Reactive deposition of Pt single-atoms on g-C₃N₄: effect of Pt-precursors

Nawres Lazaar,^{a,b} Shanshan Qin,^a Abdessalem Hamrouni,^{b,e} Hinda Lachheb,^b Jan Kolařík,^c Xuemei Zhou^d and Patrik Schmuki^{a,c}

Anchoring Pt single atoms (SAs) as co-catalysts on g-C₃N₄ has emerged as a promising approach to enhance the hydrogen production performance of this photocatalytic system. Particularly, by so-called reactive deposition, a maximum hydrogen evolution reaction performance can be achieved using a minimum amount of Pt loading. In this study, we explore the effects of different platinum (Pt) precursors on the reactive deposition of SAs onto g-C₃N₄, aiming to optimize the performance in photocatalytic hydrogen production. By examining a variety of Pt precursor types, we highlight critical parameters influencing deposition, including precursor charge, solution pH, ionic strength, and ligand properties. Our results reveal that precursors bearing anionic charges are distinctly more effective than cationic precursors for depositing highly active Pt SAs. Crucially, we find that the surface deposition reaction strongly depends on the ligand involved, with chloride-based complexes enabling more efficient Pt attachment compared to bromide-based complexes. Notably, variations in the oxidation state of platinum (Pt⁴⁺ versus Pt²⁺) did not significantly influence deposition outcomes. Among all precursors studied, (NH₄)₂[PtCl₆] achieved the highest catalytic activity, with optimal Pt loading (~0.026 wt%) and superior hydrogen evolution rates surpassing the widely utilized H₂[PtCl₆] precursor. Furthermore, adjustments to solution conditions, such as significant pH changes due to increased ionic strength, were found to negatively impact deposition and catalytic effectiveness. These insights underscore the

importance of precursor selection and solution chemistry control, providing a robust basis for the development of efficient and cost-effective single-atom photocatalysts formed by adsorption–reaction treatments.

1. Introduction

Photocatalytic H₂ generation from aqueous media, employing semiconductor materials has garnered considerable research interest as a promising strategy for sustainable green fuel generation.^{1–5} In recent years, graphitic carbon nitride (g-C₃N₄) has emerged as a highly attractive semiconductor, offering a suitable band structure for visible light water splitting as well as an excellent stability, and high structural flexibility for modification.^{6–9} However, for single-phase g-C₃N₄, the actual hydrogen production efficiency often falls short of expectations, primarily due to the fast recombination of charge carriers and slow reaction kinetics at the semiconductor-solution interface, even if hole transfer is aided by the use of sacrificial agents.^{10–13}

To overcome these limitations, the integration of suitable charge-transfer co-catalysts has been extensively explored. Platinum (Pt), in particular, has been widely identified as excellent co-catalyst for photocatalytic H₂ generation, when decorated or incorporated as nanoparticles, nanoclusters, or single atoms (SAs) on g-C₃N₄ surfaces.^{14–18}

In order to minimize cost, minimizing the catalysts size, and thus particularly Pt in the form of SAs, has recently attracted wide attention. Various synthesis approaches for Pt SAs have been reported, including wet immersion techniques, as well as gas-phase physical and chemical approaches.^{19–23} However, not all approaches deliver highly active SAs, *i.e.* depending on the synthesis approach, considerable amount of less active and hence wasted Pt is deposited.^{24–27} Or the method require a complicated high temperature reduction step in a hydrogen atmosphere.²⁸ Recently, a most effective

reactive deposition approach was reported that delivers at very low amounts (<0.1 at%) highly active Pt SAs – these SAs were deposited by direct reaction of highly dilute chloroplatinic acid solutions ($\text{H}_2[\text{PtCl}_6]$) with $\text{g-C}_3\text{N}_4$.²⁹

Notably, the H_2 production rate of the low-loaded Pt SAs surpasses the activity of Pt SAs deposited using other techniques at a comparable or even higher loading.^{18,30,31} Or *vice versa*, some other studies achieve comparable activity levels, but they typically require more than ten times the Pt SA loading.^{18,29–32}

In reactive deposition approach, the reaction to anchored Pt SA consists of a sequence of (i) precursor hydrolysis, (ii) complex-adsorption, and finally (iii) a reaction with functional features on the surface of substrate. The adsorption of any Pt precursor is strongly affected by the speciation of the precursor in the solution. According to the “strong-electrostatic-adsorption” model,^{29,33,34} adsorption of a charged complex is mainly determined by the effective charge of the adsorbate species (the charge on the Pt-complex) and the charge of the surface (protonated or deprotonated surface hydroxyls). Both factors are primarily affected by the solution pH, but also by the ionic strength of the solution (shielding of surface charges), and by possible competitive adsorption. In practical terms, for adsorption of a Pt precursor, one either may select an anionic species (e.g., PtCl_6^{2-} at low pH ($\text{pH} < \text{PZC}$)), where the oxide surface is protonated and positively charged, or cationic species [e.g. $(\text{NH}_3)_4\text{Pt}^{2+}$, at high pH ($\text{pH} > \text{PZC}$)] where the surface is deprotonated and thus negatively charged.²⁴ Nevertheless, the situation is often much more complex, as the pH and background ions in solution also affect the hydrolysis of precursors and thus the speciation (and charge) of the adsorbing complex – for example Pt–Cl complexes can form positive, negative and neutral complexes in solution³⁵ that may be fully hydrolyzed by H_2O and OH^- . Moreover, the strength of adsorption forces can strongly be attenuated by the presence of background ions.

In a true direct reactive anchoring of Pt SAs, surface reaction step follows adsorption where ligand exchange but often also redox steps take place (as widely reported for $\text{H}_2[\text{PtCl}_6]$).^{24,27,36} The Pt SAs are primarily stabilized through coordination with N4 sites on $\text{g-C}_3\text{N}_4$, which ensures both high dispersion and stability of the Pt SAs under photocatalytic conditions.^{29,32,37–39}

Considering the broad range of factors that affect reactive adsorption, it is surprising that comparative investigations, namely on various Pt complex compounds, have hardly been carried out.^{40,41}

Therefore, in the present work we examine various Pt precursors to assess their suitability for creating active single atom species on $\text{g-C}_3\text{N}_4$. We select Pt precursors that differ in their chemical properties, such as oxidation state, Pt-coordination environment, and hydrolysis properties, and explore their feasibility to attach Pt SAs on $\text{g-C}_3\text{N}_4$. We then tried to understand the mechanism behind and evaluate loading and resulting reactivity in view of photocatalytic hydrogen production.

We first establish as a bench-mark, the conventionally used platinum acid $\text{H}_2[\text{PtCl}_6]$ – then we explore $(\text{NH}_4)_2[\text{PtCl}_6]$,

$(\text{NH}_4)_2[\text{PtCl}_4]$, $\text{K}_2[\text{PtCl}_6]$, $\text{K}_2[\text{Pt}(\text{CN})_6]$, $\text{H}_2[\text{PtBr}_6]$, $\text{K}_2[\text{PtCl}_4]$, $\text{K}_2[\text{Pt}(\text{CN})_4]$, $[\text{Pt}(\text{NH}_3)_4]\text{Cl}_2$. We find that $\text{H}_2[\text{PtCl}_6]$, $(\text{NH}_4)_2[\text{PtCl}_6]$ and $(\text{NH}_4)_2[\text{PtCl}_4]$ are suitable for loading a significant amount of highly dispersed Pt SAs, all with a high hydrogen production efficiency. Optimized loading is observed from $(\text{NH}_4)_2[\text{PtCl}_6]$ solution (most effective at 2 mM) – without any solution adjustments. Best conditions for hydrogen evolution exhibit minimal ionic strength in solution, using Pt–chloro complexes (where the chloro-ligands react off during attachment). Redox processes during attachment of $\text{g-C}_3\text{N}_4$ are not key. Noteworthy is also that using cationic complex loading with $[\text{Pt}(\text{NH}_3)_4]\text{Cl}_2$ did not lead to satisfactory results for photocatalytic hydrogen evolution.

2. Results and discussion

We use for our investigations C_3N_4 synthesized by a well-established literature procedure from an equimolar mixture of melamine and dicyandiamide. Then the C_3N_4 powder is delaminated at 500 °C in air for 2 hours.^{42–44} After this treatment C_3N_4 presents a sheet-like structure with a layer thickness of ~18 nm, well in line with literature,^{8,29,45} and as evident from the scanning electron microscopy (SEM) image in Fig. 1a. These delaminated layers ($\text{g-C}_3\text{N}_4$) were then used as substrates and decorated with Pt-cocatalyst as SAs using an approach described in literature as “reactive deposition” (Pt SAs/ $\text{g-C}_3\text{N}_4$), and as described in more detail in the SI.^{26,27,46–48}

In a first set of experiments, we establish as a bench-mark, immersion of $\text{g-C}_3\text{N}_4$ in 2 mM $\text{H}_2[\text{PtCl}_6]$ for 1 h (details see also SI). Fig. 1b displays a high-resolution SEM image of the $\text{g-C}_3\text{N}_4$ after Pt deposition as SAs. The SEM image of Pt SAs/ $\text{g-C}_3\text{N}_4$ reveals no distinct particles, which is consistent with the deposition of non-aggregated single atoms, as the size is below the resolution limit of the SEM. Fig. 1c shows a high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) image taken for Pt SAs/ $\text{g-C}_3\text{N}_4$, which reveals that the thin $\text{g-C}_3\text{N}_4$ layer is decorated with single atoms of Pt at a density of $8.8 \times 10^5 \mu\text{m}^{-2}$ (this value is determined by direct counting of individual Pt atoms within a defined area in a series of HAADF-TEM images, please see Fig. S1).

For reference, also samples with Pt nanoparticles (nominal loading of 3 wt%) on $\text{g-C}_3\text{N}_4$ were prepared (details in Experimental section). The SEM image in Fig. 1d shows nanoparticles that are clearly visible and the corresponding size distribution shows a relatively narrow range, with most particles centered around an average size of approximately 7 nm (see Fig. S2). This sample is annotated as Pt NPs/ $\text{g-C}_3\text{N}_4$ in the following sections.

X-ray photoelectron spectroscopy (XPS) of the Pt SA/ $\text{g-C}_3\text{N}_4$ sample shows in the Pt 4f region (Fig. 1e) a clear Pt doublet peak at a position of Pt 4f_{7/2} at 72.6 eV and Pt 4f_{5/2} at 76.0 eV, which is typical for Pt SA coordinated on the $\text{g-C}_3\text{N}_4$ surface^{29,49}—the peak position corresponds to a formal charge

Fig. 1 (a) SEM image of pure g-C₃N₄; (b) SEM image of Pt SAs supported on g-C₃N₄; (c) HAADF-STEM image of Pt SAs/g-C₃N₄; (d) SEM image of Pt NPs on g-C₃N₄; (e) XPS spectrum of Pt SAs/g-C₃N₄; (f) XPS spectrum of Pt NPs/g-C₃N₄; (g) photocatalytic H₂ evolution performance of Pt SAs/g-C₃N₄, Pt NPs/g-C₃N₄ (prepared using H₂[PtCl₆] as the Pt precursor), and pure g-C₃N₄.

of Pt^{δ+} with $\delta^+ \approx 2$. The observed oxidation state aligns with the anchoring of Pt SAs at nitrogen sites within g-C₃N₄, consistent with findings reported in previous studies.^{32,37–39} This

configuration is widely regarded as the catalytically active SA state responsible for facilitating the H₂ evolution reaction.^{50,51} In contrast, the XPS analysis of Pt NPs/g-C₃N₄ (Fig. 1f) shows Pt 4f_{7/2} at 70.6 eV and Pt 4f_{5/2} at 73.9 eV, which corresponds to metallic Pt⁰ (well in line with literature⁵²). From above considerations one can see that SEM (no detectable Pt nanoparticles) in combination with XPS (characteristic binding energy of Pt SAs) allows to indirectly confirm the presence of Pt single atoms on the g-C₃N₄ surfaces (this we used to screen deposits from different precursors as discussed further down). One may note that Cl ions are not detected from XPS Cl 2p spectra (Fig. S3c), which indicates that the Cl reacted off during dark deposition.

Then the photocatalytic H₂ generation activity of Pt SAs/g-C₃N₄, Pt NPs/g-C₃N₄, and neat g-C₃N₄ samples is evaluated in an electrolyte with a 10 vol% triethanolamine sacrificial agent in water (Fig. 1g), using a 365 nm LED light source (65 mW cm⁻²). The H₂ evolution, for all samples, occurs linearly over the measured time, and the rates were thus determined from the slopes of the curves. Evidently, Pt SAs/g-C₃N₄ exhibits a 2.3 times higher H₂ evolution rate compared to the Pt NPs/g-C₃N₄ sample, which both provide a significantly higher activity than the neat g-C₃N₄. When the activity was normalized by Pt loading, the Pt SAs/g-C₃N₄ showed an H₂ evolution rate of 1.7 mmol h⁻¹ (mg Pt)⁻¹, that is 10 times higher than the activity of Pt NPs/g-C₃N₄ (0.18 mmol h⁻¹ (mg Pt)⁻¹). Notably, in our previous study, XPS and SEM analyses confirmed that Pt remains atomically dispersed (δ^+ state) on g-C₃N₄ after photocatalytic H₂ evolution, with no observable metallic Pt NP formation.²⁹

Against this H₂[PtCl₆] benchmark,²⁹ we tested a range of Pt-precursors as given in Table 1. Every Pt-salt was used at 2 mM aqueous solution, and immersion of g-C₃N₄ sample was done equal to the H₂[PtCl₆] experiment. XPS and AAS were carried out to determine Pt loading and the results are given in Table 1, as well as the pH and the conductivity of the 2 mM salt solutions. For all samples after Pt loading and cleaning, the photocatalytic H₂ production activity was determined (Fig. 2). From XPS data in Table 1, Fig. S3 and S4 it is clear that only H₂[PtCl₆], (NH₄)₂[PtCl₆] and (NH₄)₂[PtCl₄] lead to a considerable Pt loading while the other salts lead to no Pt loading or a Pt loading below the detection limit of XPS. In accord with these findings, for H₂[PtCl₆] and (NH₄)₂[PtCl₆] a

considerably high H₂ evolution activity could be observed (Fig. 2). For all active samples, the XPS Pt peak shows the typical SA signature at 72.6 eV (Fig. S3a and b) (and no nanoparticles can be seen in SEM as shown in Fig. S5). XPS fitting and peak deconvolution shows an amount of $\approx 100\%$ SA contribution and no detectable contribution of Pt⁰.

Noteworthy is also that for all Pt⁴⁺ precursors the attached species is Pt^{δ+} with $\delta \approx 2$, *i.e.* a reduced species is formed and attached. In most of the cases, no ligand species (*e.g.*, Cl[−]) can be found, *i.e.*, in the attachment process these ligands are exchanged against nitrogen, either in the solution hydrolysis or in the surface attachment process.

From the comparison of the precursors, some important conclusions can be drawn. Namely, (i) that the exit group Cl[−] or Br[−] plays a very important role in the attachment of the Pt SA on the surface. H₂[PtCl₆] and H₂[PtBr₆] have a similar pH in the solution and provide a similar conductivity, *i.e.* the surface charge on the g-C₃N₄ and ionic strength of the solution are similar – nevertheless, the Br[−] complex is hardly reacting with the surface (likely due to the more stable nature of the Pt–Br bond).⁵³ (ii) The redox process in the attachment reaction Pt⁴⁺ → Pt²⁺ is not a key factor in the attachment of SAs – this is evident from a similar loading and reactivity of using (NH₄)₂[PtCl₆] and (NH₄)₂[PtCl₄] onto g-C₃N₄, where Pt⁴⁺ and Pt²⁺ precursors are loaded as active (chloride-free) SAs. This suggests that for the Pt⁴⁺ precursor, reduction even may take place (*e.g.* by a red-ox process in the solution as has been suggested in literature³⁵) prior to the final surface attachment reaction.

The fact that many precursors do not show adsorption/reaction can be explained by comparing their solution pH (Table 1) with the PZC of g-C₃N₄. In literature^{54,55} and by the data in Fig. S6 one can determine a value of ≈ 3.5 – 4.5 for the g-C₃N₄ used in this study. This means that a significant adsorption (according to the SEA model) only occurs for anionic species at acidic pH below 4.0 (pH = 2.3 for H₂[PtCl₆], and pH = 2.8 for (NH₄)₂[PtCl₆]).

It is also interesting to note for (NH₄)₂[PtCl₄] that the pH of the solution is above 5.0 (pH = 5.4). The negatively charged surface indeed leads to adsorption/reaction with Pt²⁺, suggesting that the hydrolysis species of the precursor in the solution may matter, *i.e.*, the hydrolysis reaction may provide uncharged or even mildly positively charged species.^{35,56,57}

It is thus worthy to study the reverse adsorption, *i.e.* using a Pt-cation at elevated pH and compare the results to anionic loading. Thus, we tested [Pt(NH₃)₄]Cl₂ at various pH values where a positively charged [Pt(NH₃)₄]²⁺ is the adsorptive species present in the solution. Table 2 shows that for pH ≤ 9.0, no Pt species is detected by XPS and AAS, however with the increase of pH from 10.9 to 12.0, the loading of Pt increases, suggesting that the classic SEA is operative. Nevertheless, the amount of deposited Pt is low (at the detection limit of XPS) for every investigated pH. Also, the results from H₂ evolution (in 3 h) show that the hydrogen evolution activity is positively related to the loading of Pt (see Fig. 3 and Table 2) but due to the overall low loading of Pt, such photocatalyst is clearly less effective than the Pt deposited from anionic precursors under acidic conditions.

Moreover, if we inspect the data in Fig. 2 in detail, we find the highest activity (and the highest specific activity) for SAs deposited from (NH₄)₂[PtCl₆] (Fig. 4a). We evaluated the superior H₂ production efficiency over (NH₄)₂[PtCl₆] for a wide

Fig. 3 Photocatalytic H₂ evolution performance of g-C₃N₄-supported Pt SAs synthesized from 2 mM [Pt(NH₃)₄]Cl₂ with pH adjustment.

Fig. 4 (a) Normalized photocatalytic H₂ evolution performance of Pt SAs/g-C₃N₄ synthesized using different Pt precursors. (b) Photocatalytic activity as a function of precursor concentration for Pt SAs/g-C₃N₄ prepared using (NH₄)₂[PtCl₆] or H₂[PtCl₆]. (c) Bar diagram of H₂ evolution rates for Pt SAs/g-C₃N₄ synthesized with using (NH₄)₂[PtCl₆] or H₂[PtCl₆] at pH = 2, in comparison to Pt SAs/g-C₃N₄ synthesized with corresponding unmodified precursor solution.

concentration range (loading of samples given in Table S1), as illustrated in Fig. 4b. The highest hydrogen evolution rate is reached when the solution concentration is at 2 mM, further increase in the concentration of precursor (to 10 mM) does not lead to the increase of activity anymore.

Based on above considerations one may consider pH-adjustments to further improve the adsorption step. Therefore, we adjusted a 2 mM H₂[PtCl₆] solution and a (NH₄)₂[PtCl₆] solution to the same pH value of 2.0 using either HClO₄ (as “inert” acid) or HCl (affects the hydrolysis equilibrium also *via* Cl[−]). Evidently, both acids are detrimental for the loading of Pt and thus the hydrogen evolution activity (Table 3 and Fig. 4c), compared to the samples prepared without pH adjustment. The loading of Pt is half of the amount for H₂[PtCl₆] solution (0.0369 wt%) prepared using HCl (0.0148 wt%) or HClO₄ (0.0158 wt%) adjustment. Therefore, the adsorption behavior of anionic complexes, *e.g.* [PtCl₆]^{2−}, under acidic conditions cannot be explained solely by the SEA mechanism. The impact of pH adjustment solution is even worse for (NH₄)₂[PtCl₆] precursors – the loading of Pt decreases to 0.0056 wt% using HCl and 0.0123 wt% using HClO₄, which may be ascribed to the fact that for (NH₄)₂[PtCl₆] more HCl or HClO₄ solution is needed to adjust pH, in order to buffer the NH₄⁺ ions in the solution. Or the protonation of surface groups by acid treatment may reduce the binding of platinum complexes.

Overall, the change in pH (by both acids) leads to significantly higher ionic strength (measured as conductivity), and this high ionic strength can provide a shielding effect for the negatively charged complex to deposit on the surface.⁵⁸ Or the pH in acidic solution leads to protonation of surface thus reduce the loading of Pt complex. Therefore, based on all above investigations, the photocatalysts prepared using (NH₄)₂[PtCl₆] precursor without pH adjustment gives the best hydrogen evolution activity, due to the most beneficial attachment of SAs on the C₃N₄. This is due to an ideal hydrolysis of this precursor in view of solution pH and ionic strength in the deposition solution, which is a result of both surface SEA and reactive deposition mechanism.

3. Conclusions

In the present work, we systematically explored the “reactive deposition” approach to anchor Pt SAs on g-C₃N₄ using various Pt precursors, revealing crucial insights into the critical factors affecting deposition and conditions required for

Table 3 Summary of Pt loading, proportion of single-atom Pt, and H₂ evolution rates for Pt SAs/g-C₃N₄ synthesized with 2 mM (NH₄)₂[PtCl₆] or H₂[PtCl₆] precursors at pH = 2, alongside the conductivity of the corresponding precursor solutions

optimal photocatalytic activity. Crucially, we demonstrate that both adsorption and subsequent surface reaction steps are essential to achieve effective reactive deposition. Our study highlights that anionic precursors significantly outperform cationic counterparts in adsorption on g-C₃N₄. Optimal conditions were identified at solution pH values below the point of zero charge (PZC \approx 3.5–4.5) of g-C₃N₄, combined with minimal ionic strength to prevent electrostatic shielding effects from background ions. Even relatively inert ions such as ClO₄[−] were found to notably impede active Pt precursor adsorption.

Furthermore, the choice of the leaving ligand in the Pt precursor dramatically influences deposition efficiency, with chloride complexes (Cl[−]) significantly surpassing bromide complexes (Br[−]), due to weaker Pt–Cl bond stability facilitating ligand exchange during attachment. Interestingly, redox processes associated with Pt⁴⁺ to Pt²⁺ reduction do not critically impact the deposition efficiency, as evidenced by comparable performance between Pt⁴⁺ and Pt²⁺ chloride precursors.

Among all tested precursors, (NH₄)₂[PtCl₆] emerged as the most effective, achieving superior catalytic activity with an optimized Pt loading of approximately 0.026 wt%. This precursor delivered an H₂ evolution rate surpassing even the widely employed H₂[PtCl₆] precursor under identical conditions. Additionally, adjusting precursor solutions to higher ionic strengths or significantly altering solution pH, negatively affected deposition efficiency and catalytic activity, underscoring the importance of maintaining suitable ionic strength conditions for optimal results.

Overall, this study provides critical insights into the parameters influencing Pt single atom deposition, offering a robust guideline for the development of highly efficient photocatalysts utilizing minimal Pt loading on g-C₃N₄.
