Photoredox-catalyzed selective head-to-head reductive coupling of activated alkenes†

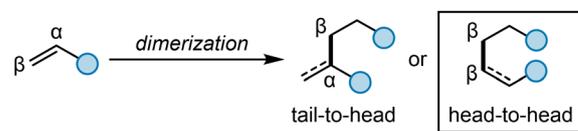

Shenhao Chen,^{‡a} Zongchang Han,^{‡b} Han-Shi Hu,^{id b} Jun Li^b and Chanjuan Xi^{id *a,c}

Head-to-head reductive hydrodimerization of activated alkenes offers access to valuable bulk or fine chemicals such as adipates or adiponitrile as an intermediate for the industrial synthesis of nylon. We herein report a novel reaction to realize head-to-head reductive coupling of activated alkenes by a photoinduced Ir/PPh₃/H₂O system, providing smooth access to various adipate derivatives in high chemo- and regioselectivity. In this reaction, a [Ph₃P-OH] radical generated from a photoinduced interaction between H₂O and PPh₃ enables the PCET process with activated alkenes to form a C-centered radical at the β-position, which is rarely reported.

Dimerization of alkenes is a significant reaction for synthesizing essential intermediates for the production of bulk or fine chemicals.¹ Among them, selective head-to-head reductive dimerization of activated alkenes such as acrylates or acrylonitrile offers access to valuable adipates or adiponitrile as an intermediate for the industrial synthesis of nylon.² Early strategies for hydrodimerization of activated alkenes critically rely on utilizing stoichiometric metals as the reductant, which generates a large amount of metal wastes and limits the substrate scope due to unsatisfactory functional group tolerance.³ Recently, transition-metal-catalyzed strategies have attracted much effort; however, the use of metal reductants is still necessary.⁴ Meanwhile, a C=C bond remains in the dimerized products (Fig. 1a). Although electrolytic hydrodimerization of acrylonitrile to adiponitrile under aqueous conditions has been developed, this process is inapplicable to the synthesis of adipic derivatives (Fig. 1b).⁵ Therefore, it is desirable to explore an environmentally friendly reduction mode for a head-to-head hydrodimerization of activated alkenes.

Recently, Studer's group developed a photocatalyzed Ir/PPh₃/H₂O system to realize hydrogenation of alkenes,⁶ where

the generated [Ph₃P-OH] radical provided a platform that mimics the reactivity of a 'free' hydrogen atom, which can be directly transferred to alkenes. The resulting H-adduct carbon radical shows the possibility to dimerize alkenes by radical coupling reaction.⁷ Herein, we report a photoinduced Ir/PPh₃/H₂O system for a head-to-head (β,β-coupling) reductive dimerization of activated alkenes. In this reaction, the [Ph₃P-OH] radical is generated, enabling the proton coupled electron

Head-to-head coupling of activated alkenes

‡ These authors contributed equally to this work.

transfer (PCET) process⁸ with activated alkenes, producing a nucleophilic β -C radical, followed by the Giese-type addition to the second molecule of activated alkenes, resulting in a reductive head-to-head coupling. Activated alkenes including acrylates, acrylamide, acrylonitrile and vinyl ketones with α or β substituents are well-tolerated in this conversion, providing approaches to various valuable adipate derivatives, adiponitrile and 1,6-diones (Fig. 1c).

We initiated the study by employing *tert*-butyl acrylate **1a** as the substrate, Ir[dF(CF₃)ppy]₂(dtbbpy)PF₆ as the photocatalyst and PPh₃ as the reductant. After irradiation under a N₂ atmosphere for 21 hours, di-*tert*-butyl adipate **2a** as the head-to-head coupling product was successfully obtained in 77% yield (Table 1, entry 1). Notably, the tail-to-head coupling (α,β -coupling) product was not observed, showing high regioselectivity of this reaction. Reducing the volume of acetonitrile (CH₃CN) to 1 mL resulted in an obvious loss of yield, while increasing the volume of CH₃CN to 3 mL did not affect the reaction, indicating that dilute conditions were more suitable (entries 2 and 3). Changing CH₃CN to dimethylformamide (DMF) or dimethyl sulfoxide (DMSO) resulted in a messy mixture with only a trace amount of **2a** detected (entries 4 and 5). To accelerate the reaction, excess PPh₃ was necessary, but a larger excess amount also led to the hydrogenation of alkenes as the side reaction, and 1.0 equivalent of PPh₃ was found to be the best amount (entries 6 and 7). The decrease in the amount of water resulted in a slight drop of the yield of product **2a**, and 21 hours were enough for this reaction (entries 8–11). The reaction was inhibited without either photocatalyst, PPh₃, H₂O or light irradiation (entry 12).

Table 1 Optimization of the reaction conditions^a

| Entry | Verified conditions | Yield ^b (%) |
|-------|---|------------------------|
| 1 | Standard conditions | 77 (72) |
| 2 | Solvent: CH ₃ CN (1 mL) | 40 |
| 3 | Solvent: CH ₃ CN (3 mL) | 77 |
| 4 | Solvent: DMF (2 mL) | Trace |
| 5 | Solvent: DMSO (2 mL) | Trace |
| 6 | Amount PPh ₃ : 2.0 equiv. | 70 |
| 7 | Amount PPh ₃ : 0.5 equiv. | 48 |
| 8 | Volume of H ₂ O: 0.50 mL | 68 |
| 9 | Volume of H ₂ O: 0.15 mL | 61 |
| 10 | Reaction time: 12 h | 30 |
| 11 | Reaction time: 48 h | 78 |
| 12 | Without [Ir] or PPh ₃ or H ₂ O or light irradiation | N.D. |

^a Standard conditions: *tert*-butyl acrylate **1a** (0.2 mmol), Ir[dF(CF₃)ppy]₂(dtbbpy)PF₆ (2.0 mol%), PPh₃ (1.0 equiv.), H₂O (1.0 mL) and CH₃CN (2.0 mL), under a N₂ atmosphere, 15 W blue LEDs, 21 h irradiation at room temperature. ^b Yields determined by ¹H NMR using CH₂Br₂ as the internal standard, isolated yield given in parenthesis. N. D.: not detected.

With the optimized conditions in hand, various activated alkenes were tested to explore the substrate scope of this reductive coupling system. The representative results are shown in Fig. 2. Terminal acrylate with a *tert*-butyl group on the ester side (**1a**) was tolerated and the corresponding product (**2a**) was isolated in 72% yield. Acrylates with α -methyl group (**1b**) were capable of the conversion, while epoxy group and chloride at the ester part were also tolerated and generated products (**2c** and **2d**) in excellent yield, respectively. α -Fluoride (**1e**) and α -phenyl acrylate (**1f**) were also suitable for the conversion to afford hydrodimerized products (**2e–2f**) in 76% and 33% yields, respectively. The lower yield of **2f** can be attributed to the steric hindrance and hydrogenation of the vinyl group as the by-product. γ -Lactone with an exocyclic C=C bond also completed this transformation smoothly to produce **2g** in moderate yield. Moreover, β -substituted and α,β -disubstituted acrylates performed well with two ester groups on substrates (**1h–1i**). The benzylic and phenyl acrylates (**1j–1k**) were tolerated, but suffered from the hydrolysis of the ester group, resulting in poorer yields [for details see Fig. S3 in the ESI†]. In addition, acrylonitrile could be converted into adiponitrile

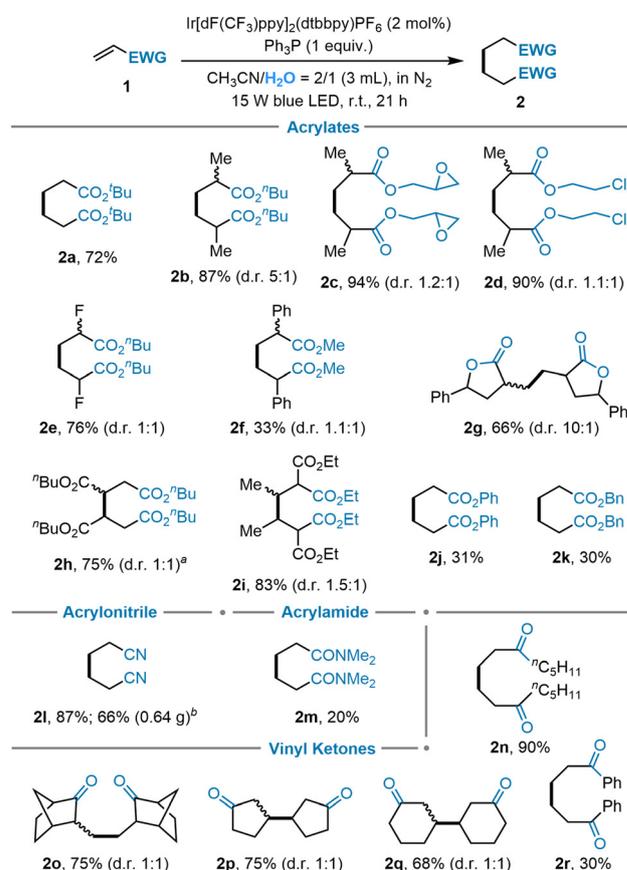

Fig. 2 Substrate scope of the reductive coupling system. Standard conditions: activated alkene **1** (0.2 mmol), Ir[dF(CF₃)ppy]₂(dtbbpy)PF₆ (2.0 mol%), PPh₃ (1.0 equiv.), H₂O (1.0 mL), CH₃CN (2.0 mL), under a N₂ atmosphere, 15 W blue LEDs, 21 h irradiation at room temperature. ^a(*E*)-Dibutyl succinate as the substrate. ^b18 mmol scale.

2l in high yield, and the scale-up reaction (18 mmol) proceeded smoothly to produce **2l** in moderate yield (0.64 g, 66%). Acrylamide **1m** was also tolerated; however, it resulted in poor chemoselectivity due to the competitive hydrogenation of the C=C bond as a byproduct. Vinyl ketones were also applicable in this reaction, including linear ketones (**1n**), ketone with an exocyclic C=C bond on a norbornene skeleton (**1o**), and ketones with an endocyclic C=C bond in five/six-membered rings (**1p-1q**), to give the corresponding products in high yields. Phenyl vinyl ketone could be transformed into product **2r**, but the hydrogenation of the carbonyl group⁹ interfered with the reaction. Propargyl ester with a carbon-carbon triple bond was also suitable for this conversion with 2.0 equivalents of PPh₃ to produce head-to-head coupling product **2a** in 33% yield.

To gain insight into the reaction process, several experiments were designed. The reaction was completely inhibited by the addition of 3.5 equivalents of 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO) (Fig. 3A-(i)), revealing the involvement of a potential radical process. When employing cyclopropyl group at the α -position of acrylate **3**, the reductive coupling reaction was inhibited, and the acrylate **3** underwent a ring-opening process to generate linear product **4** by the hydrogenation instead (Fig. 3A-(ii)), which further indicates the radical process in this reaction. To verify whether the reaction proceeded *via* a [2 + 2] cycloaddition and direct hydrogenation of the cyclobutyl motif, **1a** was first exposed to light irradiation and products **5** with a cyclobutene skeleton were not detected in the presence/absence of the photocatalyst. Then, 1,2-cyclobutanedioicates (*trans*-**5** and *cis*-**6**) were also tested under stan-

dard conditions and it was found that the reaction did not proceed and the starting materials remained. These results excluded the possibility of cyclobutanedioic acid as the intermediate (Fig. 3B). When replacing H₂O with D₂O under the standard conditions, the deuterium ratio at the α -position in **d-2a** reached 77/23, indicating that water was the hydrogen source in this reaction. Additionally, an unexpected deuterium ratio of 15/85 at the β -position of **d-2a** was observed, suggesting the possibility of the formation of a β -activated intermediate in this reaction (Fig. 3C).

Stern-Volmer experiments demonstrated that PPh₃ exhibited the strongest fluorescence quenching ability of the iridium-based catalyst, while acrylate **1a** and acrylonitrile **1l** barely affected the fluorescence strength of the photocatalyst. Vinyl ketone **1n** presents a degree of quenching ability, but it is weaker than that of PPh₃. The quenching ability of PPh₃ changed slightly in the presence of H₂O, implying a low possibility of interaction between PPh₃ and H₂O in the quenching process, indicating that PPh₃ was the dominant quencher of the photocatalyst (Fig. 4).

In order to further explain the anomalous selectivity, computational studies have been carried out. All quantum chemical calculations were carried out using Gaussian 16B and ORCA 6.0, while all crossing points were found using KST48 (see section 9.1 in the ESI for details[†]).¹⁰ The Gibbs free energy diagram of the stepwise pathway is shown in Fig. 5. The

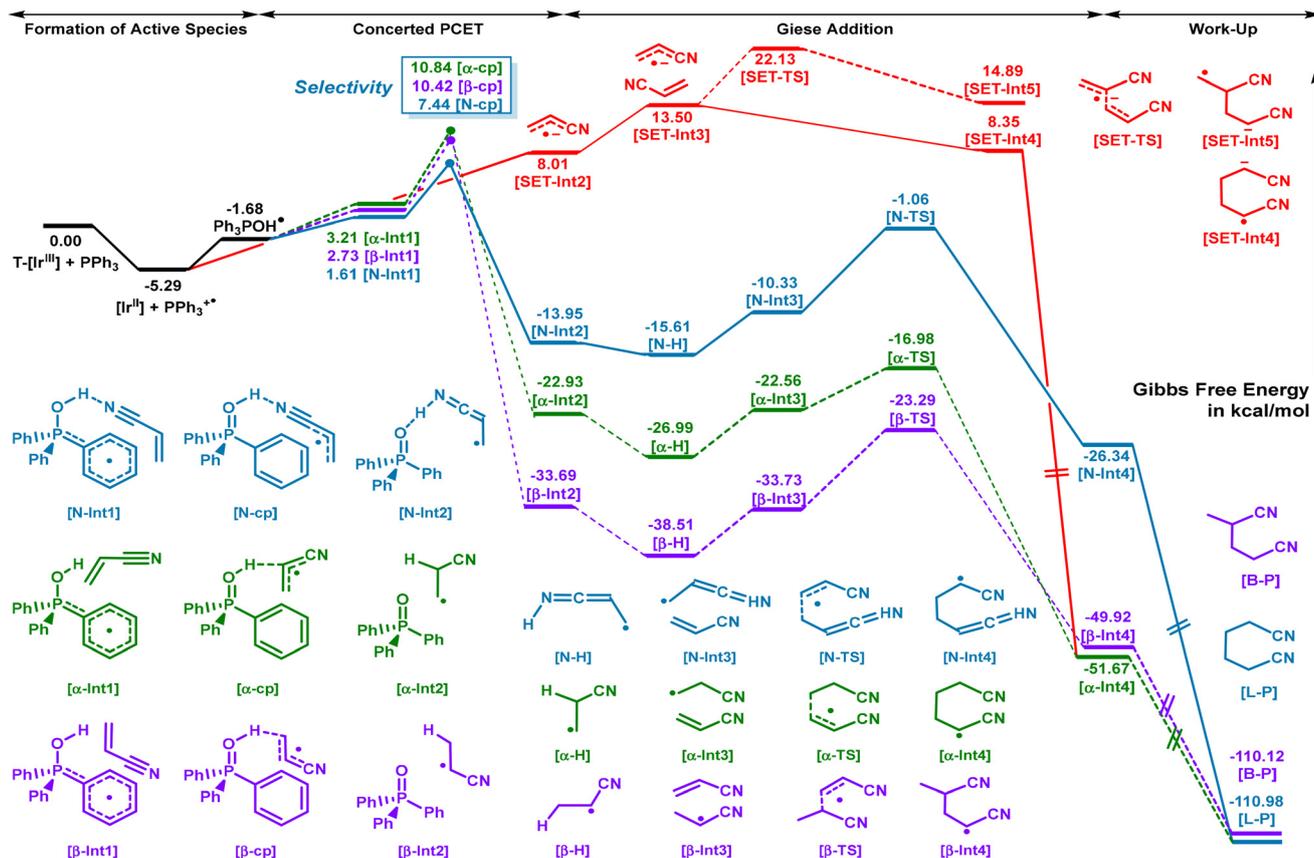

Fig. 5 Gibbs free energy diagram of the reaction with acrylonitrile as substrates. T = Triplet, L = Linear, B = Branched, Int = Intermediate, TS = Transition State, cp = crossing point, P = Product, SET = Single Electron Transfer; α , β and N are sites of hydrogen transfer; see section 9.4 in the ESI† for additional details.

reaction is initiated by a single electron transfer (SET) process between the photocatalyst ($T\text{-[Ir}^{\text{III}}]$) in the triplet state and Ph_3P , followed by interaction with H_2O to form the $[\text{Ph}_3\text{P-OH}]$ radical.^{6,9,11} Calculations show that the generation of the $[\text{Ph}_3\text{P-OH}]$ radical [$E_{1/2}(\text{Ph}_3\text{POH}^+/\text{Ph}_3\text{POH}^\bullet) = -1.75$ V vs. SHE] is energetically permissible, and the following reactions with three sites of acrylonitrile (N, α -C and β -C) are concerted PCET processes. The lowest total Gibbs free energy barrier is 12.73 kcal mol⁻¹ for the crossing point to **[N-cp]**, while that of **[β -cp]** and **[α -cp]** is about 3.0 kcal mol⁻¹ and 3.4 kcal mol⁻¹ higher respectively, leading to an anomalous selectivity. Time-scale reactions with $\text{H}_2\text{O}/\text{D}_2\text{O}$ showed a primary isotope effect ($k_{\text{H}}/k_{\text{D}} > 5$, see Fig. S4†), indicating the possibility of a concerted PCET step as the rate determining step. The structures then dissociate into Ph_3PO and three types of C-centered radicals respectively, which could undergo Giese addition to another acrylonitrile molecule. Although the barrier for the **[N-H]** is slightly higher than the other two processes, the global barrier for this pathway is more favorable. The following spontaneous reduction and protonation processes produce the linear structure as the major product. Another possible pathway is the direct reduction of acrylonitrile by $[\text{Ir}^{\text{II}}]$ to form the acrylonitrile radical anion **[SET-Int2]** and then the pre-complex **[SET-Int3]** with an 18.79 kcal mol⁻¹ barrier, followed

by barrierless Giese addition to give the linear product. The higher energies of **[SET-TS]** and **[SET-Int5]** inhibit the formation of the branched product. This SET pathway is likely to be a side pathway for the generation of the linear product (see section 9.4 in the ESI† for details†).

The effect of weak interactions in the concerted PCET process was also studied, indicating that the hydrogen bonding between the $[\text{Ph}_3\text{P-OH}]$ radical and activated alkenes accounts for the anomalous selectivity (see detailed IGMH and ETS-NOCV analysis¹² in Fig. S7 of the ESI†). The reaction coordinates of the two PES before and after electron transfer were defined by the species before and after hydrogen transfer, and the crossing point was approximated by a straight line connecting the two surfaces. When neglecting the hydrogen bonding effect in the concerted PCET process, the crossing point energy of **[β -cp]** is lower than **[N-cp]**, leading to non-existent branched products (Fig. 6a). When the hydrogen bonding effect is considered, both the reactant and the product experience a significant energy decrease, resulting in a lower crossing point energy of **[N-cp]**, thus explaining the selective generation of the linear product (Fig. 6b). The possibility of stepwise ET-PT (electron transfer-proton transfer) and concerted HAT (hydrogen atom transfer) instead of a concerted PCET process is also ruled out (see Fig. S8 of the ESI†).

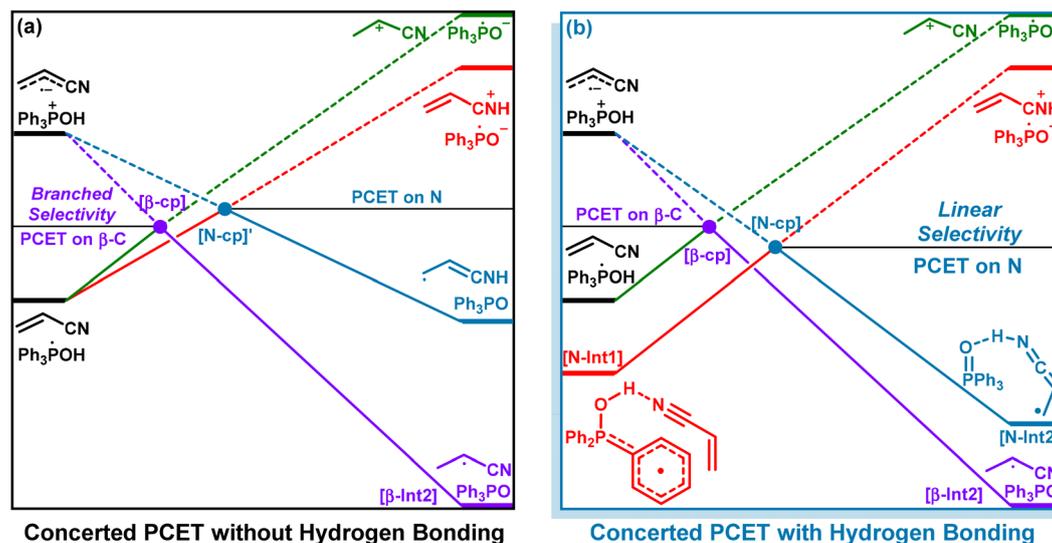

Fig. 6 Mechanism diagram of PCET to acrylonitrile.

A plausible mechanism is proposed and shown in Fig. 7. The reaction is initiated by photoinduced single electron transfer (SET) from PPh_3 to $\text{T}[\text{Ir}^{\text{III}}]$ in the excited state, forming a PPh_3 radical cation ($\text{PPh}_3^{+\bullet}$), which could accept nucleophilic H_2O and deprotonate to afford the $[\text{Ph}_3\text{P}\cdot\text{OH}]$ radical. The $[\text{Ph}_3\text{P}\cdot\text{OH}]$ radical could undergo a concerted PCET process with substrates (acrylonitrile as an example), and the energy barrier for PCET *via* the crossing point $[\text{N}\cdot\text{cp}]$ ($12.73 \text{ kcal mol}^{-1}$) is lower than that of $[\alpha\cdot\text{cp}]$ ($16.13 \text{ kcal mol}^{-1}$) and $[\beta\cdot\text{cp}]$ ($15.71 \text{ kcal mol}^{-1}$), which results in the selective formation of the radical $[\text{N}\cdot\text{H}]$ (A). A then undergoes Giese addition to a second molecule of acrylonitrile to generate the radical $[\text{N}\cdot\text{Int4}]$, which could receive electrons from Ir^{II} , followed by tautomerization and protonation to produce the head-to-head coupling product. Even though the radical $[\beta\cdot\text{H}]$ (C) from the ET-PT or HAT process is thermodynamically

more stable than A, the formation of C is not favored because it leads to the head-to-tail coupling product that is not detected.

Conclusions

In summary, we have disclosed a photoinduced strategy for the head-to-head reductive coupling of activated alkenes, producing various adipate derivatives, adiponitrile and 1,6-diones with high chemo- and regio-selectivity with water as the hydrogen source. In this reaction, the $[\text{Ph}_3\text{P}\cdot\text{OH}]$ radical is generated from a photoinduced interaction between H_2O and PPh_3 , followed by a PCET process with activated alkenes to form a nucleophilic radical at the β -position. The $\beta\text{-C}$ activation strategy provides insights into different regioselectivity reactions

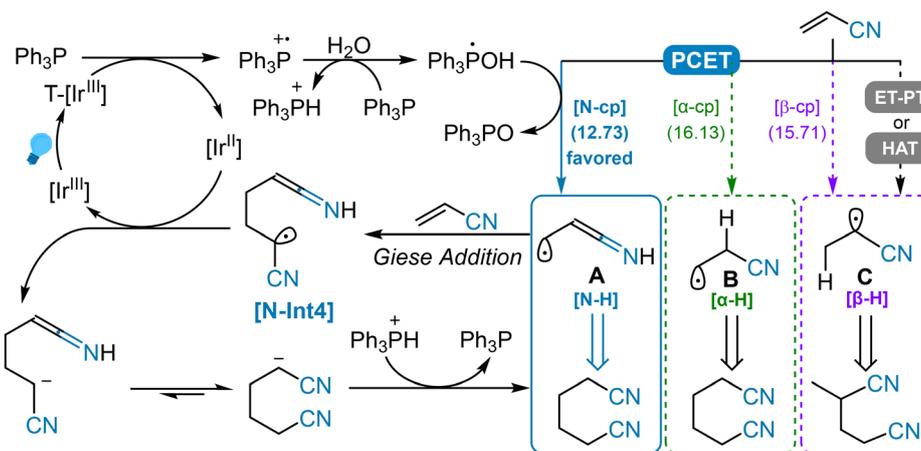

Fig. 7 Proposed mechanism for the reductive coupling of activated alkenes (total Gibbs free energy barrier for the PCET process is given in parenthesis, kcal mol^{-1}).

with activated alkenes, building new synthetic methods through radical processes.
