Preparation of a nanoporous CoFe₂O₄/CoMoO₄ composite electrode material and a study on its performance in water electrolysis

 Haorui Liu,^{bc} Qi Zhou^{*ab} and Dedong Duan^b

In this study, a CoFe₂O₄/CoMoO₄ composite electrode material with a spinel structure (CoFe₂O₄) and a scheelite structure (CoMoO₄) was prepared by a hydrothermal method. The rich valence states and its unique morphological and structural advantages made the CoFe₂O₄/CoMoO₄ composite electrode material play a more effective synergistic catalytic role. Results of the electrochemical characterization showed that CoMoO₄ was attached to the CoFe₂O₄ skeleton structure in the composite electrode in a sheet form. At a current density of 50 mA cm⁻², the hydrogen evolution overpotential was 193 mV and the respective Tafel slope was 100.44 mV dec⁻¹, while the oxygen evolution overpotential was 319 mV and the corresponding Tafel slope was 70.47 mV dec⁻¹. At the same time, the overall water decomposition voltage was 1.55 V at a current density of 10 mA cm⁻², and the voltage changed only 11 mV for a 12 h continuous electrolysis, which suggested a good electrocatalytic water decomposition performance.

1 Introduction

The development of safe, clean and sustainable energy sources is a major topic and technological challenge of the 21st century.^{1–5} As a green energy source with high energy density, H₂ is widely regarded as the most promising clean and renewable energy source. Electrolysis of water for hydrogen production is an extremely attractive solution, which can produce hydrogen sustainably.^{6,7} Because the overpotential loss caused by the oxygen evolution reaction (OER) is usually much greater than the potential loss caused by the hydrogen evolution reaction (HER), the OER is often regarded as the bottleneck of water decomposition.^{8–10} Although precious metal catalysts such as Pt and RuO₂ have high catalytic activity, they are expensive and their reserves are limited, making it difficult to achieve large-scale application. In recent years, transition metal alloys,^{11,12} oxides,^{13,14} sulfides^{15,16} and phosphates^{17,18} have become hot topics in the field of electrocatalysis. Transition metal oxides are attractive alternatives to noble metal catalysts due to their low cost and high redox activity.

The development of non-precious metal oxide-based catalysts in alkaline solutions has become one of the most active

research areas in chemistry and materials science. Du *et al.*¹⁹ designed NiCo₂O₄ nanowires as the precursors with NiMoO₄ nanosheets compounded on the surface. The flower-like NiCo₂O₄@NiMoO₄ core-shell hybrid nanostructures were prepared by hydrothermal calcination. The OER overpotential of the composites was 250 mV at a current density of 10 mA cm⁻². When applied to integral water decomposition, the decomposition voltage was 1.55 V at a current density of 10 mA cm⁻². Zhang *et al.*²⁰ reported a novel NiMoO_{4-x}/MoO₂ hybrid electrocatalyst with atomically coupled nanointerfaces and a large number of Mo⁵⁺ ions. The NiMoO_{4-x}/MoO₂ electrocatalyst showed excellent electrocatalytic performance for both the HER and OER in alkaline media. The Tafel slopes were 31 mV dec⁻¹ and 69 mV dec⁻¹, and the overpotential of the HER and OER at a current density of 10 mA cm⁻² were 41 mV and 233 mV, respectively. It was used as a bifunctional electrode material for integral water decomposition and achieved a current density of 10 mA cm⁻² at a voltage of only 1.56 V.

In order to further improve the catalytic activity and stability of polymetallic oxide nanoporous electrode materials, a composite functional material was synthesized in this study. The flake-like CoMoO₄ was hydrothermally synthesized on a CoFe₂O₄ spinel skeleton, forming a composite with synergistic catalytic effects for efficient overall water splitting. The composite electrode exhibited a high catalytic activity and durable stability for the electrochemical reactions of OER and HER. In this study, the electrocatalytic water decomposition performance of transition metal oxides and their composites was also tested. The relationship between phase composition, microstructure and electrocatalytic performance was studied,

which provided a reference for the preparation of transition metal oxides and their composites in the field of electrocatalytic water decomposition.

2 Experimental

2.1 Preparation of the electrocatalysts

The precursor alloy ingots with theoretical atomic ratios of $\text{Co}_{1.7}\text{Fe}_{3.3}\text{Al}_{9.5}$ and $\text{Co}_{2.5}\text{Mo}_{2.5}\text{Al}_{9.5}$ were prepared by arc-melting the metal particles of cobalt (Co), iron (Fe), molybdenum (Mo) and aluminium (Al) with purity higher than 99.9%. After removing the oxide skin of the alloy ingots, the alloy strips were rapidly solidified in a vacuum strip machine under an argon atmosphere (the pressure of the quartz tube of the strip machine was 0.12 MPa, and the speed of the copper roller was 25 r s^{-1}), and subsequently, precursor alloy strips with a width of about 3–5 mm and a thickness of about 30–40 μm were obtained. The nanoporous Co–Fe and Co–Mo alloys were obtained by chemical dealloying. The corrosion of the $\text{Co}_{2.5}\text{Mo}_{2.5}\text{Al}_{9.5}$ alloy thin strip was carried out in a 1 mol L^{-1} KOH solution at $25 \text{ }^\circ\text{C}$ for 24 h, while the corrosion of $\text{Co}_{1.7}\text{Fe}_{3.3}\text{Al}_{9.5}$ was carried out in a 6 mol L^{-1} KOH solution at $65 \text{ }^\circ\text{C}$ for 12 h. The dealloyed samples were thoroughly rinsed with deionized water and anhydrous ethanol until a neutral pH was achieved, followed by drying in a 563 vacuum oven at $60 \text{ }^\circ\text{C}$ for 6 h. The dried samples were then transferred to a porcelain boat and placed in a heat treatment furnace, with the temperature increased at a rate of $1 \text{ }^\circ\text{C min}^{-1}$. The samples were heated to $350 \text{ }^\circ\text{C}$ and maintained at this temperature for 2 h. Finally, nanoporous CoFe_2O_4 and CoMoO_4 were obtained after cooling to room temperature.

Preparation of the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite electrode: A mixture of 0.01 mol L^{-1} $\text{Co}(\text{NO}_3)_2$, 0.01 mol L^{-1} Na_2MoO_4 and 0.1 mol L^{-1} urea was prepared for ultrasonic treatment. 30 mg of CoFe_2O_4 was added to this mixture and reacted at $150 \text{ }^\circ\text{C}$ for 8 h. Then, the obtained product was dried in a vacuum drying oven at $60 \text{ }^\circ\text{C}$ for 6 h. The dried powder was placed in a porcelain boat and kept at $400 \text{ }^\circ\text{C}$ in a heat treatment furnace for 2 h. After cooling to room temperature, the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite electrode material was obtained.

Preparation of CoMoO_4 on nickel foam: The nickel foam was first pretreated with 3 mol L^{-1} HCl and anhydrous ethanol for 10 minutes by sequential ultrasonic cleaning to remove surface impurities and oxide scales, respectively. Then, it was transferred to a vacuum drying oven and dried at $60 \text{ }^\circ\text{C}$ for 6 hours. CoMoO_4 was then synthesized *via* a hydrothermal method, using the same solution preparation and experimental conditions as those employed for the preparation of the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite electrode.

20 mg of the porous material obtained after drying was taken as the active material and mixed evenly with acetylene black, conductive graphite and polytetrafluoron according to the mass percentage of 80 : 7.5 : 7.5 : 5. Appropriate amount of anhydrous ethanol was added to this paste, coated on pre-treated nickel foam with an area of 1 cm^2 , and pressed into sheets after vacuum drying at $60 \text{ }^\circ\text{C}$ for 6 h. A three-electrode system was selected for the electrocatalytic test. The auxiliary electrode was a $15 \text{ mm} \times 10 \text{ mm}$ platinum sheet, the reference electrode was

saturated with calomel electrode, the working electrode was a foam nickel collector loaded with the active substances, and the electrolyte was a 1 mol L^{-1} KOH solution. N_2 was permeated throughout the electrocatalytic test.

2.2 Electrochemical measurements

A standard three-electrode cell system was employed, using the as-prepared sample as the working electrode, a $15 \text{ mm} \times 15 \text{ mm}$ Pt sheet as the counter electrode, and a saturated calomel electrode (SCE) as the reference electrode. The electrolyte was a 1 mol L^{-1} KOH solution. Throughout the electrochemical measurements, the electrolyte was continuously purged with N_2 to maintain a saturated environment. Prior to LSV testing, the prepared electrode was electrochemically activated by performing 30 cycles at a fast scan rate of 20 mV s^{-1} until the curve was stabilized. Then LSV measurements were conducted at 5 mV s^{-1} . For the HER and OER LSV test results, 80% IR compensation was applied; for the overall water splitting test results, IR compensation was not performed.

3 Results and discussion

Fig. 1 shows the XRD patterns of the $\text{Co}_{1.7}\text{Fe}_{3.3}\text{Al}_{9.5}$ and $\text{Co}_{2.5}\text{Mo}_{2.5}\text{Al}_{9.5}$ precursor alloys before and after strip dealloying and after oxidation. As can be seen from Fig. 1(a), the $\text{Co}_{1.7}\text{Fe}_{3.3}\text{Al}_{9.5}$ alloy is composed of two phases, Al (PDF#89-2769) and Co_2Al_9 (PDF#65-6460). No corresponding peak lines of Fe and Fe-containing phases are observed in the figure, which is due to the existence of a face-centered cubic structure of Co and Fe at the same time, resulting in a solid solution between them. After dealloying, two phases, namely, Co–Fe and Fe_3O_4 , (PDF#88-0315) are obtained. Due to the formation of the solid solution between Co and Fe, compared with the standard Fe (PDF#85-1410), the peak position here is shifted to a higher angle by 0.43° . Some amount of Fe is easily oxidized to Fe_3O_4 in the hot alkali environment of dealloying. So, there is a peak of Fe_3O_4 . As can be seen from Fig. 1(b), the $\text{Co}_{2.5}\text{Mo}_{2.5}\text{Al}_{9.5}$ alloy is composed of two phases, Al (PDF#89-2769) and Al_{12}Mo (PDF#29-0052). No Co is detected in the XRD pattern, which is also caused by the formation of a solid solution between Co and Mo. Compared with the standard Co (PDF#89-7093), the overall diffraction peak of the Co–Mo alloy obtained after dealloying of $\text{Co}_{2.5}\text{Mo}_{2.5}\text{Al}_{9.5}$ is shifted to a lower angle by 0.74° as the atomic radius of Mo is greater than that of Co after the formation of the solid solution between Co and Mo, resulting in the lattice distortion of Co. At the same time, the half-peak width of the diffraction peak becomes significantly wider after dealloying, indicating that the crystallinity of the Co–Mo alloy obtained after dealloying is low. Comparing XRD patterns after dealloying, it is found that no Al phase is detected after dealloying of the two precursor alloys, indicating that the dealloying is basically complete. Fig. 1(c) shows the phases of the CoFe_2O_4 and CoMoO_4 bimetallic oxides obtained by oxidation after dealloying. It can be seen from the figure that pure CoFe_2O_4 (PDF#79-1744) and CoMoO_4 (PDF#21-0868) are obtained after oxidation.

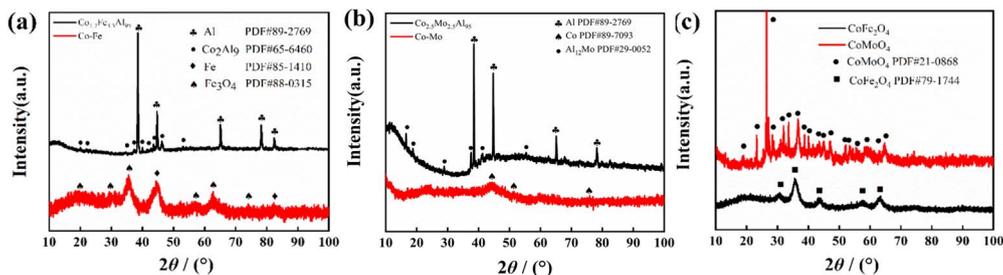

Fig. 1 XRD patterns of the precursor alloys (a) $\text{Co}_{1.7}\text{Fe}_{3.3}\text{Al}_{9.5}$ and (b) $\text{Co}_{2.5}\text{Mo}_{2.5}\text{Al}_{9.5}$ after dealloying and after oxidation (c).

Fig. 2 shows the SEM images of the precursor alloys after dealloying and oxidation. According to the SEM image of $\text{Co}_{1.7}\text{Fe}_{3.3}\text{Al}_{9.5}$ after dealloying (Fig. 2(a)), it can be seen that a small skeleton structure of 100 nm grows on a large skeleton structure, forming a unique “attachment” structure. It is worth noting that small mesoporous structures are distributed on the surface of both large and small scaffolds. This kind of “dependent” structure loaded with mesoporous structures can provide a broad active surface area in electrochemical processes and more active sites for electrocatalytic processes. Fig. 2(b) shows CoFe_2O_4 obtained after oxidation of $\text{Co}_{1.7}\text{Fe}_{3.3}$. Compared with the structure before oxidation, the small skeleton structure becomes rough, while the large skeleton structure supporting the small skeleton remains intact. It can be seen from Fig. 2(c) that the skeleton structure of the Co–Mo alloy after the corrosion of $\text{Co}_{2.5}\text{Mo}_{2.5}\text{Al}_{9.5}$ by KOH solution presents an “island” structure connected by ligaments. This is because the

$\text{Co}_{2.5}\text{Mo}_{2.5}\text{Al}_{9.5}$ alloy is composed of two phases: Al and Al_{12}Mo . Al, as an active phase, preferentially reacts at the solid/liquid interface to form a large pore structure, and then, the corrosive liquid enters the deep structure to react with Al atoms in the Al_{12}Mo phase. At the same time, under the unique “pinning” action of the Mo element,²¹ the corrosion liquid is able to react with the Al atoms in the Al_{12}Mo phase, forming an “island” structure with ligamentous connections. Fig. 2(d) shows that the ligament structure of the Co–Mo alloy still exists after oxidation, but the former “island” structure disappears and changes into a smaller skeleton structure, and a secondary ligament structure with a size of about 10–20 nm grows on the ligament structure. The evolution of this structure is due to the fact that after the Co–Mo alloy skeleton structure is oxidized, the introduced oxygen atoms cause the skeleton structure to be rough and the volume to expand, and the original “island” structure is completely transformed into a ligament-like

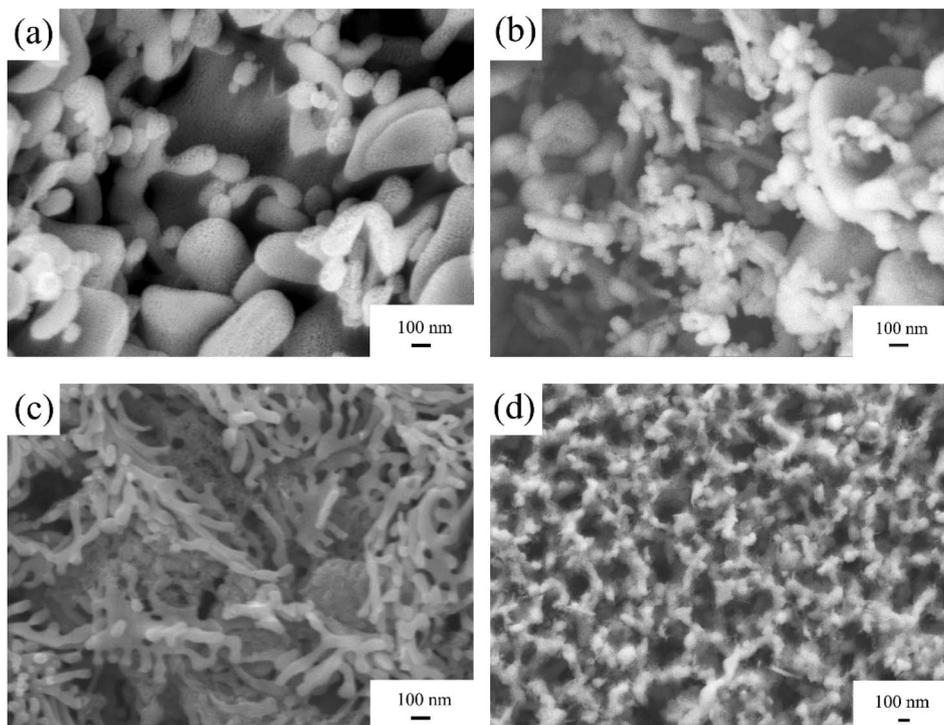

Fig. 2 SEM images of the precursor alloys after dealloying and oxidation: (a) $\text{Co}_{1.7}\text{Fe}_{3.3}$; (b) CoFe_2O_4 ; (c) $\text{Co}_{2.5}\text{Mo}_{2.5}$; and (d) CoMoO_4 .

structure, which is beneficial to the electrode material to provide more abundant reaction sites during the catalytic process.

Fig. 3(a) shows the XRD patterns of CoMoO_4 synthesized by the hydrothermal method on the nickel foam (NF) matrix. As can be seen from the figure, the peak position of CoMoO_4 (PDF#21-0868) is clearly visible, indicating that simple CoMoO_4 samples can be synthesized by this method. Fig. 3(b) shows the XRD patterns of the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite. It can be seen from the figure that the phase structure of the CoFe_2O_4 matrix (PDF#79-1744) did not change after the introduction of CoMoO_4 composite, indicating that two oxides with different phase structures were successfully prepared in this experiment.

Fig. 4 shows the SEM image of the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite electrode material. It can be seen from the figure that CoMoO_4 grows vertically on the surface of the CoFe_2O_4 skeleton in the form of sheets and folds *in situ*. This heterostructure with good compatibility can not only exert a synergistic effect of the composite materials but also increase the active surface area of the material, which is conducive to more abundant H^+ and OH^- adsorption and desorption, improving the electrocatalytic performance of the electrode material. In addition, the CoMoO_4 and CoFe_2O_4 structures show great structural compatibility. The vertically grown CoMoO_4 does not extensively cover the abundant structures on the CoFe_2O_4 matrix, thus preserving and

taking full advantage of its high specific surface area. The combination of the two structures will further increase the active sites for the electrochemical reaction and offer the structural advantages of both in the electrocatalytic reaction. Therefore, the CoFe_2O_4 matrix plays an important role in the composite material, providing support strength for the composite electrode material, and CoMoO_4 prepared by the hydrothermal method grows uniformly on the surface of the matrix. Both of them play important roles in the catalytic performance of the composite material due to their unique structural advantages.

In order to further study the composition of the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite electrode material and the distribution of each element, EDS surface scanning analysis was performed, as shown in Fig. 5. The EDS mapping shows a spatially uniform distribution of all elements (Co, Fe, Mo, O) without clear phase boundaries. This suggests that CoMoO_4 grows uniformly over the CoFe_2O_4 skeleton, thereby confirming the good compatibility between the two phases. It is worth noting that the distribution of the O element is more dense, indicating the higher content of O in CoFe_2O_4 and CoMoO_4 than those of other elements. At the same time, combined with the illustrations in the EDS spectrum, it can be found that the atomic percentage contents of the Co, Fe and Mo elements in the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite are 1 : 2 and 1 : 1, respectively, which further indicate

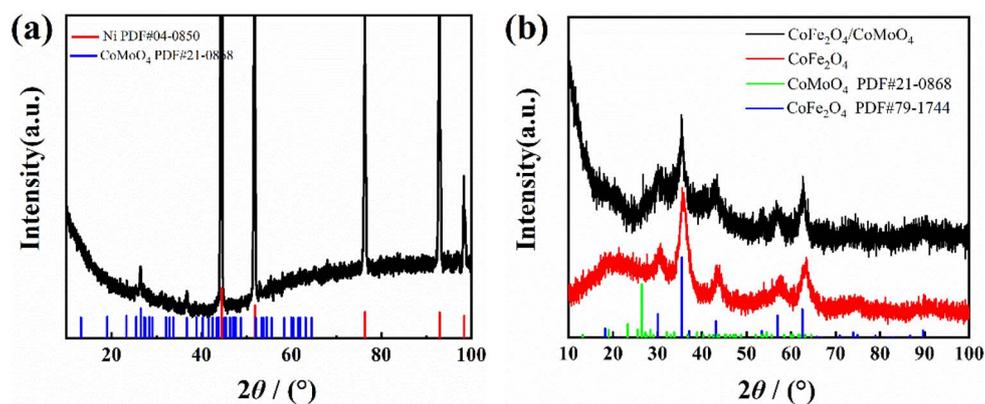

Fig. 3 XRD patterns of (a) CoMoO_4/NF and (b) $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$.

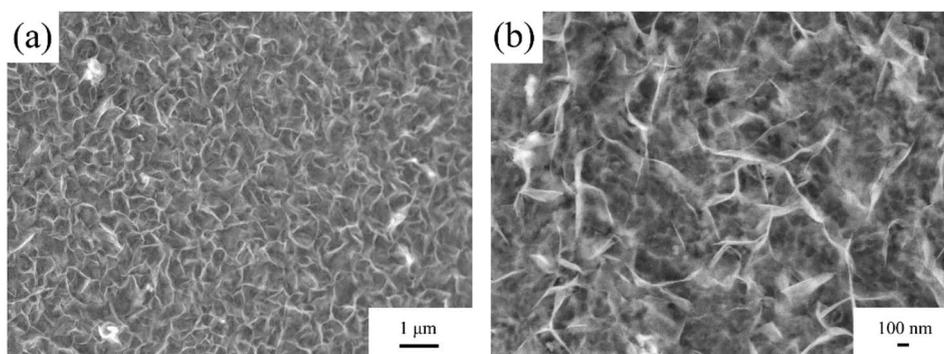

Fig. 4 SEM images of the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite electrode material at different magnifications (a and b).

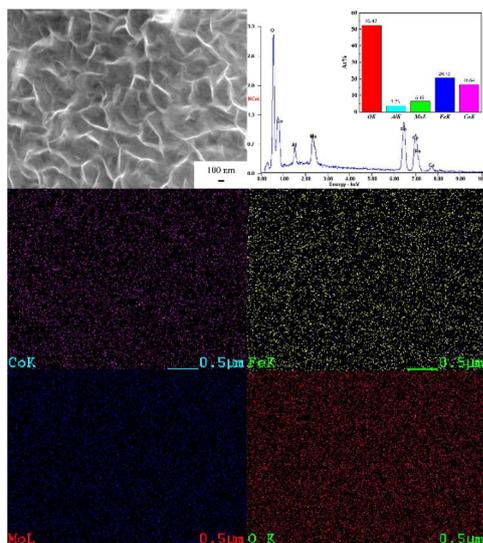

Fig. 5 Surface scan element distribution diagram of $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$.

that the composite material is reasonable in composition, uniform in distribution, and in line with the expected design. In addition, a small amount of Al (3.73 at.%) was detected, which is attributed to inadequate removal of AlO_2^- ions during washing, as well as the possibility of unreacted Al atoms remaining in the skeleton due to incomplete corrosion.

The microstructure of the two bimetallic oxides and the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite electrode material is studied and characterized by TEM. The TEM image of CoFe_2O_4 shown in Fig. 6(a) shows a rod-like skeleton structure distributed at multiple levels, while small holes distributed on the large skeleton structure can be seen, which is consistent with the structure shown by SEM. Fig. 6(b) shows the high-resolution transmission image of CoFe_2O_4 . The crystal face spacings calculated by the analysis are 0.261 nm and 0.483 nm, corresponding to the (311) and (111) crystal faces of CoFe_2O_4 . Fig. 6(c) shows the TEM image of the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite, in which the sheet-like CoMoO_4 is grown on the

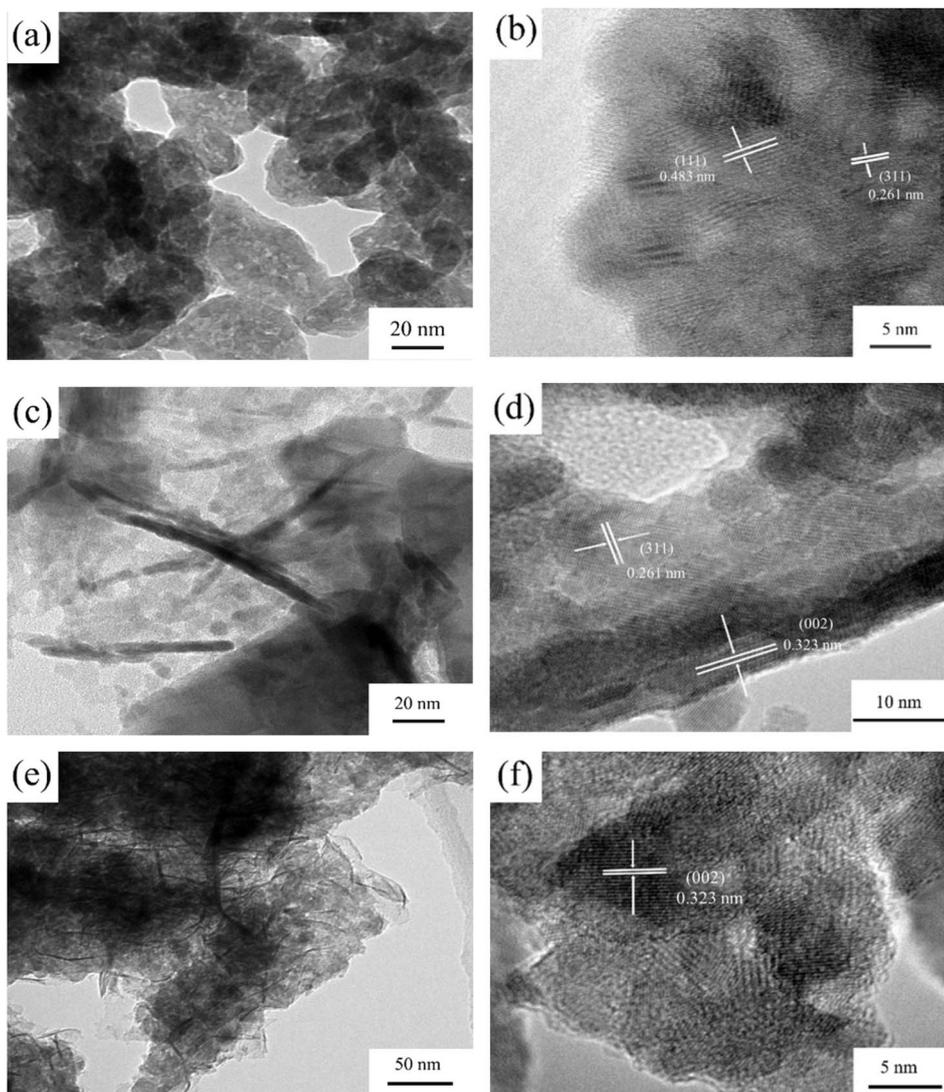

Fig. 6 TEM images of CoFe_2O_4 (a and b), $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ (c and d) and CoMoO_4 (e and f).

skeleton structure, and the distributed mesoporous structures can still be observed on the matrix skeleton of CoFe_2O_4 , indicating that the skeleton structure of CoFe_2O_4 is not affected or damaged after CoMoO_4 is compounded. Lamellar CoMoO_4 intergrowths will provide a more favorable reaction site for electrochemical reactions. Fig. 6(d) is the high-resolution transmission image of the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite, in which mesoporous structures of about 10 nm exist on the skeleton structure, and ligament structures and lattice stripes are also observed on the skeleton. The measured lattice spacings of 0.261 nm and 0.323 nm correspond to the (311) plane of CoFe_2O_4 and the (002) plane of CoMoO_4 in the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite, respectively. Fig. 6(e) shows the TEM image of CoMoO_4 , in which abundant ligament structures are wrapped around the skeleton, agreeing well with the rich ligament structures shown in the SEM image. Fig. 6(f) shows its high-resolution transmission image, in which lattice streaks with different orientations can be observed on the lamellar structure with a hierarchical distribution. The crystal face spacing of 0.323 nm in the figure corresponds to the (002) crystal face of CoMoO_4 . These TEM findings further confirm the composite structure indicated by XRD. Moreover, they offer a more direct view of the heterogeneous structure—a lamellar CoMoO_4 phase supported by the CoFe_2O_4 skeleton—compared to the SEM images.

The $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite was analyzed by X-ray photoelectron spectroscopy (XPS). Fig. 7(a) shows the high-resolution spectral fitting of the Co element. The peaks at the

binding energies of 780.95 eV and 796.59 eV correspond to the characteristic peaks of Co 2p, which belong to the Co $2p_{3/2}$ and Co $2p_{1/2}$ orbitals, respectively, indicating that Co exists in the +2 valence state.²² At the same time, satellite peaks appeared at 784.01 eV, 787.11 eV, 790.35 eV, and 803.01 eV. Fig. 7(b) is the spectral diagram obtained by fitting the high-resolution spectrum of the Fe element. The peaks at 710.79 eV and 724.08 eV are assigned to Fe^{2+} , while those at 713.64 eV and 727.48 eV are assigned to Fe^{3+} . This shows that Fe exists in the +2 and +3 valence states,^{23,24} while satellite peaks appear at 716.98 eV, 720 eV, and 732.85 eV. Fig. 7(c) is the spectrum obtained by fitting the high-resolution spectrum of Mo. The characteristic peaks corresponding to the energies of 232.44 eV and 235.56 eV belong to the Mo $3d_{5/2}$ and Mo $3d_{3/2}$ orbitals, respectively, with an energy difference of 3.12 eV. It is shown that Mo exists in the +6 valence state,^{25,26} while satellite peaks appear at 233.73 eV and 236.52 eV. Fig. 7(d) is the spectrum obtained by fitting the high-resolution spectrum of O. The two peaks at the binding energies of 530.09 and 531.17 eV correspond to the characteristic peaks of O 1s, which is due to the interaction between Co–O, Fe–O and Mo–O in the sample of the $\text{CoFe}_2\text{O}_4/\text{CoMoO}_4$ composite electrode material. At the same time, oxygen present due to the physical adsorption or chemisorption in the OH or C–O functional groups is reflected in it. To sum up, there are abundant valence states of Co, Fe and Mo in spinel CoFe_2O_4 and scheelite CoMoO_4 , which contribute to electron transfer during the hydrogen evolution and oxygen evolution reactions and enhance the conductivity of the material.

| Electrode | b (mV ⁻¹ dec ¹) | | η@50 mA cm ⁻² mV ⁻¹ | |
|--|--|--------|---|-----|
| | HER | OER | HER | OER |
| CoMoO ₄ | 121.21 | 132.09 | 248 | 381 |
| CoFe ₂ O ₄ | 111.84 | 82.06 | 216 | 351 |
| CoFe ₂ O ₄ /CoMoO ₄ | 100.44 | 70.47 | 193 | 319 |

Fig. 8(a) shows the cathode polarization curves of each electrode material. The overpotential of each electrode material at a current density of 50 mA cm⁻² is compared, as shown in

Table 1. As can be seen from the figure, CoFe₂O₄/CoMoO₄ has the best electrocatalytic hydrogen evolution activity, the lowest overpotential at the current density of 50 mA cm⁻², and the best catalytic hydrogen evolution activity. Combined with its SEM and TEM results, it is clear that CoMoO₄ nanosheets grown on the CoFe₂O₄ skeleton provide abundant active sites for the adsorption of H⁺. In addition, it is worth noting that CoFe₂O₄ has an obvious reduction peak in the low overpotential region. Combined with the XPS analysis results, it can be seen that this is due to the inherent REDOX pairs of Co²⁺/Co³⁺ and Fe²⁺/Fe³⁺ in the spinel structure CoFe₂O₄ and abundant valence state changes of CoMoO₄. Therefore, the composite electrode

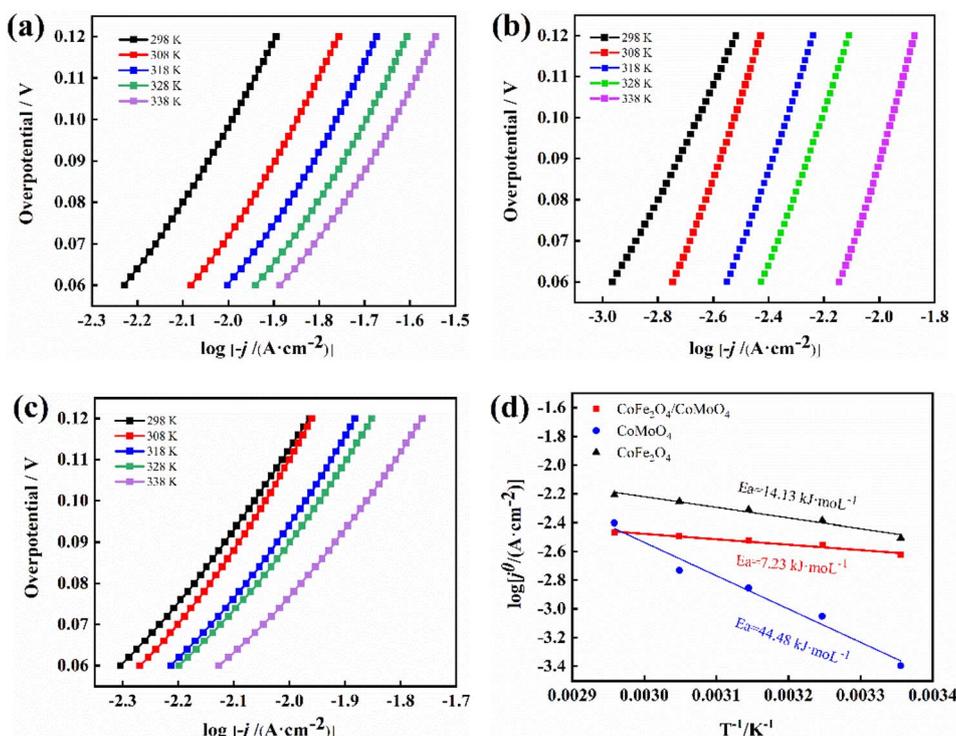

Fig. 9 Tafel curves of CoFe₂O₄ (a), CoMoO₄ (b) and CoFe₂O₄/CoMoO₄ (c) at different temperatures and Arrhenius curve of each electrode material (d).

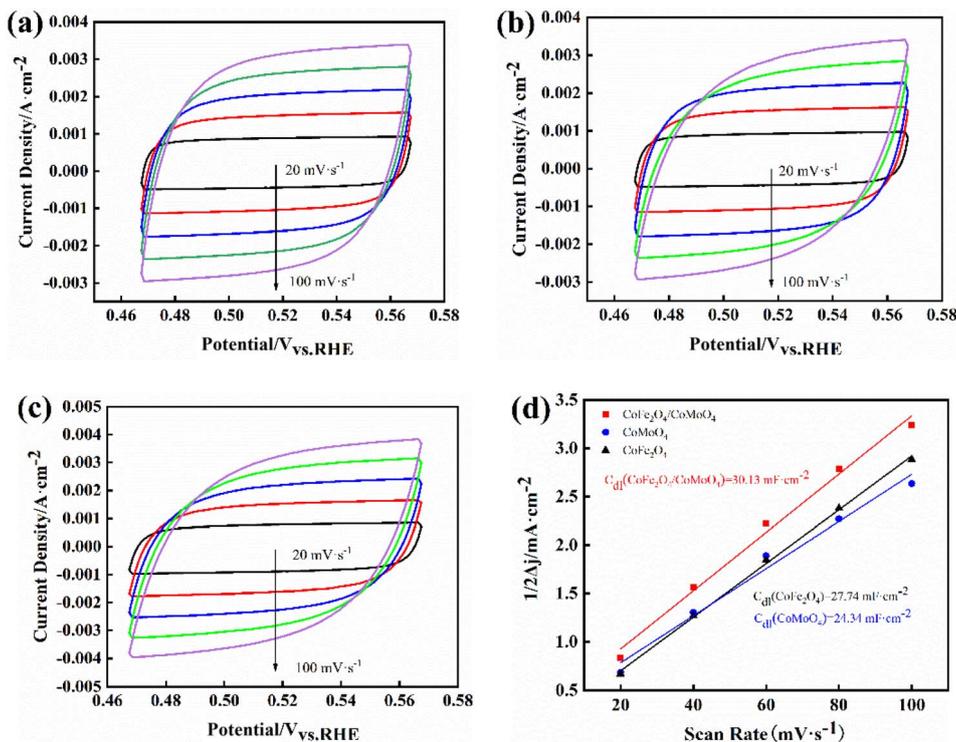

Fig. 10 CV curves of CoFe₂O₄ (a), CoMoO₄ (b), and CoFe₂O₄/CoMoO₄ (c) at different scan rates. Relationship curve of Δj and scan rate of each electrode material (d).

material has a more favorable electron and ion transport process. At the same time, it can be seen from the Fig. 8(a) that the hydrogen evolution performance of CoMoO₄ is lower than that of CoFe₂O₄, which is mainly due to the unique structure of the small skeleton of CoFe₂O₄ dependent on the large skeleton and the rich valence states of their respective elements. Furthermore, the skeleton structure of CoFe₂O₄ after oxidation is rough and uneven, and there is a mesoporous structure of about 10 nm. Fig. 8(b) shows the anode polarization curves of electrocatalytic oxygen evolution of the above-mentioned electrode materials, and their overpotentials at a current density of 50 mA cm⁻² are compared. CoFe₂O₄/CoMoO₄ has the best electrocatalytic oxygen evolution activity and the lowest oxygen evolution overpotential at the current density of 50 mA cm⁻². This shows that CoFe₂O₄/CoMoO₄ has the advantages of an excellent bifunctional catalyst. The hydrogen evolution properties and oxygen evolution properties of all electrode materials have the same catalytic properties, indicating that the oxide materials have similar properties in electrocatalytic hydrogen evolution and oxygen evolution.

Table 1 shows that CoFe₂O₄/CoMoO₄ has the lowest HER and OER Tafel slopes, with the HER slope of 100.44 mV dec⁻¹, indicating that its hydrogen evolution process is controlled by the Volmer–Heyrovsky step,²⁶ which indicates that at low overpotentials, the CoFe₂O₄/CoMoO₄ composite electrode material can rapidly absorb/desorb H⁺ and OH⁻ ions in the electrolyte, thus breaking the dynamic balance between the oxidation and reduction reactions at the electrode/solution interface, and H⁺ and OH⁻ in the solution begin to accumulate on the electrode

surface. A sufficiently fast interfacial reaction rate is critical to effectively mitigate surface polarization. The lowest Tafel slope of the CoFe₂O₄/CoMoO₄ composite confirms its superior kinetics and thus the strongest depolarization ability during electrocatalysis. Fig. 9(d) shows the apparent activation energy of each electrode. The CoFe₂O₄/CoMoO₄ composite electrode has the lowest apparent activation energy of 7.23 kJ mol⁻¹, indicating that it has the highest conversion efficiency and the fastest reaction speed in the catalytic reaction process.

In order to further study the electrochemically active surface area of CoFe₂O₄, CoMoO₄ and the CoFe₂O₄/CoMoO₄ composite electrode material participating in the reaction during electrocatalysis, the charging current in the potential window of the non-Faraday process was tested, obtaining a double-layer capacitance. Fig. 10(a)–(c) show the CV curves of the electrode materials at 0.47–0.57 V vs. RHE at scanning rates of 20, 40, 60, 80 and 100 mV s⁻¹. It can be seen from the figure that the CV curves of the three electrodes all exhibit typical rectangular characteristics of double-layer capacitors. By calculating the current density difference Δj between the cathode and anode at 0.52 V vs. RHE, the double layer capacitance values of CoFe₂O₄,

Table 2 Surface parameters of each electrode material

| Electrode | C_d μF^{-1} | S_r cm^{-2} | r |
|--|--------------------------|------------------------|-----|
| CoFe ₂ O ₄ | 27 740 | 462 | 462 |
| CoMoO ₄ | 24 340 | 406 | 406 |
| CoFe ₂ O ₄ /CoMoO ₄ | 30 130 | 505 | 505 |

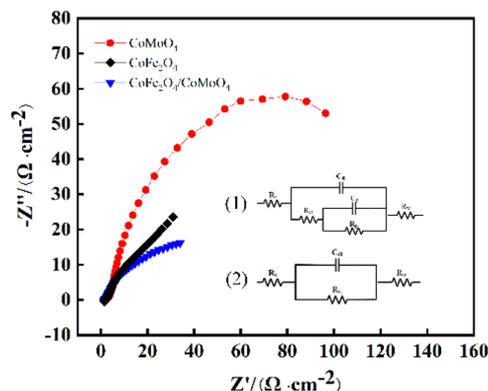

Fig. 11 Electrochemical impedance spectra and equivalent circuit diagrams of each electrode (inset). (1) CoMoO₄ and CoFe₂O₄/CoMoO₄ and (2) CoFe₂O₄.

CoMoO₄ and the CoFe₂O₄/CoMoO₄ composite electrode material are 27.74, 24.43 and 30.13 mF cm⁻², respectively. The calculated surface parameters of each electrode are shown in Table 2. The CoFe₂O₄/CoMoO₄ composite electrode material has the largest electrochemical active surface area and roughness, indicating that it has the most exposed active sites.

To further probe the electrode reaction kinetics during the catalytic OER process, electrochemical impedance spectroscopy (EIS) measurements are performed within a frequency range of 10⁻² to 10⁵ Hz, using an AC potential amplitude of 5 mV s⁻¹ (Fig. 11 and Table 3). For all samples, the tests were conducted at an overpotential of 100 mV. The comparable solution resistance (*R*_s) confirms consistent electrolyte environments.²⁷ Nyquist plots reveal that the CoFe₂O₄/CoMoO₄ composite electrode material exhibits the lowest charge-transfer resistance (*R*_{ct} = 0.2657 Ω

cm⁻²), which was significantly lower than those of CoMoO₄ (*R*_{ct} = 0.8904 Ω cm⁻²) and CoFe₂O₄ (*R*_{ct} = 6.919 Ω cm⁻²). This reduction indicates accelerated electron transfer across engineered interfaces, attributed to the synergistic effects of the CoFe₂O₄/CoMoO₄ heterojunction. Concurrently, the composite achieves the highest double-layer capacitance (*C*_{dl} = 0.4927 μF), confirming an expanded electroactive surface area, while its minimal Warburg impedance (*Y*₀ = 0.06289 S sec^{0.5}) demonstrates an optimized ion diffusion. Flaky CoMoO₄ nanosheets are vertically aligned on the CoFe₂O₄ skeleton surface, providing abundant electrochemically active sites and maintaining efficient ion diffusion channels. Moreover, electronic structure modulation at the heterointerfaces reduces the energy barrier for electron transfer. Consequently, synergistic effects at the CoFe₂O₄/CoMoO₄ interface collectively enhance the OER activity.

The HER and OER together constitute electrolytic water reaction. Compared with the individual CoFe₂O₄ and CoMoO₄, the CoFe₂O₄/CoMoO₄ composite exhibited the best electrocatalytic performance for both HER and OER. Therefore, to evaluate its overall water-splitting performance, a two-electrode electrolyzer was constructed with the composite serving as both the anode and the cathode. The corresponding electrolytic curve is shown in Fig. 12(a). The electrolyzer achieved a low cell voltage of 1.55 V at a current density of 10 mA cm⁻², demonstrating the excellent bifunctional electrocatalytic activity of the composite electrode. To preliminarily investigate the durability of the CoFe₂O₄/CoMoO₄ catalyst, a short-term stability test is performed at a constant current density of 30 mA cm⁻² for 12 hours, as shown in Fig. 12(b). The cell voltage increased by only 11 mV (0.6%) after continuous electrolysis, suggesting that the electrode maintains relatively stable performance under mild conditions. The porous skeleton obtained by dealloying and oxidation provides good support strength for the composite

material and further indicates the good bonding strength between the flaky CoMoO₄ and CoFe₂O₄.

4 Conclusion

In this study, a type of oxide composite material with different phase structures was synthesized by a hydrothermal method. CoFe₂O₄ was used as the skeleton structure, and the sheet and fold structures of CoMoO₄ grew vertically on the surface of the CoFe₂O₄ skeleton structure. This unique attachment structure was conducive to exposing more active sites. The structure offers abundant active sites and a extensive reaction interface, thereby facilitating highly efficient mass transport of H⁺ and OH⁻ ions as well as rapid charge transfer. In addition, the Co, Fe and Mo elements with abundant valence states provided favorable conditions for the transport of electrons and ions through abundant REDOX reactions in the electrocatalytic process, which helped to improve the electrocatalytic activity and reduce the reaction overpotential. Based on the unique structural advantages of spinel structure and scheelite structure and their synergistic effect, CoFe₂O₄/CoMoO₄ offered the best electrocatalytic activity. The skeleton structure obtained by dealloying combined with oxidation treatment exhibited a good structural stability and stable catalytic performance after long-term electrolysis.
