Investigating the enhancement of the rate of CO₂ capture of CaO in the presence of steam through ¹⁸O isotope labeling: pitfalls and findings

Felix Donat * and Christoph R. Müller *

The reaction of CO₂ with CaO to form CaCO₃ can be used to remove CO₂ from gas streams in post-combustion CO₂ capture schemes at high temperatures (>600 °C). The rate of CO₂ uptake is increased substantially in the presence of steam, but the underlying reasons have not yet been resolved, although several explanations have been proposed in the literature. In our study we generated steam from labeled water (H₂¹⁸O) to track ¹⁸O in the gas and solid products using mass spectrometry and Raman spectroscopy, aiming to understand whether oxygen (or OH⁻) contained in H₂O participates directly in the formation of CaCO₃. Unfortunately, it was not possible to investigate the interaction of H₂¹⁸O with CaO/CaCO₃ isolated, because in the presence of CO₂ oxygen was exchanged between H₂O and CO₂ in the high-temperature reaction chamber of the thermogravimetric analyzer before any interaction of the gaseous reactants with the sorbent. ¹⁸O was detected in the CaCO₃ product, but it originated from ¹⁸O in CO₂ rather than H₂O. Yet, our measurements suggest that oxygen exchange occurs between CaO and H₂O under reaction conditions, but not between CaCO₃ and H₂O/CO₂, which may motivate further investigations.

1. Introduction

Calcium looping is a promising technique to capture CO₂ from point sources at high efficiency.^{1–3} On a process level, CaO-based sorbents react with CO₂ contained in flue gases from combustion or other CO₂ emitting processes at temperatures between 600 and 700 °C (carbonation), removing up to 90% of the CO₂.^{4–6} The resulting CaCO₃ is decomposed subsequently at a high temperature (>900 °C) to release CO₂ and recover the CaO-based sorbent (calcination). The CO₂ obtained from the decomposition of CaCO₃ can be compressed and stored underground, or used as a feedstock in chemical conversion processes.^{7,8} CaO-based sorbents tend to lose their activity for fast CO₂ sorption with increasing number of cycles of CO₂ sorption and release. The high theoretical CO₂ uptake capacity of 0.78 g CO₂ per g CaO is practically not achievable owing to sintering that reduces surface area and pore volume.³ During carbonation, CO₂ molecules need to diffuse through a network of narrow pores within the sorbent particle, and as pores close due to the built-up of the product CaCO₃, the rate of CO₂ sorption decreases; some of the CaO contained in the sorbent particle is not even accessible for CO₂ at all within typical residence times.

Interestingly, small quantities of steam (even <1 vol%) present in the CO₂-containing gas increase the rate of CO₂

sorption of CaO (*viz.*, the rate of CaCO₃ formation).⁹ The increase is most significant when intraparticle diffusion controls the rate of CO₂ sorption, indicating that steam influences the diffusional transport of CO₂ within the sorbent. Steam is also known to accelerate the decomposition of CaCO₃ (ref. 10–13) and affect the structural and morphological properties of the CaO formed,^{11,14,15} resulting sometimes even in an increase in mechanical strength.^{16,17} It has been observed that the CO₂ uptake of limestone-derived CaO was improved under dry conditions when the decomposition of CaCO₃ in the previous reaction step was performed in the presence of steam, because the resulting pore structure of CaO was more favorable for fast CO₂ sorption, offering less intraparticle diffusional resistance for CO₂ molecules.^{9,18}

Despite numerous studies, the mechanism of the enhancing effect of steam during CO₂ sorption at high temperatures (>600 °C) is still not fully understood. An overview of relevant investigations concerning the effect of steam on the carbonation reaction has been provided recently by Dunstan *et al.*,³ building up on earlier work by Zhang *et al.*¹⁹ Several studies have hypothesized that OH⁻ groups originating from the dissociative adsorption of steam on the surface of CaO play an important role,^{20,21} but no experimental evidence has been provided yet; note that the phase Ca(OH)₂ is thermodynamically not stable at ambient pressure at temperatures >550 °C, and is therefore not expected to contribute as an intermediate species to the faster CO₂ sorption. Coverage of the CaO surface with OH⁻ would not explain why the enhancement of the rate of CO₂ sorption is

Laboratory of Energy Science and Engineering, Department of Mechanical and Process Engineering, ETH Zürich, Leonhardstrasse 21, 8092 Zürich, Switzerland. E-mail: donatf@ethz.ch; muelchri@ethz.ch

most noticeable once a significant amount of CaO has been converted into CaCO₃ already. Li *et al.*^{22,23} proposed a mechanism that considers diffusional transport in the CaCO₃ product layer: H₂O molecules dissociate on the CaCO₃ surface (gas–solid interface), forming H⁺ and OH[−]. Given the small radius of H⁺, it diffuses rapidly through the CaCO₃ product to the CaO–CaCO₃ interface, where it reacts with O^{2−} to form OH[−]. OH[−] diffuses outwards to the CaCO₃–gas interface to react with CO₂, forming CO₃^{2−} that diffuses inwards through the CaCO₃ product layer to the CaO–CaCO₃ interface, where new CaCO₃ is ultimately formed. OH[−] diffusion is faster than O^{2−} diffusion under dry conditions and so is assumed to explain the increase in the rate of CaCO₃ formation in the presence of steam; note that the counter-current diffusion mechanism of CO₃^{2−} and O^{2−} under dry conditions was experimentally demonstrated by Sun *et al.*²⁴ through an inert marker experiment. Strictly speaking, it is not the OH[−] on the surface (which originates from the dissociation of H₂O) that participates in the formation of CaCO₃, but the OH[−] formed following proton (H⁺) diffusion and reaction with O^{2−}. This is different from recent density functional theory (DFT) results to understand the promotion of CO₂ sorption on Li₄SiO₄-based sorbents with water vapor, which conclude that surface OH[−] contributes to the enhanced CO₂ uptake.²⁵

An interesting body of literature deals with the diffusion of oxygen, hydrogen and carbon in minerals (including the calcite polymorph of CaCO₃), relevant to many geological processes such as fluid–rock interactions or the growth of minerals.²⁶ Using isotope tracers such as ¹⁸O or ¹³C and ion microprobes, it was found that volume/lattice diffusion of oxygen is improved substantially (by at least 1–2 orders of magnitude) in the presence of water, whereas carbon and cations diffusion are hardly affected by the presence of water (400–800 °C, total pressure 0.1–350 MPa).^{27,28} In many types of minerals such as quartz, feldspars and calcite, molecular H₂O rather than OH[−] was identified as the dominant diffusing species bearing oxygen under hydrothermal conditions, as oxygen transport depended linearly on water fugacity.^{29–31} The rate of diffusion of oxygen is believed to be controlled by reactions at the surface of calcite,^{32,33} which may be relevant also for typical calcium looping conditions. Specifically, adsorption of H₂O and the creation of vacancy defects at the surface explain the dependence of the diffusivity of oxygen on the fugacity of water. The dissociation of water on the calcite surface supplies protons that hydrolyze and weaken C–O bonds in calcite akin to Si–O bonds in silicates, and thus makes oxygen exchange between H₂O and structurally bound oxygens energetically favorable.^{30,32} Carbonate ion (CO₃^{2−}) was identified as the dominant carbon-containing diffusing species in calcite from measurements of the oxygen/carbon exchange rate ratio.³⁴ Furthermore, there has been little evidence that hydrogen itself diffuses into calcite, and it has been concluded that hydrogen cannot be responsible for the increased diffusivity of oxygen in calcite.³²

In this work, we investigate whether oxygen contained in steam (or OH[−] groups originating from steam) is involved directly in the formation of the CaCO₃ product. Such involvement (or non-involvement) would shed light on the sequence of reactions that lead to CaCO₃ formation, and help understand

whether steam contributes to the increased rate of CO₂ uptake as a carrier of oxygen. Thus, we co-feed steam containing the oxygen isotope ¹⁸O (*i.e.*, H₂¹⁸O) during the carbonation reaction, use Raman spectroscopy to detect ¹⁸O in the CaCO₃ formed, and mass spectrometry to detect ¹⁸O in the CO₂ released from the CaCO₃.

If, as proposed by Li *et al.*,²³ OH[−] groups originating from the reaction of H⁺ (from the dissociation of H₂¹⁸O) with O^{2−} at the CaO–CaCO₃ interface interact with CO₂ molecules and form CO₃^{2−}, then any CO₂ released during the decomposition of CaCO₃ should not contain ¹⁸O because the origin of O^{2−} is not the H₂¹⁸O molecule. If, however, oxygen or OH[−] groups from H₂¹⁸O on the surface of CaO/CaCO₃ (the solid–gas interface) participate in the formation of CO₃^{2−}, then the CO₂ released during the decomposition of CaCO₃ should indeed contain ¹⁸O, *e.g.*, as C¹⁶O¹⁸O or C¹⁸O₂. Generally, any indication of ¹⁸O in the CO₂ released from the sorbent (beyond their natural abundance) would imply that steam participates actively in the formation of CaCO₃ rather than acting as a catalyst or functioning by other means; this would also disprove the mechanism proposed by Li *et al.* as the only pathway by which steam enhances the rate of CO₂ sorption/CaCO₃ formation. Not detecting ¹⁸O in the CO₂ released from the decomposition of CaCO₃ would not directly prove the mechanism proposed by Li *et al.* but demonstrate that oxygen or OH[−] groups originating from steam do not contribute to the formation of CO₃^{2−} and CaCO₃.

2. Experimental materials and methods

2.1 CaO-based sorbent

Natural limestone (Rheinkalk, >98 wt% CaCO₃, surface area ~1 m² g^{−1}) was used in all experiments as the precursor for CaO. Prior to the experiments using a thermogravimetric analyzer (TGA), limestone particles were calcined at 900 °C in N₂ for 30 min, followed by cooling to room temperature. The sorbent particles were then sieved to 150–212 μm to ensure that in the TGA experiments their packing inside the crucible had no influence on the CO₂ transport that would otherwise affect the observed rate of CO₂ uptake.³⁵

2.2 Material characterization

Raman spectroscopy on powdery, partially carbonated samples was performed using a Thermo Scientific DXR Raman microscope (laser wavelength 455 nm). The crystalline phases of the powdery samples were analyzed *via* X-ray diffraction (XRD) using a PANalytical Empyrean X-ray diffractometer (Cu K α radiation, 45 kV and 40 mA) equipped with a X'Celerator Scientific ultrafast line detector and Bragg–Brentano HD incident beam optics.

2.3 Thermogravimetric analyzer (TGA) setup

CO₂ sorption experiments were carried out using a TGA (Mettler Toledo, TGA/DSC1, volume of the high-temperature reaction chamber: 16 ml) following the same principal protocol: sorbent

particles (15–20 mg) were loaded into a shallow, 30 μl crucible made of aluminum oxide and heated to 900 $^{\circ}\text{C}$ in N_2 . After 15 min, the temperature was reduced to 650 $^{\circ}\text{C}$ (CO_2 sorption temperature). The gas atmosphere was changed from pure N_2 to 15 vol% CO_2/N_2 for 20 min for CO_2 sorption in the presence or absence of steam. 15 vol% CO_2/N_2 was used to reflect typical CO_2 concentrations in post-combustion CO_2 capture, and enable comparison with previous works. Subsequently, the gas atmosphere was changed back to N_2 , and the temperature was increased to 950 $^{\circ}\text{C}$ (CO_2 release temperature). After holding at 950 $^{\circ}\text{C}$ for 10 min, the temperature was decreased to 650 $^{\circ}\text{C}$ for a new reaction cycle to begin. Note that only the CO_2 sorption stage was performed in the presence of steam, but not the heating, cooling and CO_2 release stages. Heating and cooling rates were 30 $^{\circ}\text{C min}^{-1}$ and the total flow rate was always 100 ml min^{-1} (incl. 25 ml min^{-1} of dry N_2 purge over the micro-balance), as measured and controlled at normal temperature and pressure by mass flow controllers (Bronkhorst, EL-FLOW).

Steam was generated by flowing 60 ml min^{-1} of N_2 (or 60 ml per min N_2 and 15 ml per min CO_2 , see details below) through a small gas washing bottle (volume 5 ml) filled with deionized water or water containing the isotope ^{18}O (labeled water, H_2^{18}O , 97 atom% ^{18}O , Sigma-Aldrich) at ambient temperature, as shown in Fig. 1. Separate measurements using a humidity probe (Sensirion, SHT31) showed $\sim 90\%$ saturation of the gas stream with water. The temperature of the laboratory (and the water in the gas washing bottle) varied between 22 and 24 $^{\circ}\text{C}$, and hence the steam concentration in the reaction chamber of the TGA was $\sim 1.5\text{--}2.0$ vol% (a larger flow rate through the saturator and a higher ambient temperature result in a higher steam concentration). A solenoid valve synchronized with the temperature program of the TGA enabled the sharp separation of dry and humid gas environments. In addition to the two types of water used (deionized water or water containing the isotope ^{18}O), two options for mixing CO_2 and steam/water prior to entering the TGA reaction chamber were investigated (Fig. 1). The first option aimed at mixing CO_2 and steam in the gas phase; thus, pure N_2 flowed through the saturator and was mixed with the CO_2 stream after the saturator just before entering the reaction chamber of the TGA. For the second option, a mixture of N_2 and CO_2 flowed through the saturator, such that also CO_2 was mixed with liquid water to generate steam; this option was always used when deionized water was used.

The gas outlet from the TGA was connected directly to a mass spectrometer (MS, MKS Cirrus 3) through a heated transfer line

Table 1 Relative intensities of the different mass-to-charge ratios (m/z) for the relevant gas species³⁶

Mass-to-charge ratio (m/z)	Species					
	H_2^{16}O	H_2^{18}O	$^{16}\text{O}_2$	C^{16}O_2	$\text{C}^{16}\text{O}^{18}\text{O}$	C^{18}O_2
18	100	n/a	0	0	n/a	n/a
20	0.3	100	0	0	n/a	n/a
32	0	0	100	0	n/a	n/a
44	0	0	0	100	n/a	n/a
46	0	0	0	0.4	100	n/a
48	0	0	0	0	n/a	100

to analyze the composition of the product gases, and to detect ^{18}O in CO_2 and H_2O (see Table 1). When changing the atmosphere from 15 vol% CO_2/N_2 to pure N_2 after the CO_2 sorption stage, the release of CO_2 from the sample did not occur immediately, but required higher temperatures (>700 $^{\circ}\text{C}$) for kinetic reasons. The MS was sufficiently fast to resolve the two events of (i) a decreasing CO_2 signal due to the change in atmosphere from 15 vol% CO_2/N_2 to pure N_2 , and (ii) an increasing CO_2 signal due to the release of CO_2 from the sample during the decomposition reaction when heating to 950 $^{\circ}\text{C}$.

3. Results

3.1 TGA cyclic performance and MS signals

Fig. 2a and b compare the normalized sample mass of the limestone-based sorbent under dry and humid conditions over five cycles of CO_2 sorption and release. A value of one implies that the sorbent is calcined completely, and any increase in normalized sample mass is due to the sorption of CO_2 when the material transitions from CaO to CaCO_3 . The difference between the normalized sample mass and one is thus equivalent to the CO_2 uptake in g CO_2 per g sorbent , and it can reach a maximum value of ~ 0.77 for this particular sorbent for the case that all CaO is converted into CaCO_3 (the normalized sample mass would then show a value of 1.77).

Under dry conditions, the CO_2 uptake observed at the end of the CO_2 sorption stage decreased gradually with cycle number, as is commonly observed for limestone-based sorbents.³⁷ Under humid conditions, the CO_2 uptake was significantly higher and even increased slightly with cycle number. Whether deionized water, labeled water, or a mixture of deionized and labeled water was used during carbonation did not affect the observed rate and extent of the CO_2 uptake during the five cycles of CO_2

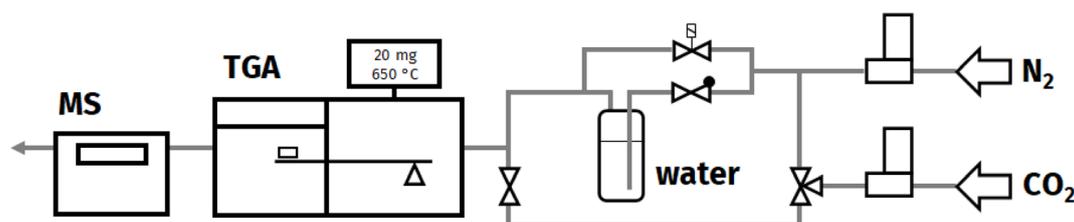

Fig. 1 Schematic illustration of the experimental setup using TGA and MS, and the steam injection system.

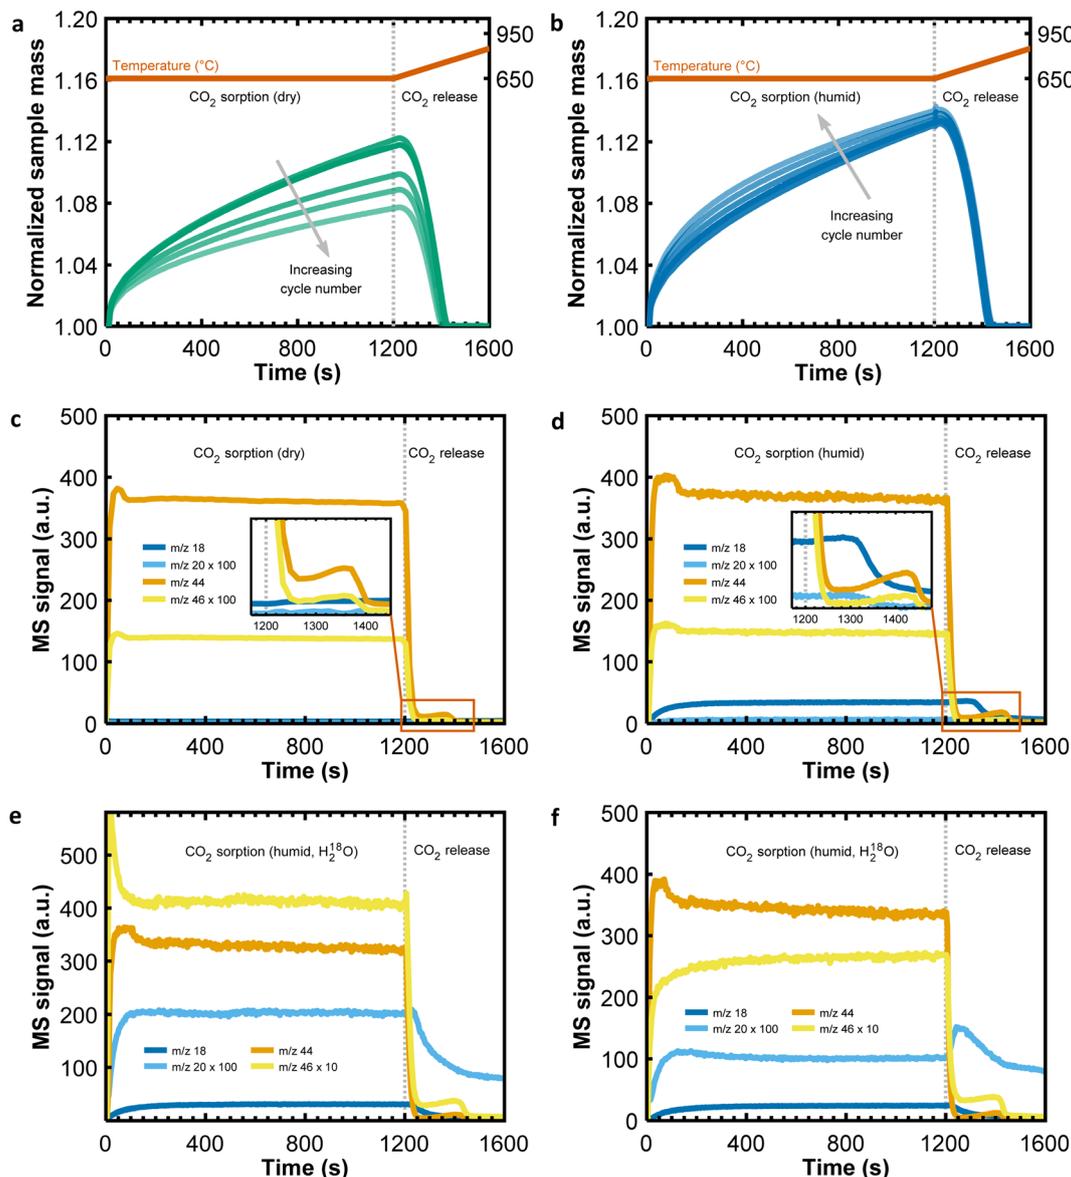

Fig. 2 Results from the TGA experiments over five cycles of CO₂ sorption and release using a limestone-based sorbent. (a) CO₂ sorption in a dry CO₂-containing atmosphere. (b) CO₂ sorption in a humid CO₂-containing atmosphere using deionized water. (c) and (d) Show the MS signals corresponding to the TGA measurements shown in (a) and (b) for the fifth carbonation cycle. (e) and (f) Show the MS signals that correspond to the same cycling experiment shown in (b), but using steam derived from labeled water (H₂¹⁸O) instead of deionized water; in (e) both N₂ and CO₂ flowed through the saturator, whereas in (f) only N₂ flowed through the saturator.

sorption and release (supplementary plots in Fig. 4a and b). Also, small variations in the steam concentration (due to minor temperature variations in the laboratory, the different flow rates of gas through the saturator, or the water level in the saturator) had no noticeable effect on the observed CO₂ uptake. Adding steam to the CO₂-containing atmosphere during the CO₂ sorption stage increased the rate of CO₂ sorption even after a substantial amount of CaCO₃ had been formed already under dry conditions (shown below in Fig. 4c). From Fig. 2a and b it is apparent that CO₂ was released from the sorbent before the CO₂ release temperature of 950 °C was reached, but whether steam was present during the CO₂ sorption stage or not did not affect the rate of the subsequent decomposition of CaCO₃ noticeably.

Fig. 2c and d plot the MS signals under dry and humid conditions, respectively, recorded during the fifth reaction cycle, whereas Fig. 2e and f show the MS signals recorded during the fifth reaction cycle when labeled water (H₂¹⁸O) instead of deionized water (H₂¹⁶O) was used to generate steam; note that the MS signals are plotted on a linear scale and that the intensity of some signals (e.g., *m/z* 20 or *m/z* 46) was magnified for illustration purposes. Under dry conditions (Fig. 2c) signals due to CO₂ (*m/z* 44 and 46) were observed, whereas in the presence of unlabeled steam (containing only ¹⁶O, Fig. 2d) also signals due to H₂O (*m/z* 18 and 20) were observed. When changing the atmosphere from (dry or humid) 15 vol% CO₂/N₂ to pure N₂ at the end of the carbonation stage,

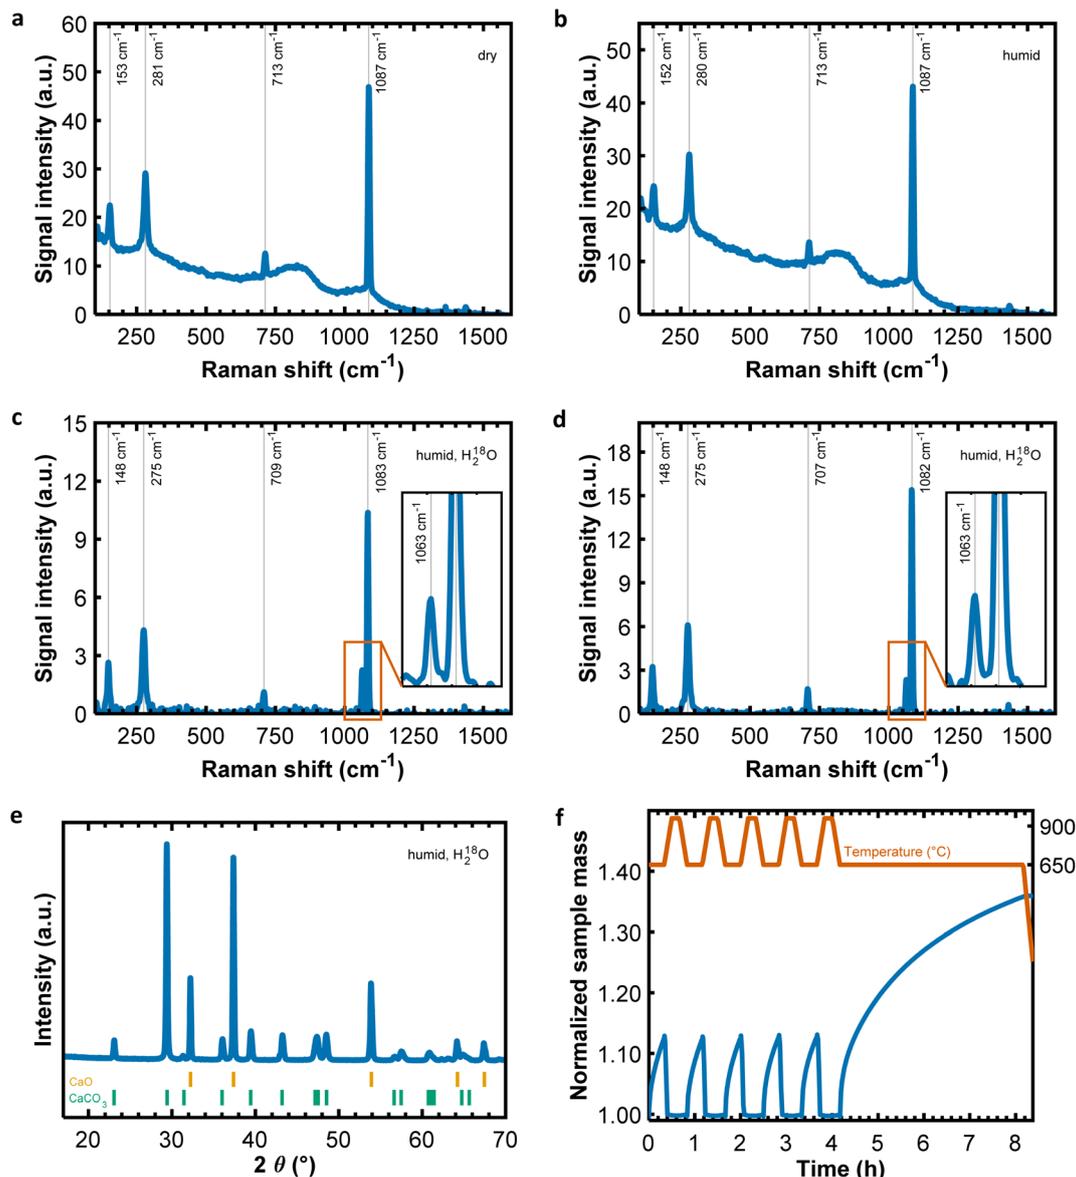

Fig. 3 (a)–(d) Raman spectroscopy measurements of partially carbonated sorbents after five reaction cycles plus an extended carbonation for 4 h. The order of the plots is the same as in Fig. 2c–f, corresponding to the different atmospheres during the carbonation stage (dry, humid (H_2^{16}O), humid (H_2^{18}O) with N_2 and CO_2 flowing through the saturator, and humid (H_2^{18}O) with only N_2 flowing through the saturator). (e) XRD measurement of a partially carbonated sorbent (using labeled water H_2^{18}O). (f) Example of a TGA experiment (here using deionized water H_2^{16}O) to produce the samples for the subsequent analyses shown in (a)–(e).

there was a rapid decrease in the signal due to CO_2 (m/z 44 and 46, seen in all of the Fig. 2c–f), followed by a slight, short increase due to the release of CO_2 from the material when the temperature approached ~ 700 °C. Under humid conditions (Fig. 2d–f), the CO_2 uptake was greater, and so it took slightly longer to release all CO_2 captured during the subsequent heating step in dry N_2 (this is seen also from the mass changes in Fig. 2a and b). Interestingly, when steam was present during the CO_2 sorption stage at 650 °C, the MS signals due to steam (m/z 18 and 20) did not return to zero immediately after the atmosphere had been changed back to dry N_2 , and even increased slightly with increasing temperature (this is seen best in the inset of Fig. 2d for m/z 18 or in Fig. 2f for m/z 20). Blank

measurements without any sample in the crucible show similar trends (Fig. 5a and b), implying that the slow decrease of the MS signals due to steam (m/z 18 and 20) when changing the atmosphere back to dry N_2 was related to the experimental setup rather than any material-related effects. Importantly, the MS signals in Fig. 2e and f show the release of CO_2 containing ^{18}O during the CO_2 release stage ($\text{C}^{16}\text{O}^{18}\text{O}$, m/z 46), indicating that a substantial amount of CaCO_3 containing one ^{18}O had formed during the previous carbonation stage in the presence of H_2^{18}O (note the difference in magnification of m/z 46 compared to Fig. 2d). At first sight, this observation would confirm that steam indeed participates actively in the formation of CaCO_3 , as discussed in the introduction.

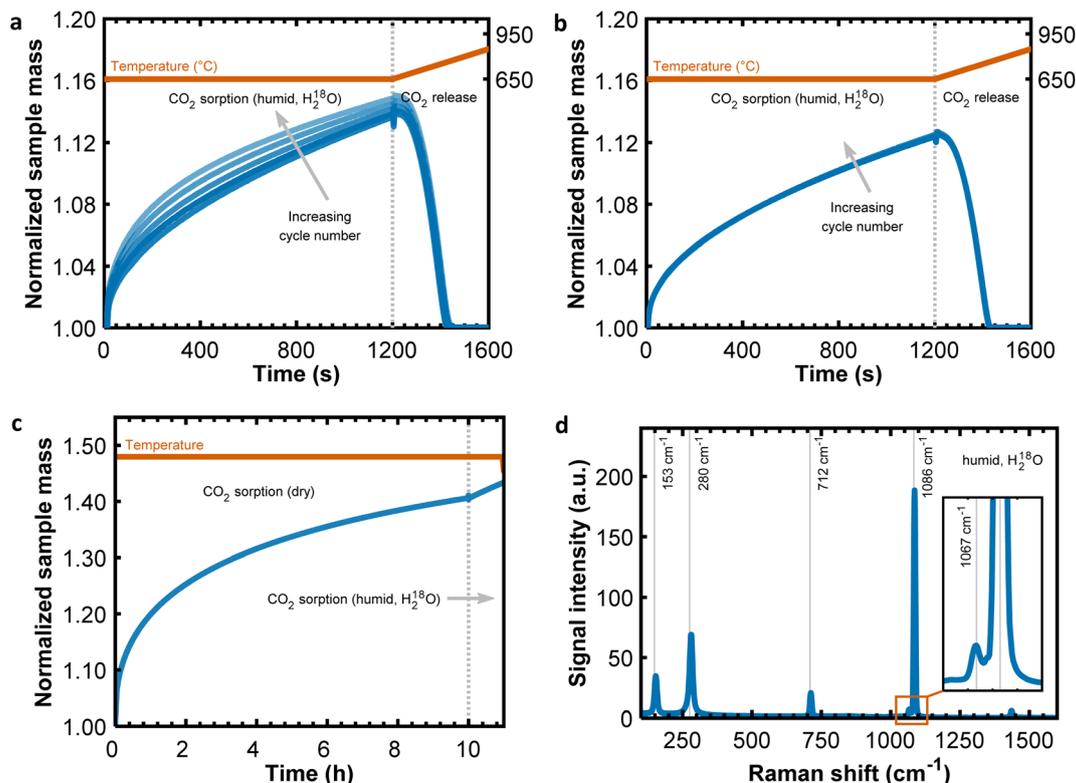

Fig. 4 Results from TGA experiments of CO₂ sorption and release using a limestone-based sorbent. (a) CO₂ sorption in a humid CO₂-containing atmosphere using steam derived labeled water (H₂¹⁸O) with both N₂ and CO₂ flowing through the saturator. (b) CO₂ sorption in a humid CO₂-containing atmosphere using labeled water (H₂¹⁸O) with only N₂ flowing through the saturator, two cycles only. (c) Long CO₂ sorption under dry conditions at 650 °C; after 10 h CO₂ sorption continued using steam derived from labeled water (H₂¹⁸O), showing an increase in the rate of CO₂ uptake. (d) Raman spectroscopy measurements of the sample shown in (c).

3.2 Oxygen exchange between steam and carbon dioxide at elevated temperature

However, the release of CO₂ containing ¹⁸O (C¹⁶O¹⁸O, *m/z* 46) is not sufficient to confirm the participation of steam in the formation of calcium carbonate, because the origin of ¹⁸O is not clear yet. From control experiments (Fig. 6) and literature reports for CaCO₃ (ref. 38) and MgCO₃,³⁹ there is no indication that oxygen of crystalline CaCO₃ would be exchanged with ¹⁸O contained in gas-phase H₂O or CO₂ that would have resulted in the formation CaC¹⁸O¹⁶O₂. However, although almost pure labeled water (>97 atom% ¹⁸O) was used in the measurements shown in Fig. 2e and f, the intensity of *m/z* 18 (due to H₂¹⁶O) was significantly greater than the intensity of *m/z* 20 (due to H₂¹⁸O). Similarly, the intensity of *m/z* 46 (due to C¹⁶O¹⁸O) relative to *m/z* 44 (due to C¹⁶O₂, for simplicity written as CO₂) during the CO₂ sorption stage was greater than expected from Table 1 or Fig. 2c and d, suggesting that ¹⁸O was exchanged between the H₂¹⁸O and CO₂ in the reaction chamber of the TGA before interacting with the sorbent. A comparison of the MS signals (in particular the ratio *m/z* 46/20) in Fig. 2e (mixing of CO₂ and H₂¹⁸O in the saturator) and Fig. 2f (mixing of CO₂ and H₂¹⁸O in the gas phase downstream of the saturator just before entering the reaction chamber of the TGA) hints that the mixing of CO₂ and H₂¹⁸O in the gas phase led to a slightly stronger oxygen exchange/scrambling (*m/z* 46/20 ≈ 26, compared to *m/z* 46/20 ≈ 20 for

the mixing of CO₂ and H₂¹⁸O in the saturator). The ratio *m/z* 44/46 was ~10 and agreed reasonably well with the ratio of the nominal concentrations of CO₂ (15 vol%) and H₂¹⁸O (~1.6 vol%) in these experiments when most of the ¹⁸O has been exchanged between H₂¹⁸O and CO₂. The initial peak of *m/z* 44 when switching from pure N₂ to 15 vol% CO₂/N₂ at the beginning of the CO₂ sorption stage was due to a short overshoot of the CO₂ flow rate when activating the mass flow controller (Fig. 2c–f). A corresponding spike in *m/z* 46 due to oxygen exchange (not due to the natural appearance of *m/z* 46 in CO₂, as seen in Fig. 2c, d and Table 1) was observed only when CO₂ and H₂¹⁸O mixed in the saturator, because slightly more H₂¹⁸O was taken up by the larger flow of gas (Fig. 2e), but not when CO₂ and H₂¹⁸O mixed in the gas phase (Fig. 2f).

Interestingly, there was hardly any signal due to *m/z* 48 in any of the experiments shown in Fig. 2a–f, suggesting that the ¹⁸O in H₂¹⁸O was exchanged with only one of the two ¹⁶O atoms in CO₂; for C¹⁸O₂ to form through exchange reactions with H₂¹⁸O, multiple collisions of the same CO₂ molecule with H₂¹⁸O would have been required that are unlikely given the plug flow-type gas flow pattern in the reaction chamber of the TGA (Fig. 1). This is reflected also in the Raman spectra of the carbonated samples in Fig. 3 (collected after 5 cycles plus an additional carbonation for 4 h to enhance the signal intensity due to CO₃²⁻ species, shown exemplarily in Fig. 3f). The samples carbonated under dry or humid (H₂¹⁶O) conditions showed the most dominant

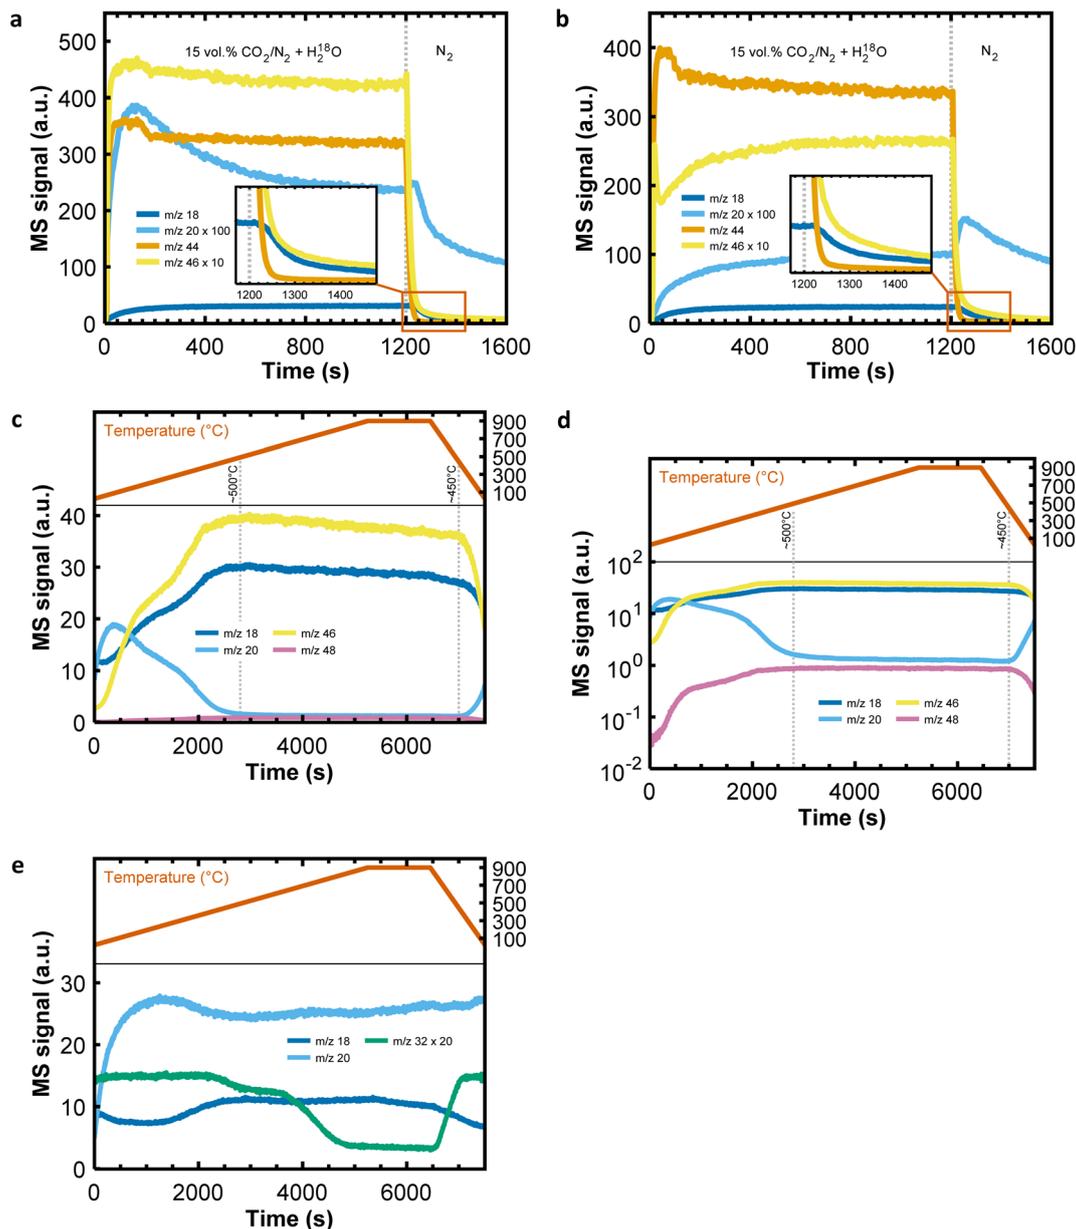

Fig. 5 Blank measurements (empty crucible) using the TGA-MS. (a) and (b) Show the MS signals corresponding to the experimental conditions in Fig. 2; in (a) both N_2 and CO_2 flowed through the saturator filled with labeled water (H_2^{18}O), whereas in (b) only N_2 flowed through the saturator. (c) and (d) MS signals showing the influence of temperature on the exchange of oxygen between H_2O and CO_2 ; in (c) the MS signals are plotted on a linear scale, whereas in (d) the MS signals are plotted on a logarithmic scale. (e) Influence of temperature on the stability of the MS signals due to water (m/z 18 and m/z 20) in the absence of CO_2 ; here, pure N_2 flowed through the saturator filled with a mixture of deionized water and labeled water (H_2^{18}O).

bands due to the ν_1 ($\sim 1087\text{ cm}^{-1}$), ν_4 ($\sim 713\text{ cm}^{-1}$), ν_{13} ($\sim 281\text{ cm}^{-1}$) and ν_{14} ($\sim 153\text{ cm}^{-1}$) vibrational modes of CO_3^{2-} species (Fig. 3a and b). The corresponding bands for the samples carbonated under humid conditions using H_2^{18}O were red shifted slightly, and an additional peak due to ^{18}O replacing one of the three ^{16}O atoms in the carbonate group was observed (ν_1 vibration, $\sim 1063\text{ cm}^{-1}$, Fig. 3c and d). Additional peaks near $\sim 1050\text{ cm}^{-1}$ and $\sim 1030\text{ cm}^{-1}$ would have been observed had more than one ^{18}O in the carbonate group been replaced;⁴¹ the absence (or presence below the detection limit) of these peaks agrees well with the insignificance of the MS signal m/z 48 (see

control experiments in Fig. 5c and d). The XRD pattern in Fig. 3e confirms that the partially carbonated samples consisted of unconverted CaO and the calcite phase of CaCO_3 only, but not any other polymorph of CaCO_3 (e.g., aragonite or vaterite), which might have produced similar additional ν_1 vibrations as the ^{18}O in the carbonate group.⁴⁰ Considering that the sorbent was exposed to no more than ~ 1.5 – $2\text{ vol}\%$ $\text{C}^{16}\text{O}^{18}\text{O}$ (assuming an extreme case in which all ^{18}O of H_2^{18}O was exchanged with ^{16}O in CO_2) and ~ 13 – $13.5\text{ vol}\%$ C^{16}O_2 , it is interesting to note that the ratio of the peak areas due to CaCO_3 with zero ^{18}O ($\text{CaC}^{16}\text{O}_3$ at $\sim 1087\text{ cm}^{-1}$) to CaCO_3 with one ^{18}O ($\text{CaC}^{18}\text{O}^{16}\text{O}_2$ at

$\sim 1063\text{ cm}^{-1}$) was \sim four, *i.e.*, much lower than expected from the CO_2 isotope composition in the gas stream.

3.3 Implications for the goal of this study to understand the role of steam

The exchange of oxygen between H_2^{18}O and CO_2 in the reaction chamber of the TGA is a problem for the examination of the promotional mechanism of steam for the carbonation reaction, because the presence of ^{18}O in the CaCO_3 formed (or the release of ^{18}O -containing CO_2 from the material upon decomposition) cannot be attributed solely to a reaction mechanism that involves steam (or its oxygen component); in fact, it is much more likely that the presence of ^{18}O in CaCO_3 (as observed by Raman spectroscopy in Fig. 3c and d) originated from $\text{C}^{16}\text{O}^{18}\text{O}$ rather than the remaining small quantity of H_2^{18}O in the gas stream. Fig. 5c shows that the exchange of oxygen between H_2^{18}O (here only $\sim 0.1\text{ vol}\%$ due to the dilution of H_2^{18}O with H_2^{16}O (5:95) in the saturator) and CO_2 (15 vol%) is temperature-dependent, and with increasing temperature, more oxygen was exchanged between the two.⁴² Above $\sim 500\text{ }^\circ\text{C}$ the ratios of the MS signals due to steam (m/z 18 and 20) and CO_2 (m/z 44, 46 and 48) remained constant. From Fig. 5e it is apparent that in the absence of ^{16}O -containing gas species there

was no significant change in the intensity of the MS signal due to m/z 20. Traces of O_2 present in N_2 ($\sim 80\text{ ppm}$, m/z 32) appear to have exchanged ^{16}O with H_2^{18}O , but m/z 34 or m/z 36 were not measured in this experiment to confirm this observation.

Interestingly, the ratio m/z 18/20 ≈ 22 above $500\text{ }^\circ\text{C}$ (Fig. 5c) was an order of magnitude lower than ~ 330 expected from Table 1 when assuming that ^{18}O from H_2^{18}O is exchanged to the level of its natural abundance in water; the short residence time (a few seconds) of the gas molecules in the high-temperature reaction chamber of the TGA may possibly have prevented an even higher degree of oxygen exchange to reach isotopic equilibrium. The lack of significant back-mixing in the reaction chamber of the TGA (as opposed to a closed system such as an autoclave), the fast rate of oxygen exchange above $500\text{ }^\circ\text{C}$, and the short gas residence time may have resulted in the exchange of only one ^{16}O in the CO_2 molecule by H_2^{18}O . The MS signal due to m/z 48 followed the same trend as m/z 46 (this is seen best when Fig. 5c is plotted on a logarithmic scale, Fig. 5d), indicating that indeed for a small fraction of CO_2 molecules entering the reaction chamber of the TGA both ^{16}O atoms in the CO_2 molecule were exchanged by two different H_2^{18}O molecules; however, the high ratio m/z 46/48 ≈ 42 shows that the exchange of only one oxygen atom in the CO_2 molecule with H_2^{18}O was dominant.

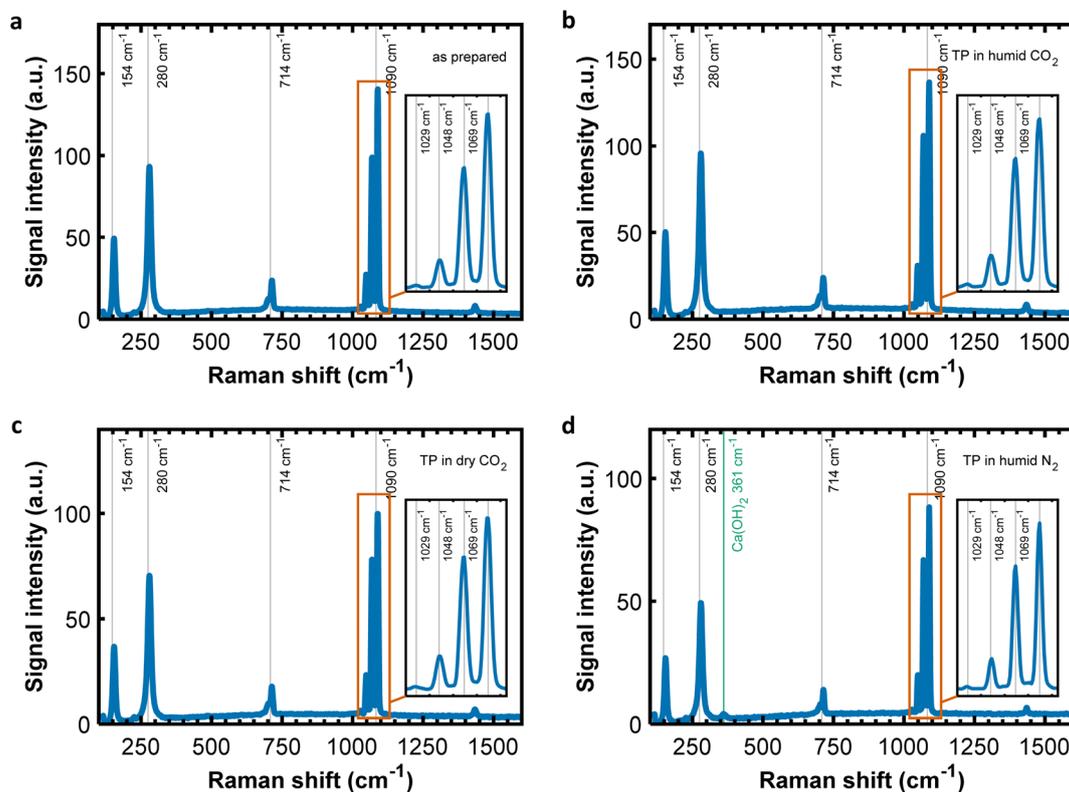

Fig. 6 Raman spectroscopy measurements of partially carbonated sorbents following a temperature-programmed (TP) treatment in a larger TGA under different conditions. (a) The partially carbonated sorbent was prepared by calcining CaCO_3 powder at $900\text{ }^\circ\text{C}$, followed by exposure to $5\text{ vol}\%$ CO_2 and $2\text{ vol}\%$ steam derived from labeled water (H_2^{18}O) at $700\text{ }^\circ\text{C}$ for 12 h. The CO_2 uptake was 0.75 g CO_2 per g sorbent. (b) The material prepared in (a) was heated from room temperature to $600\text{ }^\circ\text{C}$ in $5\text{ vol}\%$ CO_2 and $2\text{ vol}\%$ steam derived from deionized water. (c) The material prepared in (a) was heated from room temperature to $600\text{ }^\circ\text{C}$ in $5\text{ vol}\%$ CO_2 . (d) The material prepared in (a) was heated from room temperature to $600\text{ }^\circ\text{C}$ in $2\text{ vol}\%$ steam derived from deionized water. Ratio of peak areas ($\text{CaC}^{16}\text{O}_3$ at 1090 cm^{-1} and $\text{CaC}^{18}\text{O}^{16}\text{O}_2$ at 1069 cm^{-1}): 1.4 (a), 1.3 (b), 1.3 (c) and 1.3 (d).

For completeness, we performed an additional series of experiments using a TGA with a larger reaction chamber (~ 46 ml) to facilitate back-mixing of the reaction gas, and thereby enhance the probability of oxygen exchange between H_2O and CO_2 molecules. Commercial CaCO_3 powder (extra pure, Fisher Scientific) was calcined at 900°C in N_2 , followed by carbonation at 700°C in steam (~ 2 vol%, derived from labeled water) and CO_2 (~ 5 vol%) for 12 h. Indeed, Raman spectroscopy revealed additional features of the ν_1 vibration (Fig. 6a), indicating that the partially carbonated sorbent contained, in addition to the experiments performed in the smaller TGA, two and three ^{18}O in the carbonate group.⁴⁰ Upon further treatment of the material in atmospheres without ^{18}O , there was no noticeable change in the ratio of peak areas in the ν_1 region ($\text{CaC}^{16}\text{O}_3$ at 1090 cm^{-1} and $\text{CaC}^{18}\text{O}^{16}\text{O}_2$ at 1069 cm^{-1}), Fig. 6a–c. Thus, no measurable oxygen exchange occurred between gaseous CO_2 and, or, H_2O and the solid CaCO_3 over the timescale and conditions of our experiments (for comparison see *e.g.*, the work by Rosenbaum³⁴ who has reported carbon and oxygen isotope exchange for CO_2 and CaCO_3 at 900°C). The material treated in $\text{H}_2\text{O}/\text{N}_2$ decomposed slightly, explaining an additional Raman band due to $\text{Ca}(\text{OH})_2$ in Fig. 6d. Interestingly, the small peak at 1029 cm^{-1} in Fig. 6a–c originated from CaCO_3 containing three ^{18}O ($\text{CaC}^{18}\text{O}_3$). Since oxygen exchange between H_2^{18}O and CO_2 in the high-temperature reaction chamber of the larger TGA yielded, at best, C^{18}O_2 , a mixture of $\text{CaC}^{18}\text{O}_2^{16}\text{O}$, $\text{CaC}^{18}\text{O}^{16}\text{O}_2$ and $\text{CaC}^{16}\text{O}_3$ would be expected upon reaction with CaO . Thus, the results from Raman spectroscopy indicate that there must have been additional oxygen exchange between ^{18}O -containing H_2O or CO_2 and the solid phases CaO or CaCO_3 . With CO_3^{2-} diffusing through the CaCO_3 product layer toward the CaO – CaCO_3 interface,²⁴ oxygen (and carbon) exchange would be expected as part of the volume/lattice diffusion mechanism (involving possibly recrystallization or Ostwald ripening),^{34,43,44} but this was not observed in our experiments (Fig. 6a–c) and therefore ruled out as an explanation for the formation of $\text{CaC}^{18}\text{O}_3$. Given the relatively fast rates of carbonation under both dry and humid conditions (Fig. 2a and b), it is unlikely that volume/lattice diffusion was rate-controlling in our experiments.⁴⁵ Instead, diffusion along grain boundaries or narrow pores (note that CaCO_3 crystals formed during carbonation are far from perfect⁴⁶) may have dominated mass transport,⁴⁷ decreasing the likelihood of oxygen exchange between $\text{CO}_2/\text{CO}_3^{2-}$ and CaCO_3 .²⁶ It is thus possible that the presence of three ^{18}O in CaCO_3 originates from oxygen exchange with CaO . CO_2 would immediately form CaCO_3 when in contact with CaO , implying that H_2O is responsible for the exchange of oxygen with CaO that results in the formation of $\text{CaC}^{18}\text{O}_3$ upon further reaction with C^{18}O_2 . Similar results have been reported previously, suggesting that steam can interact with CaO above the decomposition temperature of $\text{Ca}(\text{OH})_2$.³⁸ Whether the oxygen exchange between steam and CaO under reaction conditions contributes to the accelerated rates of CO_2 uptake remains, however, uncertain but may motivate future research activities. The presence of steam alters the dominant transport mechanism of species required to form CaCO_3 (*viz.* carbon and oxygen),⁴⁸ but its identification and quantification is difficult

due to the challenging reaction conditions and the relatively short timescale of the carbonation reaction. From the absence of measurable oxygen exchange between H_2O or CO_2 and CaCO_3 we conclude that volume/lattice diffusion appears to play a negligible role in the carbonation reaction using limestone-derived particles, and therefore many mechanisms discussed in the literature such as the hydrolyzation and weakening of C–O bonds in CaCO_3 through protons, or the faster OH^- diffusion over O^{2-} diffusion through CaCO_3 may not apply under relevant reaction conditions.

Investigations of oxygen isotope exchange may not be suited to unveil the enhancement effect of steam during the carbonation of CaO at high temperatures, as there will always be oxygen exchange between the gaseous oxygen-containing reactants. The intrinsic properties of steam causing the acceleration of CO_2 uptake cannot be linked with the oxygen or hydrogen components, and oxygen atoms originating from the water molecule will inevitably end up in the CaCO_3 product through different sequences of oxygen exchange. However, our experiments did provide insights into the presence or absence of oxygen exchange between the gas and solid components involved in the carbonation reaction, from which information on the relevant transport processes can be obtained.

4. Conclusions

In calcium looping, the presence of steam is known to accelerate the rate of CO_2 uptake. We designed experiments in which steam derived from labeled water (H_2^{18}O) was used to promote CO_2 sorption in a TGA, and tracked ^{18}O in gaseous and solid products through mass spectrometry and Raman spectroscopy to obtain mechanistic insights into the enhancement effect, for example whether oxygen contained in steam contributes directly to carbonate formation. While we indeed observed the incorporation of ^{18}O into the calcite structure (and the release of ^{18}O -containing CO_2 in the subsequent decomposition step), we found that most of ^{18}O contained in labelled water was exchanged with ^{16}O contained in CO_2 in the high-temperature reaction chamber of the TGA before reaching the sorbent. Thus, the CO_2 contained a substantial fraction of ^{18}O before reacting with CaO to form CaCO_3 that contained ^{18}O . The degree of oxygen exchange between H_2O and CO_2 depended greatly on temperature, but also the contact time and the gas flow pattern in the high-temperature reaction chamber of the TGA. With the given reaction conditions and our experimental setup, it was not possible to eliminate oxygen exchange between H_2O and CO_2 completely. Using a larger TGA furnace facilitated back-mixing of gas and increased its residence time in the TGA, which in turn enhanced the degree of oxygen exchange such that not only $\text{C}^{18}\text{O}^{16}\text{O}$ but also C^{18}O_2 was formed. Consequently, Raman spectroscopy revealed the formation of CaCO_3 with zero, one, two and three ^{18}O atoms in the carbonate group.

Although the use of labelled water/steam was not suitable under the given reaction conditions to obtain unequivocal insight into why steam accelerates CO_2 uptake, oxygen interactions between solid and gas phases could be probed. Our results indicate that there is no oxygen exchange between solid

CaCO₃ and H₂O/CO₂ under reaction conditions relevant to calcium looping. However, oxygen exchange appears to occur between solid CaO and H₂O, which may contribute to the enhancement effect of steam, and motivate further investigations.
