Determination of gold content in rock gold ore samples based on closed water bath aqua regia digestion-polyurethane foam enrichment and using flame atomic absorption spectrometry

 Shunxiang Wang,^a Cang Gong,  ^{*a} Hongcheng Wang,^a Xiang Xia,^a Jiufen Liu^b and Haichuan Lu^{*a}

At present, due to the uneven distribution and low content of gold (Au) in rock gold ore samples, the separation, enrichment and accurate determination of Au have become daunting tasks in the analysis of rock gold samples. This study established a method for determining the Au content in rock gold ore samples with the advantages of high efficiency, low cost, safety and more environment-friendliness. It was based on closed water bath digestion-polyurethane foam (PUF) enrichment and thiourea release, and then, flame atomic absorption spectrometry was used to determine the Au content. By eliminating interference and optimizing the PUF pretreatment method, aqua regia dosage, water bath dissolution time, oscillation frequency and time, thiourea concentration, release time and temperature and other working conditions, technical problems such as the low adsorption efficiency of the PUF and interference from tungsten, antimony and iron elements were solved. The Au detection limit of this method was $0.03 \mu\text{g g}^{-1}$, the lower limit of determination was $0.1 \mu\text{g g}^{-1}$, and the optimal determination range was $0.1\text{--}40 \mu\text{g g}^{-1}$. This method was used to determine 7 national standard materials of gold ores with different high and low contents (GBW07808b, GBW07809b, GBW07297a, GBW07298, GBW07300a, GBW(E)070012a and GBW07807a); the relative error (RE) was $\leq 3.06\%$ and the relative standard deviation (RSD) was $\leq 8.35\%$. This method was performed in 9 laboratories to compare and verify the 7 national standard materials of gold ores with different high and low contents (GBW(E)070067, GBW(E)070262, GBW(E)070138a, GBW07300a, GBW07809b, GBW(E)070141 and GBW07298a); the RE was $\leq 10.55\%$ and the RSD was $\leq 3.93\%$, achieving good results. A total of 85 rock gold ore samples were selected for determination using this method and compared with the results of activated carbon enrichment-flame atomic absorption spectrometry. The qualification rate was 97.65%, and the analysis and testing efficiencies were improved by nearly 10 times.

1 Introduction

Gold (Au) is a precious metal with high ductility, corrosion resistance and chemical stability. Owing to its special properties, it plays a vital role in many fields, such as economic development, national defense, geology, materials science, and biology.^{1–3} According to the China Mineral Resources Report 2024, China's Au mine reserves in 2023 were 3203.77 t, with an increase of 2.4% over 2022. As of 2023, global Au reserves were 193000 t, of which 167000 t are on the surface and 26000 t are under the sea. With the development of economy, the demand for Au is still increasing, and hence, rational development and

utilization of Au mines are of great significance for the sustainable development of Au industry. Rapid, sensitive and accurate determination of Au has been a long-term priority in earth science, analytical chemistry and spectroscopy.^{4–7} However, the non-uniform distribution of Au in various geological samples and low Au content make the separation, enrichment and accurate determination of Au difficult in geological analysis.

There are two main methods for decomposing rock Au ores: dry method and wet method. The dry method is mainly a fire assay, which has always been the most important method in Au analysis owing to its large sampling volume, good sampling representativeness, high enrichment efficiency, wide application range, and accurate and stable test results, and it can also be combined with other detection methods. It is recognized by domestic and foreign laboratories as the most authoritative analysis method for Au detection.^{8–12} Despite its advantages, fire

^bNatural Resources Comprehensive Survey Command Center of China Geological Survey, Beijing, 100055, China

assay is accompanied by several limitations, including prolonged processing times, high labor demands, significant blank values, unfavorable working conditions, and substantial environmental pollution.^{13–16} The most common wet method is the aqua regia dissolution method, which uses an open hot plate to dissolve the sample. Due to the temperature gradient across the hot plate surface, the elevated temperature at the center often causes sample splashing and evaporation, while the peripheral samples may not dissolve adequately, leading to poor precision in the measurement results.^{17–19} In addition, the aqua regia dissolution method uses an electric heating plate to heat the aqua regia, which volatilizes and produces a large amount of nitrogen oxides, causing environmental pollution. The number of samples dissolved each time is limited by the surface area of the electric heating plate, resulting in low efficiency.^{6,16} The closed sample dissolution method is a special wet sample dissolution method. This method uses the solvent to increase the temperature and pressure in a closed space to digest the sample. Compared with the open sample dissolution of the electric hot plate, it can greatly eliminate the pollution of aqua regia to the environment, and the temperature is constant and uniform, the acidity is easy to control, and the number of samples dissolved in a single time can reach hundreds, which greatly saves production and labor costs and greatly improves work efficiency.^{20,21}

In addition to the decomposition of rock Au ore, enrichment and separation are necessary, often for sensitive and accurate measurement of the Au content. The main methods used for the separation and enrichment of Au include polyurethane foam adsorption, fire assay coprecipitation, solvent extraction, activated carbon adsorption, ion exchange, hanging droplet microextraction, on-line separation and enrichment by micro-column, sulfhydryl cotton adsorption, extraction chromatography, and liquid membrane separation and enrichment.^{22–29} In recent years, some emerging technologies have been applied to the separation and enrichment of gold. Yu³⁰ established a CIP-MS method for the determination of gold in geological samples with 5-mercapt-3-phenyl-1,3,4-thiadiazole-2-thione potassium salt as a complexing agent and polyethylene glycol octyl phenyl ether as an extractant. Chen *et al.*³¹ added Cu²⁺ to an alkaline Na₂S₂O₃ solution to conduct experimental research on the leaching of gold in waste-integrated circuit chips, with a gold leaching rate as high as 92.25%. Zan³² used 717 strong alkaline styrene anions to pre-separate and enrich copper tailings, and studied the effects of the flow rate of the upper column liquid, the acidity of the upper column liquid, and the sample volume on the adsorption rate. Hao *et al.*³³ used the cloud point phenomenon of the nonionic surfactant TritonX-114 to extract gold complexes and used spectrophotometry to determine trace gold in geological samples. The spiking recovery rate was 97.8–103.0%. He *et al.*²⁸ used a P350 microchromatography column to establish online separation enrichment-flame atom absorption spectrometry to determine trace gold in ores, and the adsorption rate of gold reached almost 100%. Xiao *et al.*²⁹ established a method of ashing, acid dissolution, and suspended droplet microextraction of tributyl phosphate in platinum dishes for ultra-trace gold analysis in high-purity

graphite. The relative standard deviation of the measurement results is 1.5–4.9%, and the spiking recovery rate is 94.9–105.3%. Considering comprehensive separation and enrichment efficiency, operational complexity, cost and other factors, the activated carbon adsorption method has gained extensive application in gold ore laboratories. Fire assay has the advantages of high enrichment rate and good stability, which is called the classic method. The PUF adsorption method has become the most common method for the separation and enrichment of geological samples because of its batch operation.^{19,34} Bowen first applied PUFs to adsorb Au in an acidic medium in 1970.¹⁹ The PUF is a sponge-like foam plastic with certain cross-links made of toluene diisocyanate and polyether polyol. When Au in the solution meets the foam, adsorption and exchange occur on the foam membrane.¹⁹ The PUF has been widely used in the determination of Au in geological samples due to its strong adsorption performance and low price.

The purpose of this work is to select the best PUF and discuss the pretreatment method of PUFs. Reasonable sample dissolving time and aqua regia dosage were chosen, and the traditional open digestion was replaced with more efficient closed water bath digestion. Furthermore, the elimination of interfering elements was optimized, the best oscillation frequency and time were determined, and the best thiourea concentration, desorption time and desorption temperature were selected to establish closed water bath aqua regia digestion-polyurethane foam enrichment thiourea elution-flame atomic absorption spectrometry to realize the accurate determination of gold content in rock gold ores.

2 Materials and methods

2.1 Instrumentation

The samples were crushed into coarse medium-sized particles using a jaw crusher (XPC-100 × 60, Guiyang Prospecting, China) and a disc mill (MP-ø250, Guiyang Prospecting, China) and then finely ground using a multifunctional rod mill (ZN-II, Huangshi Angtai, China). The sample powder was weighed using an electronic balance (JJ500, Changshu Shuangjie, China) and turned into ashes in a muffle furnace (SX-10-12PII, Taister, China). A self-made closed sample dissolving water bath with a lid was used for sample digestion. A cyclotron oscillator (DC-400, Chengdu Haiguang, China) was used to ensure that Au was completely adsorbed by the PUF. A constant temperature water bath (SY-100, Chengdu Haiguang, China) was used to desorb Au. A flame atomic absorption spectrometer (AAS) (GG-910, Beijing Haiguang, China) was used to determine Au. AAS working conditions: wavelength = 242.8 nm, lamp current = 10 mA, acetylene gas flow rate = 1.5 L min⁻¹, spectral bandwidth = 0.2 nm, integration time = 1 s, air-acetylene flame, and Au hollow cathode lamp.

2.2 Reagents and standards

Hydrochloric acid (HCl), nitric acid (HNO₃), ferric chloride (FeCl₃·6H₂O), ammonium fluoride (NH₄F) and thiourea (CH₄N₂S) used in sample digestion were all of analytical grade,

and ultrapure deionized water with a resistivity of $18.2\text{ M}\Omega\text{ cm}$ at $25\text{ }^\circ\text{C}$ was used throughout the experiment. The main reagents prepared in the experiment were $250\text{ g L}^{-1}\text{ FeCl}_3\cdot6\text{H}_2\text{O}$ solution, 20% NH_4F solution, $10\text{ g L}^{-1}\text{ CH}_4\text{N}_2\text{S}$ solution and aqua regia. The national standard Au single-element solution (GSB04-1715-2004, $1000\text{ }\mu\text{g mL}^{-1}$) dissolved in $1.5\text{ mol L}^{-1}\text{ HCl}$ was provided by the National Nonferrous Metals and Electronic Materials Analysis and Testing Center. The Au standard solution required for the experiment was prepared by a stepwise dilution method. Gold's 17 Certified Reference Substances (CRMs): GBW07802b purchased from Yantai Zhaoyuan Inspection and Testing Center (Yantai, China); GBW(E)070067 purchased from Shaanxi Experimental Institute of Geology and Mineral Resources (Xi'an, China); GBW(E)070138a, GBW(E)070140 and GBW(E)070141 purchased from Changchun Au Research Institute Co., LTD (Changchun, China); GBW(E)070262 and GBW(E)070266 purchased from Shandong Metallurgical Research Institute Co., LTD (Jinan, China); GBW07856 and GBW07857 purchased from the Armed Police Au Research (Langfang, China); and GBW07297a, GBW07298, GBW07298a, GBW07300a, GBW(E)070012a, GBW07807a, GBW07808b and GBW07809b purchased from the Institute of Geophysical and Geochemical Exploration, Chinese Academy of Geological Sciences (Langfang, China). Actual samples were collected from Yangshan Gold Mine, Gansu Province, China. Actual samples were collected from Yangshan Gold Mine, Gansu Province, China.

2.3 PUF treatment

First, the PUF was cut into small cuboids ($30\text{ mm} \times 10\text{ mm} \times 10\text{ mm}$, 0.2 g), boiled in water for 2 h , dried, and put into clean plastic bottles for later use.

2.4 Sample digestion

First, 20.0 g sample (accurate to 0.1 g) was weighed in a 50 mL porcelain crucible, placed in a muffle furnace from low temperature to $700\text{ }^\circ\text{C}$, and roasted for 2 h . The sample was removed and placed at room temperature, and the roasted sample was transferred to a 250 mL polyethylene plastic bottle, followed by the addition of 50 mL aqua regia ($1:1$), 1 mL $250\text{ g L}^{-1}\text{ FeCl}_3\cdot6\text{H}_2\text{O}$ solution, and 5 mL 20% NH_4F solution. The sample was covered, heated in a water bath for 120 min and then cooled.

2.5 Proposed experimental procedure for Au enrichment and desorption

About 100 mL of water was added to a polyethylene plastic bottle, a piece of PUF was placed, and the plastic cup was tightened and placed on an oscillator, followed by oscillation for 60 minutes at an amplitude of 2 cm and a frequency of 180 Hz . After the oscillation is completed, the PUF in the sample was taken out, and the remaining acid and residue were rinsed with tap water and then with deionized water. The PUF was squeezed to dryness and completely soaked in a colorimetric tube containing 20 mL thiourea solution using a foam hook, and then the colorimetric tube was put into a boiling water bath

for 30 minutes. After the liberation was completed, the boiling water state was maintained and the foam was removed while it is hot, cooled, and waited for measurements.

At the same time, a blank control experimental sample was prepared in the same manner.

2.6 Calibration merit

For plotting the calibration curves, 0 mL , 0.50 mL , 1.00 mL , 2.00 mL , 4.00 mL , and 6.00 mL of $10\text{ }\mu\text{g mL}^{-1}$ Au standard working solution were pipetted into a 250 mL polyethylene plastic bottle, and 50 mL of aqua regia, 1 mL of $\text{FeCl}_3\cdot6\text{H}_2\text{O}$ solution, 100 mL of water, and 1 piece of PUF were added. Then, it was placed in an oscillator for 60 min of synchronous oscillation adsorption with the sample, as discussed in section 2.5. The subsequent treatment process is the same as mentioned in section 2.5. After the obtained solution was cooled to room temperature, it was measured, and the calibration curve was drawn.

Twelve replicates of a $0.5\text{ }\mu\text{g mL}^{-1}$ gold standard solution were prepared and analyzed following the experimental methods described in section 2.5. The method detection limit (LOD) was calculated as three times the standard deviation of the blank, and the method quantification limit (LOQ) was determined as three times the standard deviation.

3 Results and discussion

3.1 Comparison of pretreatment methods for PUFs

Two types of PUFs were treated under three methods: no treatment, treatment with boiling water for 2 h , and treatment by soaking in 10% hydrochloric acid for 6 h ; the PUFs were then washed to become neutral and squeezed to dryness for use. A treated PUF was added into a polyethylene plastic bottle containing 30 mL Au standard solution ($4\text{ }\mu\text{g g}^{-1}$), enriched and released according to the experimental method described in section 2.5, and the Au content was determined by AAS. The PUFs of the three treatments were tested in parallel for 3 times, respectively. The Au recovery rates obtained by the three PUF treatment methods are shown in Table 1. The results indicated that both PUF treatment in boiling water and 10% hydrochloric acid soaking could obtain good Au recoveries, both of which were above 95% . The recovery rate of Au obtained by the PUF without treatment is lower than 90% . Considering the simple and quick operation of boiling water, this method determines to use boiling water for 2 h to treat PUFs.

In order to explore the effect of different foam sizes on Au adsorption, PUFs with specifications of $30\text{ mm} \times 10\text{ mm} \times 10\text{ mm}$ and $40\text{ mm} \times 20\text{ mm} \times 20\text{ mm}$ were selected. After treatment with boiling water, they were placed in $10\text{ }\mu\text{g g}^{-1}$ and $25\text{ }\mu\text{g g}^{-1}$ Au standard solutions and GBW07807a, GBW07809B and GBW07298a sample solutions. Duplicate experiments were conducted according to Sections 2.4 and 2.5. The results are shown in Table 2. The results show that the two sizes of PUFs have no significant effect on the determination of Au. Therefore, this method selects PUFs with specifications of $30\text{ mm} \times 10\text{ mm} \times 10\text{ mm}$.

Table 1 Effect of foam pretreatment on Au recovery

PUF features						Au recovery (%)								
No.	Colour	Density (kg m ⁻³)	25% Hardness (N)	40% Hardness (N)	Resilience (%)	No treatment			Boiling water			10% HCl soaking		
1	White	40	105	130	64	89.7	80.3	73.1	99.1	96.6	95.2	99.2	96.7	97.0
2	White	35	140	175	54	89.9	82.9	81.6	99.6	96.6	95.5	99.4	95.6	96.5

Table 2 Effect of the PUF size on Au determination

Sample	Recommended value (μg g ⁻¹)	PUF size (30 × 10 × 10) mm		PUF size (40 × 20 × 20) mm	
		Measured value 1 (μg g ⁻¹)	Measured value 2 (μg g ⁻¹)	Measured value 1 (μg g ⁻¹)	Measured value 2 (μg g ⁻¹)
1	10	10.26	10.12	10.57	10.67
2	25	24.96	24.98	26.08	26.38
GAu-16b	1.1	1.18	1.18	1.12	1.19
GAu-18b	10.4	10.03	9.97	9.95	9.98
GAu-20a	31.9	31.12	31.01	31.43	31.42

3.2 Elimination of interfering elements

Through PUF adsorption, Au and symbiotic elements in rock Au ores are effectively separated and enriched. Although Fe, Cu, Ag, Pb, Zn, Ni, Cd, Sb and other elements will be adsorbed to a certain extent, the content is low, which generally does not interfere with the determination of Au.³⁵ If the sample contains extremely high amounts of C, As, S, organic matter, W, Sb, Fe and Si, the determination of Au will be seriously low.³⁶ When the sample contains high levels of C, As, S and organic matter, the sample can be calcined at 700 °C for 2 h to eliminate their interference.

3.2.1 Interference from W and Sb. When the W and Sb contents in the ore are too high, tartaric acid can be used to mask the interference of W and Sb. Experiments show that in the 4 μg g⁻¹ Au standard solution, when the amount of W added is less than 100 mg or the amount of Sb added is less than 300 mg, the Au recovery rate is not affected; when the amount of W or Sb added is 100 mg and 300 mg, respectively, the Au recovery rate is reduced to 74.4% and 88.7%, respectively. When 1 g of tartaric acid is added, the interference of W and Sb is masked and eliminated, and the Au recovery rate is greater than 95%. The Au ore standard material GBW07856 with a W content of 5079 μg g⁻¹ was selected for the test, and it was found that without adding tartaric acid as a masking agent, the Au determination value was 2.2–2.5 μg g⁻¹, which is about half of the recommended value of 4.34 μg g⁻¹; when 1 g of tartaric acid was added, the Au test result was 4.30 μg g⁻¹, which is consistent with the recommended value. The Au ore standard material GBW07857 with a Sb content of 5341 μg g⁻¹ was selected for testing, and it was found that without adding tartaric acid as a masking agent, the Au test result was 6.17 μg g⁻¹, which is basically consistent with the recommended value of 6.30 μg g⁻¹.

This is due to the fact that W forms H₂WO₄ gel-like substances during the sample pretreatment process, which captures a portion of AuCl₄⁻, resulting in reduced ion-exchange

efficiency between AuCl₄⁻ in the solution and the active groups (−RNH₃⁺) on the foam plastic.³⁷ The interference of Sb with Au primarily arises because, during the sample pretreatment process, Sb compounds are prone to hydrolysis when acidity or temperature decreases, and their products adsorb Au, preventing complete adsorption of AuCl₄⁻ onto the foam plastic.³⁸ By controlling the acidity of the sample decomposition solution and adding proper amounts of tartaric acid to complex with tungsten and antimony, the stability of Au(III) in the solution can be ensured, converting potential H₂WO₄ gel-like substances into soluble salts and preventing the hydrolysis of Sb compounds when the acidity or temperature decreases.^{37,38}

3.2.2 Interference from acid-soluble silicates. The interference of acid-soluble silicates can be eliminated by adding NH₄F to precipitate ammonium fluorosilicate ((NH₄)₂SiF₆) crystals. Experiments show that in a 4 μg g⁻¹ Au standard solution, when the amount of soluble silica added is 200 mg, the Au recovery rate is 97.1%, which is not affected; but when the amount of soluble silica added is 400 mg, the Au recovery rate drops to 85.4%. After adding 5 mL 20% NH₄F, the interference of soluble silicon can be eliminated, and the Au recovery rate can be greater than 95%.

3.2.3 Interference from Fe. The interference of Fe can be eliminated by adding a phosphoric acid solution. Experiments show that in a 4 μg g⁻¹ Au standard solution, when the amount of Fe added is 4000 mg, the Au recovery rate is 98.5%, which is not affected; but when the amount of Fe added is 8000 mg, the Au recovery rate drops to 70.5%. The addition of 10 mL 20% phosphoric acid solution can inhibit the competition of FeCl₄⁻, making the Au recovery rate greater than 95%. The national standard substances GBW(E)070266, GBW07802b, GBW(E) 070140 and GBW(E)070141 of Au ore with TFe₂O₃ contents of 29.0%, 26.4%, 26.1% and 24.7%, respectively, were selected, and it was found that without adding the phosphoric acid solution as the masking agent, Au recoveries were 97.1%,

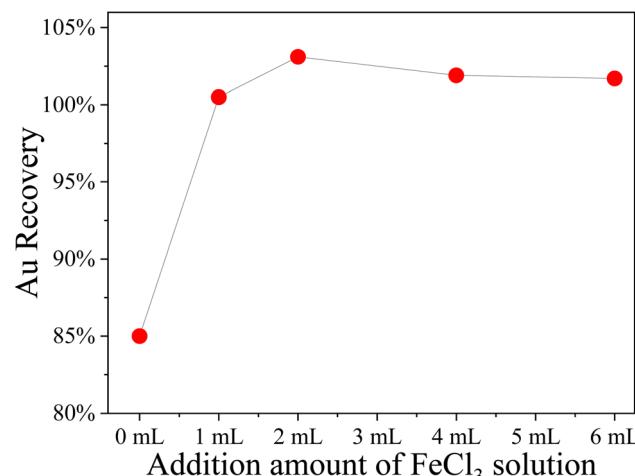

Fig. 1 Relationship between the amount of $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ solution added and Au recovery.

97.8%, 97.0% and 100%, respectively. It can be seen that Fe in the general rock Au ore sample has no obvious interference with the determination of Au.

Interestingly, the addition of a small amount of iron salt helps the PUF to adsorb Au. In five 250 mL polyethylene bottles, 500 μg of Au standard solution was added to each, and then 0, 1, 2, 4, and 6 mL of 250 g L^{-1} $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ solution were added, respectively, and the volume was fixed to 20 mL. The test was carried out according to Section 2.5, and the results are shown in Fig. 1. The results show that the addition of 1 mL of 250 g L^{-1} $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ solution can help the foam to adsorb Au. Therefore, in this method, 1 mL of 250 g L^{-1} $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ solution was added during sample digestion.

3.3 Selection of aqua regia dosage

Five 250 mL polyethylene bottles were selected and 500 μg Au standard solution was added to each bottle. Then, 20 mL, 30 mL, 40 mL, 50 mL, and 60 mL of aqua regia (1 : 1) were added, respectively, heated in a hot water bath for 30 min, removed and cooled. After that, 80 mL of water and 1 PUF were added, placed on an oscillator and operated according to Section 2.5. The results are shown in Table 3. The results show that when the

aqua regia concentration (volume ratio) is 16–20%, the adsorption rate of PUF on Au is above 100%; when the aqua regia concentration is greater than 20%, it is easy to destroy the structure of PUF, making the performance of PUF adsorbing Au worse. In this method, the concentration of aqua regia was chosen as 16.7% (1 : 1).

3.4 Selection of water bath dissolution time

Three different types of Au ore reference materials (GBW07807a, GBW07809B and GBW07298a) were selected, and 4 portions of each were weighed. The closed water bath dissolution time was set to 0.5 h, 1 h, 2 h and 3 h, respectively, and the operation was carried out according to Sections 2.4 and 2.5. The results are shown in Fig. 2. When the closed dissolution time was not higher than 1 h, the Au recovery in all the samples was less than 80%; when the dissolution time reached 2 h, the Au recovery in all the samples was more than 95%. Through observations in daily routine analysis, the closed dissolution of 2 h can basically meet the decomposition of Au in common rock Au ore samples. The dissolution time determined by this method is 2 h.

3.5 Selection of oscillation frequency and oscillation time

The oscillation frequency is an adjustable variable for the adsorption of gold by PUFs. Different oscillation frequencies may affect the adsorption of gold. According to the experimental method discussed in Section 2.5, the recovery rate test of gold standard solutions with concentrations of 1, 10, and 25 $\mu\text{g mL}^{-1}$ was carried out with only the oscillation frequency changed. The oscillation frequencies were 140, 180, 220, and 260 times/min, respectively. The results are shown in Fig. 3. When the oscillation frequency is 140 times/min, the gold recovery rate is significantly low, which may be due to the fact that Au cannot be completely adsorbed; when the oscillation frequency is 180 times/min, the gold recovery rate is close to 100%, the frequency continues to increase, and the gold recovery rate does not change much. Through observation, it was found that when the oscillator frequency is 180 times/min, the solution in the bottle shakes exactly once, so the oscillation frequency of this method is 180 times/min.

Table 3 Effect of aqua regia dosage on Au adsorption by PUFs

1 : 1 Aqua regia dosage (mL)	Aqua regia concentration (v/v) during PUF enrichment (%)	Au standard solution concentration ($\mu\text{g mL}^{-1}$)	Measured value ($\mu\text{g mL}^{-1}$)	Average adsorption rate of Au (%)
20	10	25	21.37	87.1
			22.16	
30	13.6	25	23.13	92.8
			23.28	
40	16.7	25	24.92	101.6
			25.88	
50	19.2	25	25.24	100.4
			24.96	
60	21.4	25	23.69	94.0
			23.31	

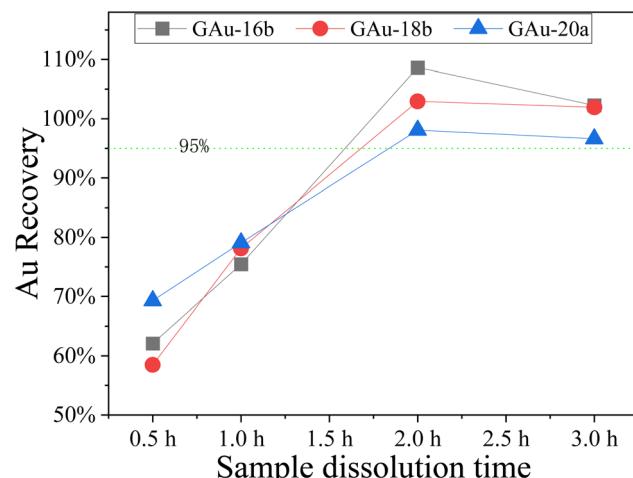

Fig. 2 Effect of sealed dissolution time on Au recovery.

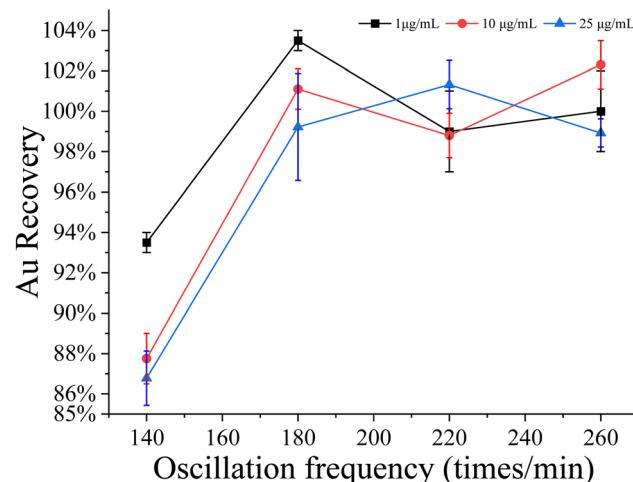

Fig. 3 Effect of oscillation frequency on Au recovery.

According to the experimental method discussed in Section 2.5, under the condition of oscillation frequency of 180 times/min, the oscillation time was set to 20, 40, 60 and 80 times/min to conduct the recovery test on gold standard solutions with concentrations of 1, 10 and 25 $\mu\text{g mL}^{-1}$, and the results are shown in Fig. 4. The results show that when the oscillation time is 20 minutes, the gold recovery rate is less than 85%; when the oscillation time is 40 minutes or more, the gold recovery rate is above 95%. This method selects an oscillation time of not less than 40 minutes.

3.6 Selection of thiourea concentration

The selection of thiourea concentration in the desorption solution is an important factor to determine whether the gold desorption is complete. According to the experimental method, thiourea desorption solutions with different concentrations of 1, 3 and 10 g L^{-1} were selected to conduct parallel sample experiments on the national primary standard material

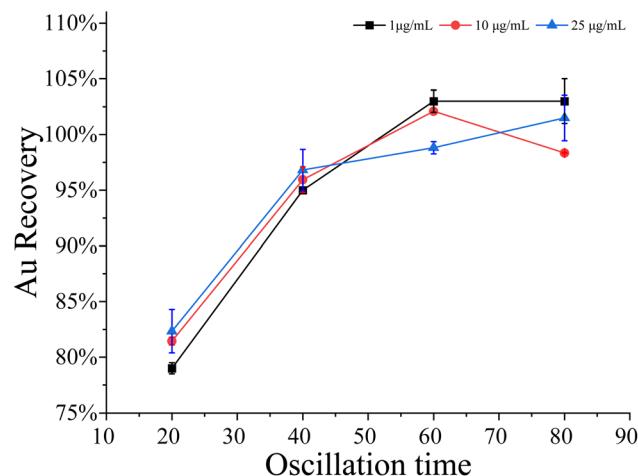

Fig. 4 Effect of oscillation time on Au recovery.

Table 4 Effect of thiourea concentration in the decomposed solution on the determination of Au

Thiourea concentration	GBW07809b recommended value ($\mu\text{g g}^{-1}$)	Measured value ($\mu\text{g g}^{-1}$)	Recovery (%)
1 g L^{-1}	10.4	8.05 7.95	77.4 76.4
3 g L^{-1}		9.23 9.23	88.8 88.8
10 g L^{-1}		10.6 10.4	102.1 100.0

GBW07809b of gold ore, and the results are shown in Table 4. The results show that when the thiourea concentration is 10 g L^{-1} , the gold recovery rate is the best. Therefore, this method selects the thiourea concentration of the desorption solution to be 10 g L^{-1} .

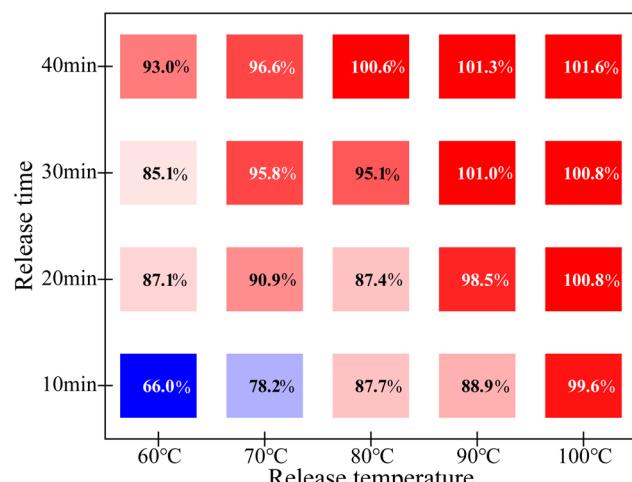

Fig. 5 Effect of release time and release temperature on Au recovery.

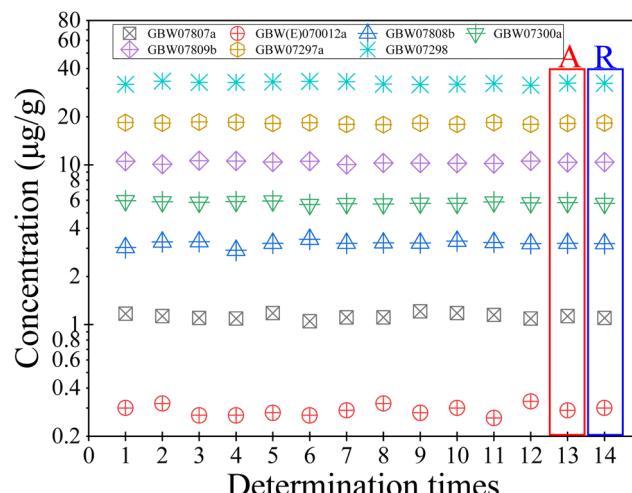

Fig. 6 Results of accuracy tests and precision tests (A: average value; R: recommended value).

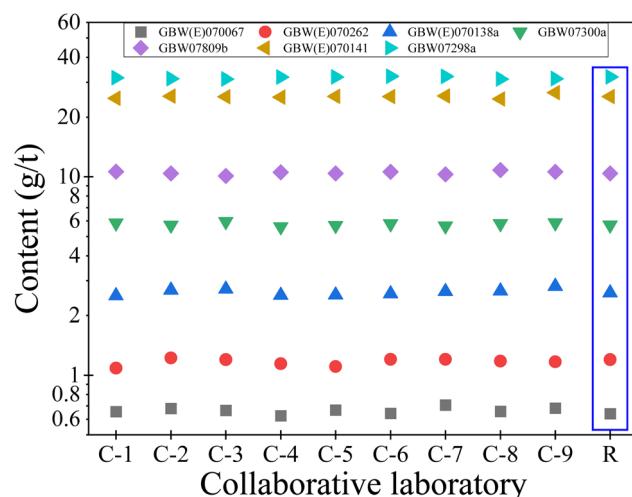

Fig. 7 Verification results of different laboratories (R: recommended value).

3.7 Selection of release time and temperature

The PUF that adsorbs 100.0 μg of gold was selected and placed in a thiourea desorption solution with a concentration of 10 g L^{-1} .

The gold recovery rates under different desorption temperatures and times were compared, as shown in Fig. 5. The results indicate that different release temperatures and release times have a significant impact on the release of gold by thiourea. When the temperature is low, it takes enough time for the gold adsorbed by PUF to be completely released. When the temperature is high, the gold adsorbed by PUF can be released in a short period of time. Considering that it can completely release without causing boiling water vapor droplets to splash into the test tube and interfere with the gold test, this method selects a release temperature of 90 $^{\circ}\text{C}$ and a time greater than 20 minutes.

3.8 Method detection limit and measurement range

According to the experimental methods in Sections 2.4 and 2.5, the blank solutions of 12 sample processes were measured. The LOD of gold was calculated as 0.03 $\mu\text{g g}^{-1}$ by 3 times the standard deviation, and the LOQ of the determination was calculated as 0.1 $\mu\text{g g}^{-1}$ by 3 times the standard deviation. In the actual sample enrichment, it was found that a large amount of slag would occupy the PUF adsorption sites, and there would also be competition in adsorption with iron, gallium, molybdenum, thallium, rhenium, *etc.* Considering comprehensively, under the experimental conditions, the optimal determination range of gold is 0.1–40 $\mu\text{g g}^{-1}$.

3.9 Method accuracy and precision

The 7 national standard materials of gold ores with different high and low contents (GBW07808b, GBW07809b, GBW07297a, GBW07298, GBW07300a, GBW(E)070012a and GBW07807a) were selected and analyzed in parallel 12 times according to the experimental method, and the relative standard deviation (RSD) and relative error (RE) of the Au determination results were calculated. The results are shown in Fig. 6. The results show that the determination results of Au in each standard material are consistent with the recommended value, $\text{RE} \leq 3.06\%$. The RSD of Au in each standard material is $\leq 8.35\%$, which meets the requirements of the Quality Management Specification for Laboratory Testing of Geological Mineral Resources (DZ/T0130-2006).

3.10 Validation results from different laboratories

The 7 national standard materials of gold ores with different high and low contents (GBW(E)070067, GBW(E)070262, GBW(E)

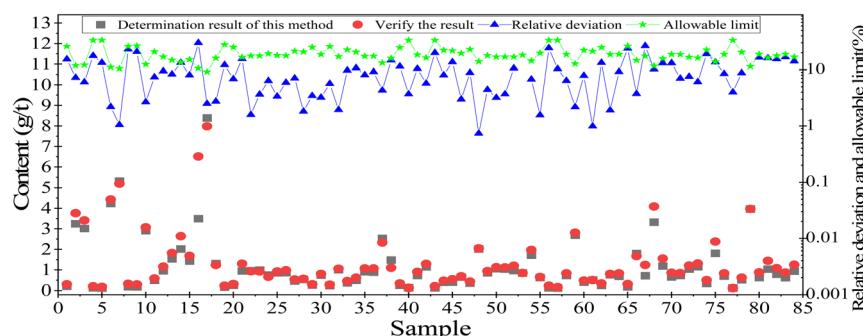

Fig. 8 Comparison of the results of Au determination in actual rock Au ore samples using different methods.

070138a, GBW07300a, GBW07809b, GBW(E)070141 and GBW07298a) were selected, and the method validation test was carried out in 9 laboratories according to the established method. The results are shown in Fig. 7. The results show that the determination results of Au of the 7 standard materials in the 9 laboratories are consistent with the recommended values, $RE \leq 10.55\%$ and $RSD \leq 3.93\%$. It can be seen that the method established in this paper has also been used very well in different laboratories.

3.11 Actual samples

The 85 rock gold ore samples were selected, and the gold content was determined according to the experimental method established in this paper. At the same time, use the activated carbon enrichment flame atomic absorption spectroscopy method in GB/T 20899.1-2019, Part 1 Determination of Gold Content, to determine the gold content of these 85 samples. Compare and verify the results of the two methods. The results are shown in Fig. 8. The results show that among the 85 samples, only 2 samples had a relative deviation of gold results exceeding the allowable limit, and the qualified rate was 97.65%. It can be seen that the determination of gold by the method established in this paper is consistent with the determination results of GB/T20899.1-2019, and the efficiency is increased by nearly 10 times.

4 Conclusions

The optimal conditions for sample digestion, adsorption and desorption were determined through the selection of PUF pre-treatment methods, elimination of interfering elements, selection of aqua regia dosage, water bath dissolution time, oscillation frequency and time, thiourea concentration, release time, and temperature. A closed water bath aqua regia digestion-PUF enrichment thiourea elution-flame atomic absorption spectrometry method was established to determine the Au content in rock gold ores, by measuring the Au content of a series of national standard reference materials for rock gold ores and actual rock gold ore samples, and pushing the established method to other laboratories for verification. The results showed that key technical indicators such as detection limit, accuracy and precision of the established method meet the relevant national standards for rock gold ore determination, and meet the requirements of geological laboratories for the determination of Au content in rock gold ores. Compared with the methods such as fire assay and activated carbon adsorption, it is safer, more environmentally friendly, time-saving, labor-saving, easy to master, efficient and cost-effective.

Data availability

All data generated or analyzed during this study are included in this published article.

Author contributions

Shunxiang Wang: conceptualization, methodology, formal analysis, data curation, writing – original draft, visualization. Hongcheng Wang and Xiang Xia: methodology, software, formal analysis, investigation, data curation. Cang Gong: conceptualization, writing – review & editing, supervision.
