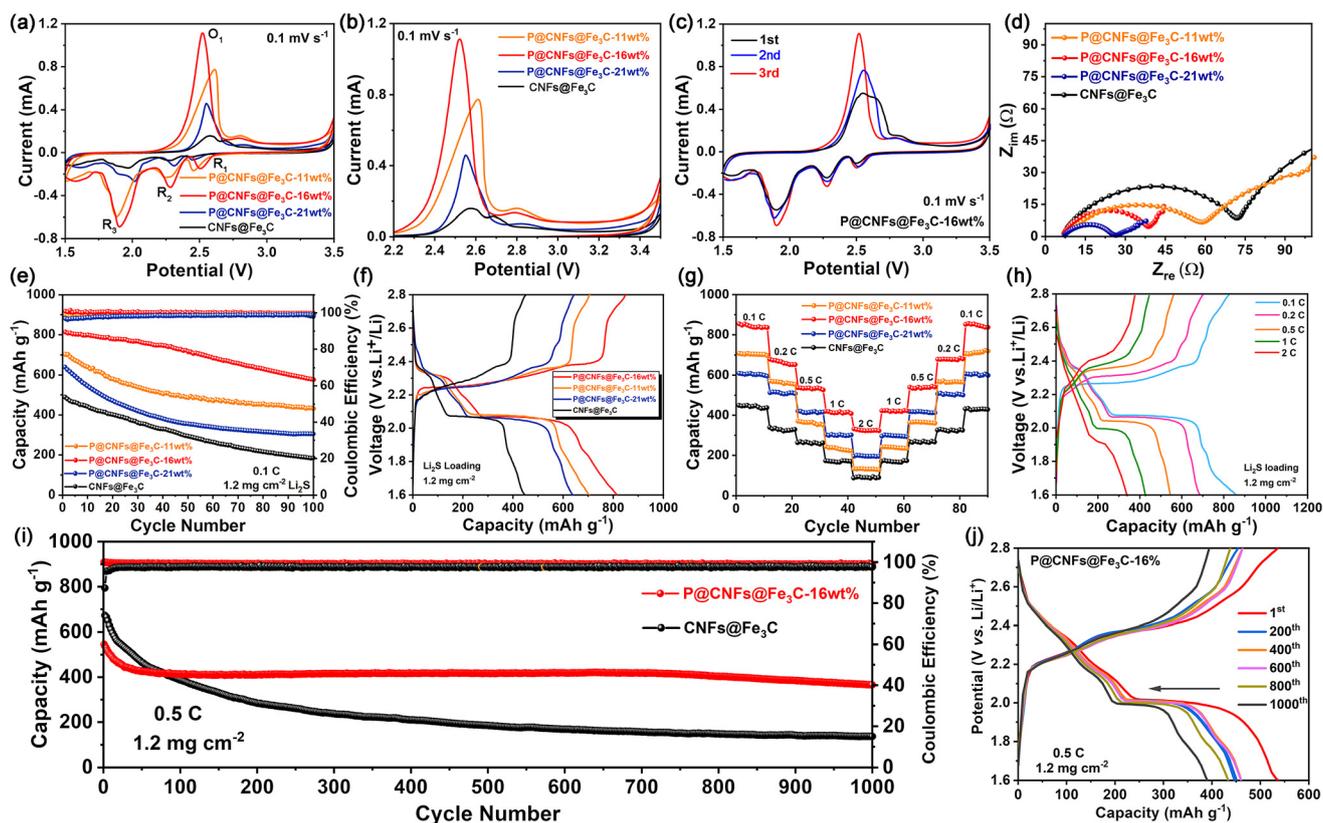

Fig. 5 CV curves of  $\text{CNFs@Fe}_3\text{C/Li}_2\text{S}$  and  $\text{P@CNFs@Fe}_3\text{C/Li}_2\text{S}$  composite cathodes with different PEDOT coating amounts (a) suggest the highest peak current and smallest electrochemical polarization of the  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode. The enlarged CV curves (b) and the first 3 cycles of the CV curves (c) further illustrate excellent redox activity and cyclic stability of the  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode. The EIS curves (d) suggest a positive correlation relationship between PEDOT coating thickness and electronic conductivity and ion diffusion resistance. Cyclic performance curves (e) together with corresponding galvanostatic charge–discharge curves (f) under 0.1 C demonstrate the best cyclic performance of the  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode. The rate performance (g) and corresponding galvanostatic charge–discharge curves under different current densities (h) also prove the best rate performance of the  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode. The long cyclic performance under 0.5 C for 1000 cycles (i) exhibits a 0.033% capacity decay per cycle for the  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode. The discharge plateaus (j) can always be observed clearly during the whole cycling process.

dition peak can be found at around 2.51 V, which corresponds to the reverse conversion from  $\text{Li}_2\text{S}_2/\text{Li}_2\text{S}$  to  $\text{LiPSs}$  and  $\text{S}_8$ . Moreover, the distance between the oxidation and reduction peaks is the smallest for  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  composite cathode, suggesting its excellent redox activity and minimal electrochemical polarization. From the enlarged CV curves illustrating the oxidation peaks in Fig. 5b, the above mentioned largest peak intensity and smallest oxidation potential can also be proved. The first 3 cycles of the CV curves for  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  composite cathode (Fig. 5c) suggest a gradually increasing peak intensity, which corresponds to the increased charge and discharge capacity. Electrochemical Impedance Spectroscopy (EIS) is further employed to investigate the reaction kinetics and interface characteristics of the cells, as shown in Fig. 5d. It is noticed that the charge transfer resistance in the high-frequency region of different cathodes is significantly reduced as the PEDOT coating amount increases, which proves the gradually enhanced electrical conductivity. In contrast, the slope of the straight line in the low-frequency region gradually decreases with the increase in PEDOT polymerization amount, which demonstrates that a thicker PEDOT layer may increase the resistance of  $\text{Li}^+$  ion transport.

The cyclic performance of the cells using  $\text{CNFs@Fe}_3\text{C/Li}_2\text{S}$  and  $\text{P@CNFs@Fe}_3\text{C/Li}_2\text{S}$  composite cathodes with different PEDOT coating amounts is displayed in Fig. 5e. The initial discharge capacities of the  $\text{CNFs@Fe}_3\text{C/Li}_2\text{S}$ ,  $\text{P@CNFs@Fe}_3\text{C-11wt\%/Li}_2\text{S}$ ,  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  and  $\text{P@CNFs@Fe}_3\text{C-21wt\%/Li}_2\text{S}$  composite cathodes are confirmed to be  $489 \text{ mA h g}^{-1}$ ,  $639 \text{ mA h g}^{-1}$ ,  $816 \text{ mA h g}^{-1}$  and  $705 \text{ mA h g}^{-1}$ , respectively. From the corresponding galvanostatic charge–discharge curves shown in Fig. 5f, it is found that the  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  composite cathode exhibits the smallest electrochemical polarization, which is consistent with the CV results. After 100 cycles, the capacity retention of the above 4 composite cathodes can be calculated to be 38%, 48%, 71% and 62%, respectively, further demonstrating the best cyclic stability of  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode. The rate performance of the 4 composite cathodes is also evaluated in Fig. 5g. The optimized  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  composite cathode can achieve the initial discharge capacity of  $860 \text{ mA h g}^{-1}$ ,  $685 \text{ mA h g}^{-1}$ ,  $543 \text{ mA h g}^{-1}$ ,  $426 \text{ mA h g}^{-1}$  and  $338 \text{ mA h g}^{-1}$  under the current densities of 0.1 C, 0.2 C, 0.5 C, 1 C and 2 C, respectively, which are highest among all the 4 composite cathodes. The corresponding galvanostatic charge–discharge curves in Fig. 5h exhibit the clearly visible discharge plateaus with the increase of discharge rates. When the current density returns to 0.1 C, the discharge capacity can also recover to  $857 \text{ mA h g}^{-1}$ , demonstrating the excellent rate performance of  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  composite cathode. Fig. 5i illustrates the long cyclic performance of  $\text{CNFs@Fe}_3\text{C/Li}_2\text{S}$  and  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  composite cathode. Under the current density of 0.5 C, the initial capacity of the cells with  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode can reach up to  $546 \text{ mA h g}^{-1}$ . After 1000 cycles, it can still remain at  $366 \text{ mA h g}^{-1}$  reversible capacity, corresponding to a capacity decay of

0.033% per cycle. The corresponding GCD curves at different cycles show clear discharge platforms, further proving the excellent cyclic stability of  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode, as shown in Fig. 5j. The surface morphology of the  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode after 1000 cycles has further been characterized by SEM, as shown in Fig. S3.† No obvious cracks or detachment of materials can be observed, illustrating the excellent structural stability of the cathode. Furthermore, the  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode is confirmed to display an areal capacity of  $1.62 \text{ mA h cm}^{-2}$  with a  $\text{Li}_2\text{S}$  loading amount of  $3.6 \text{ mg cm}^{-2}$  and an  $\text{E/Li}_2\text{S}$  ratio of  $8.3 \mu\text{L mg}^{-1}$  under a current density of 0.2 C, demonstrating the application potential under high  $\text{Li}_2\text{S}$  loading amount conditions, as shown in Fig. S4.† All the above results indicate that  $\text{P@CNFs@Fe}_3\text{C/Li}_2\text{S}$  cathode possesses both high electrical conductivity and  $\text{LiPSs}$  catalytic activity, which can effectively improve the specific capacity and cycling stability of  $\text{Li-S}$  batteries. Table S1† compares the electrochemical performance of the recently reported  $\text{Li}_2\text{S}$ -based cathodes in  $\text{Li-S}$  batteries.

## 4. Conclusions

PEDOT is successfully polymerized onto the surface of  $\text{CNFs@Fe}_3\text{C}$  composite nanofibers prepared by electrospinning combined with carbothermal reduction reaction. The polymerization amount can be precisely adjusted by changing the added amount of EDOT monomer. Through careful structural characterization, the optimized PEDOT polymerization parameters are confirmed to be  $20 \mu\text{L}$  EDOT monomer and polymerized at  $100 \text{ }^\circ\text{C}$  for 30 min. The obtained  $\text{P@CNFs@Fe}_3\text{C-16wt\%}$  composites exhibit uniform morphology and superior adsorption and catalytic performance on  $\text{LiPSs}$ . Using different  $\text{P@CNFs@Fe}_3\text{C}$  composites to load  $\text{Li}_2\text{S}$  as the cathodes to assemble  $\text{Li-S}$  batteries, it is found that the  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode possesses the highest initial specific capacity of  $816 \text{ mA h g}^{-1}$  at the current density of 0.1 C, and a capacity decay rate per cycle of 0.033% after 1000 cycles at 0.5 C. With  $\text{Li}_2\text{S}$  loading amount of  $3.6 \text{ mg cm}^{-2}$  and  $\text{E/Li}_2\text{S}$  ratio of  $8.3 \mu\text{L mg}^{-1}$  under the current density of 0.2 C, an areal capacity of  $1.62 \text{ mA h cm}^{-2}$  can also be achieved for the  $\text{P@CNFs@Fe}_3\text{C-16wt\%/Li}_2\text{S}$  cathode.
