SnO₂ quantum dot decoration of CuO nanoparticles with enhanced NO₂ and H₂ gas sensing response via p–n heterojunction interfaces

 Valentina Paolucci, *^{ab} Thirugnanam Natarajan, ^a Vittorio Ricci, ^{ab}
 Fabiola Ferrante ^a and Carlo Cantalini *^{ab}

Design and fabrication of heterostructures has emerged as a powerful strategy to improve gas sensing performances compared to single materials counterparts. In this work, we report an innovative CuO-based nanostructure decorated with SnO₂ quantum dots (QDs) for the detection of NO₂ and H₂ gases. Here, CuO serves as the base material while SnO₂ QDs are used as the decorating phase: an inversion of the conventional architecture where SnO₂ is typically the host and CuO the modifier. The composite exhibits higher sensitivity compared to pristine CuO and SnO₂, showing state-of-the-art performances in terms of relative responses (RRs) in the 20 ppb to 1 ppm range and 10 ppm to 250 ppm for NO₂ and H₂ respectively, with excellent stability and reproducibility. Moreover, the SnO₂-QDs/CuO operates at a low working temperature (*i.e.* 100 °C), offering significant advantages in terms of energy efficiency and material stability. The observed enhancements are attributed to the optimized heterointerface, increased active surface area, and modulation of the charge carrier induced by the p–n heterojunctions. These results highlight the potential of reverse-configured SnO₂/CuO as a versatile platform for improved, low-temperature gas sensors with high sensitivity.

1. Introduction

The detection of toxic and explosive gases such as nitrogen oxide (NO₂) and hydrogen (H₂) is a critical requirement in the fields of health and environmental monitoring and industrial safety. Specifically, NO₂ is an air pollutant primarily originating from combustion processes associated with vehicle traffic and industrial activities, which can cause serious respiratory diseases even at low concentrations.^{1,2} On the other hand, H₂ gas, being colourless and odourless, poses a significant risk due to its wide flammability range (4–75% in air), low ignition energy (0.017 mJ) and high combustion heat (142 kJ per g H₂), negatively influencing its exploitation as a promising fuel for the transition to a low carbon economy.^{3,4} To address these challenges, the development of sensitive and reliable gas sensors for detection of trace levels of NO₂ and H₂ remains an active area of research. Thin films of metal oxide semiconductors (MOX) have been widely employed as chemo-resistive gas sensors due to their high sensitivity, low cost and simple fabrication processes. Typically, n-type MOX materials such as SnO₂, ZnO and In₂O₃,^{5–7} and p-type CuO, NiO and Cr₂O₃ counterparts^{8–10} have been widely studied for gas sensing applications. However, one major limitation is their high operating temperature, often exceeding 200 °C, which

increases power consumption and hinders their integration in portable or wearable devices.^{11–13}

Recent studies have demonstrated that carefully engineered oxide heterostructures can significantly enhance charge separation and gas adsorption processes.^{14,15} In particular, a promising strategy is represented by the design of heterojunctions combining p-type and n-type metal oxides, leveraging the formation of p–n junctions to improve gas sensing at lower temperatures.^{16,17} Among p-type materials, CuO stands out due to its excellent surface reactivity, stability and ability to form hierarchical nanostructures in the form of flakes, nanorods and nanofibers.^{8,18–20} On the other hand, SnO₂, being one of the first MOX sensor ever studied,²¹ is well known for its strong interactions with both oxidizing and reducing gases.^{22,23} The combination of CuO and SnO₂ has been explored extensively, typically in the configuration where SnO₂ serves as the base material and CuO is introduced as the secondary phase.^{24–27} These structures, showing typical n-type response, have been extensively utilized for H₂S sensing on account of the reversible conversion of CuO in CuS, which significantly reduces the resistance.²⁸ In this work, we propose a reverse composite configuration, employing CuO as the primary sensing matrix and decorating it with SnO₂ quantum dots (QDs). This architecture leverages the predominant p-type response of CuO-based interfaces to oxidizing gases like NO₂,²⁹ while promoting intimate contact between the SnO₂ QDs edges and the underlying CuO surface, resulting in enhanced interfacial

charge transfer and gas sensing performance.³⁰ Remarkably, this SnO₂-QDs/CuO architecture exhibits superior sensing performance towards both NO₂ and H₂ at a reduced operating temperature of 100 °C. Specifically, needle-like CuO was synthesized *via* microwave irradiation of Cu₂(OH)₂CO₃, while SnO₂ QDs were produced using a colloidal solution method. The formation of nanoscale p–n junctions at the SnO₂/CuO interfaces, enhancing charge carrier separation and modulation of the depletion layer, is responsible to improve gas sensing response.¹⁷ Furthermore, the choice of SnO₂ in quantum dots form introduces significant advantages. Due to its nanoscale size and high surface-to-volume ratio, SnO₂ provides more active sites for gas adsorption, easing faster charge transfer kinetics.^{31,32} Moreover, the quantum confinement effect also modulates the electronic properties of the heterojunction, enhancing sensitivity at low temperatures (*i.e.* 100 °C). Overall, this study provides a novel perspective on CuO-based heterojunctions, proposing a simple and scalable synthesis route that make this approach suitable for practical application, demonstrating enhanced NO₂ and H₂ sensing performances at low temperatures, thus offering a promising alternative to conventional single-phase or inversely configured systems.

2. Experimental

2.1 Synthesis of CuO nanostructures

The hydrothermal synthesis of Cu₂(OH)₂CO₃ was performed according to a reported procedure:³³ 4.2 ml of 0.4 M copper(II) acetate and 4.2 ml of 0.8 M urea were dissolved into 3.3 ml DI water. After 30 min stirring, the mixture was transferred into a 40 ml Teflon-lined stainless-steel autoclave and maintained at 120 °C for 4 h. After that, the autoclave was naturally cooled down to room temperature and the obtained product was washed 5 times with DI water and 3 times with absolute ethanol and dried at 50 °C for 1 h. Then 0.1 g of Cu₂(OH)₂CO₃ were added to 20 ml of DI water, and the obtained suspension was irradiated with microwave at 560 W for 5 minutes. After collecting and washing, a brown precipitate was obtained. Finally, the powder was annealed in a muffle furnace at 400 °C for 2 h with a heating rate of 1 °C min⁻¹ to obtain crystalline CuO. A detailed flowchart of the process is reported in SI S1a.

2.2 Synthesis of SnO₂ QDs

50 ml 0.025 M ammonia solution 30% was added dropwise into 50 ml 0.05 M SnCl₄·5H₂O solution and kept stirring at 80 °C in oil bath for 3 h.³⁴ At the end of the reaction, the resulting white gel-like product was collected by centrifugation at 5000 rpm and washed five times with DI water to remove any residual precursors. The precipitate was then dried overnight at 60 °C. For further characterization, the dried SnO₂ product was redispersed in ethanol for deposition and analysis. A detailed flowchart of the process is reported in SI S1b.

2.3 Decorating CuO nanoparticles with SnO₂-QDs

The optimized procedure for SnO₂ decoration of CuO flakes was established through systematic variation of precursor

concentration and order of addition (see SI, Fig. S2). In the final protocol, 25 mg of synthesized crystalline CuO were added to 20 ml of DI water; then, 2.6 mg SnCl₄·5H₂O powder and 0.3 ml of 0.05 M ammonia solution were successively incorporated to the dispersion. After mixing, obtained dispersion was heated at 80 °C using an oil bath and maintained under stirring for 3 h. The obtained product was washed three times by centrifugation at 5000 rpm, followed by a final centrifugation at the same speed to exchange the solvent with ethanol, facilitating solvent evaporation after deposition and enhancing both microstructural and electrical characterization. A detailed flowchart of the process is reported in SI S1c.

Notably, the hydrothermal synthesis of Cu₂(OH)₂CO₃ typically afforded a yield of ~43% (~130 mg of Cu₂(OH)₂CO₃ from ~300 mg of copper(II) acetate). In contrast, both the SnO₂ and the SnO₂/CuO syntheses showed essentially quantitative conversion of the Sn precursor, as no secondary phases or unreacted material were detected by our structural analyses.

2.4 Material characterization

The crystal structure was analysed through the X-ray diffraction Grazing Incidence X-ray Diffraction (GI-XRD) by XRD-PANalytical X'PERT Pro using Cu K α ₁ radiation ($\lambda = 1.5406$ Å) with an incident angle of 0.8°. FTIR spectra were obtained by Thermo Nicolet Nexus 870, operating in the 400–4000 cm⁻¹ spectral range. Thermogravimetric and differential thermal analysis (TG-DTA) was performed in air atmosphere using a Linseis L81-I. The morphology was studied by Transmission Electron Microscopy Philips CM100 operating at 100 kV and Scanning Electron Microscopy Gemini SEM working at 5 kV. HRTEM was performed using a Talos F200S. The optical absorption and reflectance spectra were measured using a PerkinElmer LAMBDA 1050+ UV-vis-near-infrared (NIR) spectrophotometer and in diffuse reflectance spectroscopy (DRS) configuration respectively, and the Kubelka–Munk function was utilized.

2.5 Electrical characterization

CuO, SnO₂ and SnO₂-QDs/CuO based films were deposited by spin coating on Si/Si₃N₄ substrates, with comb-like Pt interdigitated electrodes (30 μ m apart) and back side heaters and inserted in a 500 cm³ Teflon chamber for chemoresistive gas sensing characterization. By stepwise tuning the current in the back side heater, sensor's substrates are almost instantaneously kept and maintained at the selected operating temperature. Electrical responses were collected using an automated volt-ampereometric system (Agilent 34970A), measuring electrical resistance of the film at operating temperatures from 25 to 150 °C and different environments. Gas concentrations were obtained by diluting NO₂ (10 ppm in air) and H₂ (500 ppm in air) certified mixtures (Nippon gases-IT) with synthetic dry air utilizing mass flow controllers (MKS147), setting the total flow rate at 500 sccm per min. 50% relative humidity (RH%) was obtained by mixing dry with water-saturated air at 25 °C and measuring RH% at 25 °C before injection into the test chamber (Thermohygrometer – Hannah Instruments).

To characterize and compare gas responses properties of the different samples, the following definitions apply: (i) baseline resistance (BLR): the resistance in dry air at equilibrium; (ii) relative response (RR): defined as $(R_{\text{Air}}/R_{\text{Gas}})$ or $(R_{\text{Gas}}/R_{\text{Air}})$ depending on the oxidizing/reducing nature of the gases; (iii) sensor's sensitivity (S): the slope of the calibration curve (*i.e.* RR vs. gas concentration); (iv) response time (τ_{ADS}) and recovery time (τ_{DES}) defined as the time required for the resistance to reach 90% of the equilibrium value after injecting the gas and the time needed to return to 10% above the original value in air, respectively.

3. Results and discussion

We have applied three different chemical syntheses to prepare: (i) needle-like CuO nanoparticles; (ii) SnO₂-QDs; and (iii) SnO₂-QDs decorated needle-like CuO (SnO₂-QDs/CuO). The detailed flowcharts of processes (i)–(iii) are reported in SI S1. Notably,

while the CuO and SnO₂ syntheses followed established literature routes,^{33,34} the synthesis of SnO₂-QDs/CuO was the result of an optimization process involving both the relative amount of precursors and the order of their addition, as extensively described in SI S2. All material interfaces, deposited on dedicated Si₃N₄ substrates provided with Pt finger-type electrodes and a backside heater, have been investigated as NO₂ and H₂ sensors under dry and humid air background conditions.

3.1 Synthesis and microstructural characterization

3.1.1 Needle-like CuO nanoparticles. Following the procedure described in the Experimental section and Fig. 1a and SI S1a, the hydrothermal synthesis utilizing copper(II) acetate and urea solution leads to the formation of round-shaped agglomerated-particles with chemical composition Cu₂(OH)₂CO₃. Specifically, Scanning Electron Microscopy (SEM) (Fig. 1b), exhibits the formation of hierarchical microspheres made of “flower-like” assembled-nanosheets, growing radially from the

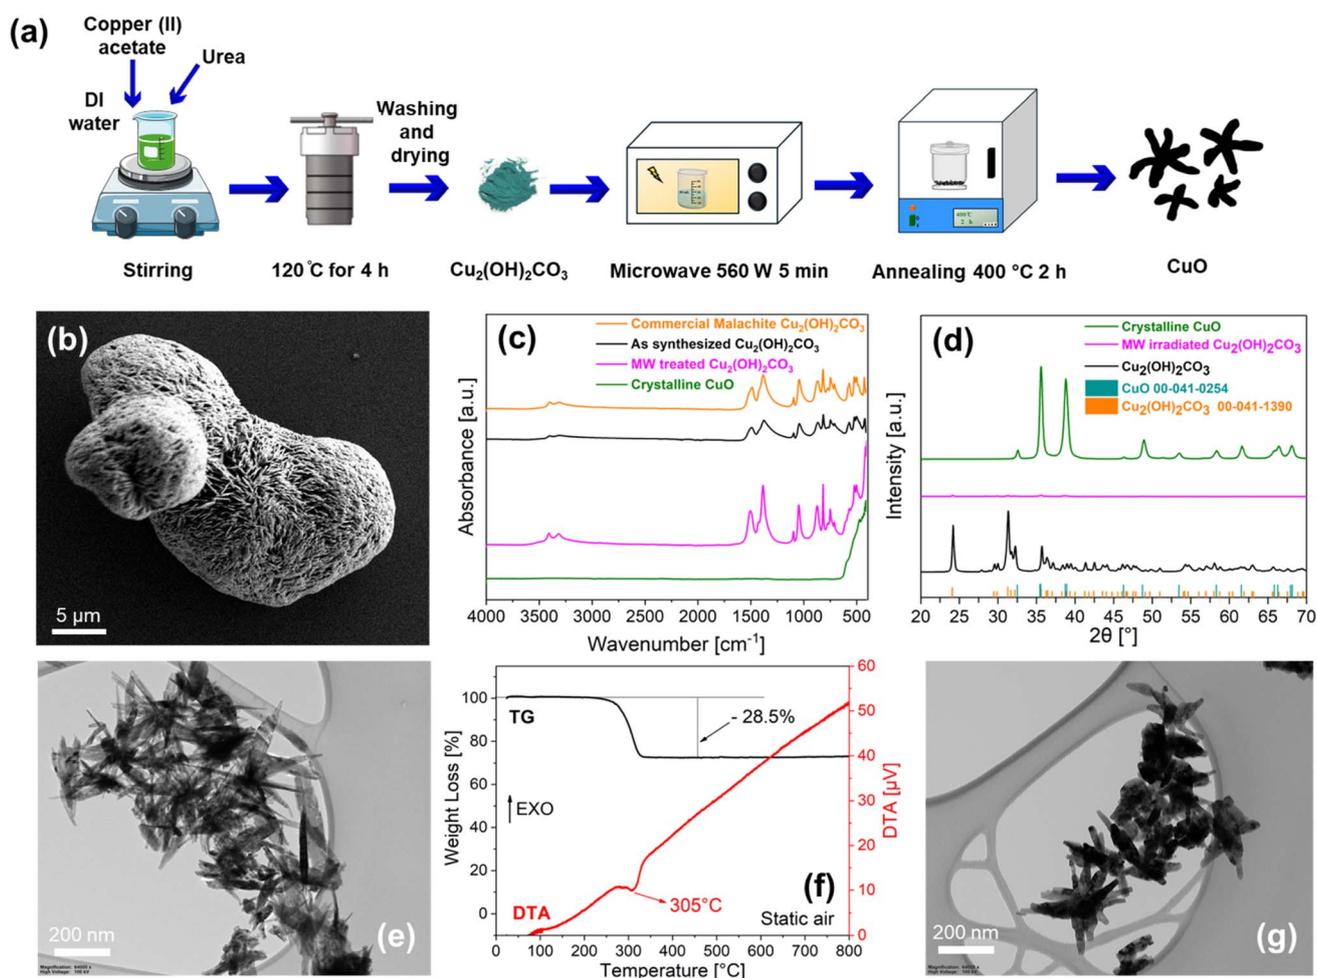

Fig. 1 (a) Schematics of the synthesis process: after hydrothermal synthesis of Cu₂(OH)₂CO₃ at 120 °C for 4 h, powder was dispersed in DI water and irradiated with microwave (MW) at 560 W for 5 min and annealed at 400 °C for 2 h to obtain crystalline needle-like CuO; (b) SEM image of Cu₂(OH)₂CO₃ after hydrothermal synthesis; (c) comparison of the FT-IR spectra of: commercial malachite (Cu₂(OH)₂CO₃, orange line), Cu₂(OH)₂CO₃ after hydrothermal synthesis (black line), microwave irradiated (pink line) and annealed (green line) Cu₂(OH)₂CO₃; (d) XRD spectra of Cu₂(OH)₂CO₃, microwave irradiated and annealed Cu₂(OH)₂CO₃ with associated JCPDS cards; (e) TEM image of needle-like Cu₂(OH)₂CO₃ after MW; (f) thermogravimetric (TG) and differential thermal analysis (DTA) plots of MW Cu₂(OH)₂CO₃ powder heated in air at 5 °C min⁻¹ from 25 to 800 °C. Black and red lines refer to TG and DTA signals, respectively; (g) TEM image of needle-like crystalline CuO after annealing.

core of the particle, with similar features as those described in literature.³³ According to Fig. 1c, the chemical composition of the synthesized “flower-like” structures (black line), correspond to $\text{Cu}_2(\text{OH})_2\text{CO}_3$ as observed by comparing the Fourier Transform Infrared (FT-IR) spectrum of the synthesized structures with that of a commercial malachite powder (orange line). X-ray Diffraction (XRD) analysis (Fig. 1d) confirms that $\text{Cu}_2(\text{OH})_2\text{CO}_3$ flower-like particles are highly crystalline (black line of Fig. 1d), consistent with JCPDS Card No. 00-041-1390 corresponding to malachite.

The “flower-like” $\text{Cu}_2(\text{OH})_2\text{CO}_3$ agglomerated structure (Fig. 1a), after microwave (MW) treatment at 560 W for 5 minutes, separates into “needle-like” free nanoparticles as those displayed in Fig. 1e, while maintaining the same chemical composition of $\text{Cu}_2(\text{OH})_2\text{CO}_3$ (pink line of Fig. 1c). Surprisingly, the XRD pattern of the microwave synthesized needle-like $\text{Cu}_2(\text{OH})_2\text{CO}_3$ particles, reveals the absence of distinct diffraction peaks (pink line of Fig. 1d), suggesting that the microwave treatment induces amorphization of the particles, while preserving their original $\text{Cu}_2(\text{OH})_2\text{CO}_3$ chemical composition. Finally, the amorphous “needle-like” $\text{Cu}_2(\text{OH})_2\text{CO}_3$ particles were subjected to annealing in dry air, to promote the formation of crystalline CuO. Preliminary simultaneous thermogravimetric (TG) and differential thermal analysis (DTA) technique was utilized to determine the most favourable annealing temperature.

Specifically, heating the amorphous “needle-like” $\text{Cu}_2(\text{OH})_2\text{CO}_3$ at $5\text{ }^\circ\text{C min}^{-1}$ from 25 to $400\text{ }^\circ\text{C}$ in a simultaneous TG-

DTA apparatus, the thermogravimetric (TG) curve (black curve of Fig. 1f) yields a weight loss of -28.5% with a maximum decomposition rate at $305\text{ }^\circ\text{C}$ (red line of the DTA signal of Fig. 1f). Remarkably, the measured weight loss of -28.5% , satisfactorily matches, within the experimental error, the theoretical weight loss of -30.5% , corresponding to the complete conversion of $\text{Cu}_2(\text{OH})_2\text{CO}_3$ into CuO, based on the following reaction:

Consequently, after oven annealing at $400\text{ }^\circ\text{C}$ for 2 h in static air, the “needle-like” amorphous $\text{Cu}_2(\text{OH})_2\text{CO}_3$ particles are isomorphically converted into “needle-like” CuO nanoparticles (Fig. 1g). Moreover, XRD characterization (green line of Fig. 1d) exhibits that CuO nanoparticles are highly crystalline (JCPDS Card 00-041-0254) and almost pure, as confirmed by FTIR analysis (green line of Fig. 1c). In conclusion, congruent with previous research,^{33,35} we synthesized pure and highly crystalline needle-like CuO nanoparticles to be utilized as scaffolds for SnO_2 -QDs decoration.

3.1.2 SnO_2 -QD synthesis and SnO_2 -QD/CuO nanoparticles decoration. The SnO_2 Quantum Dots (SnO_2 -QD) synthesis,³⁴ shown in Fig. 2a and described in Experimental section and SI S1b, yields agglomerated spherical SnO_2 nanoparticles (TEM Fig. 2c) with average radii of $R = 1.9 \pm 0.1\text{ nm}$ and diameter-size distribution shown in the inset of Fig. 2c. XRD analysis of the

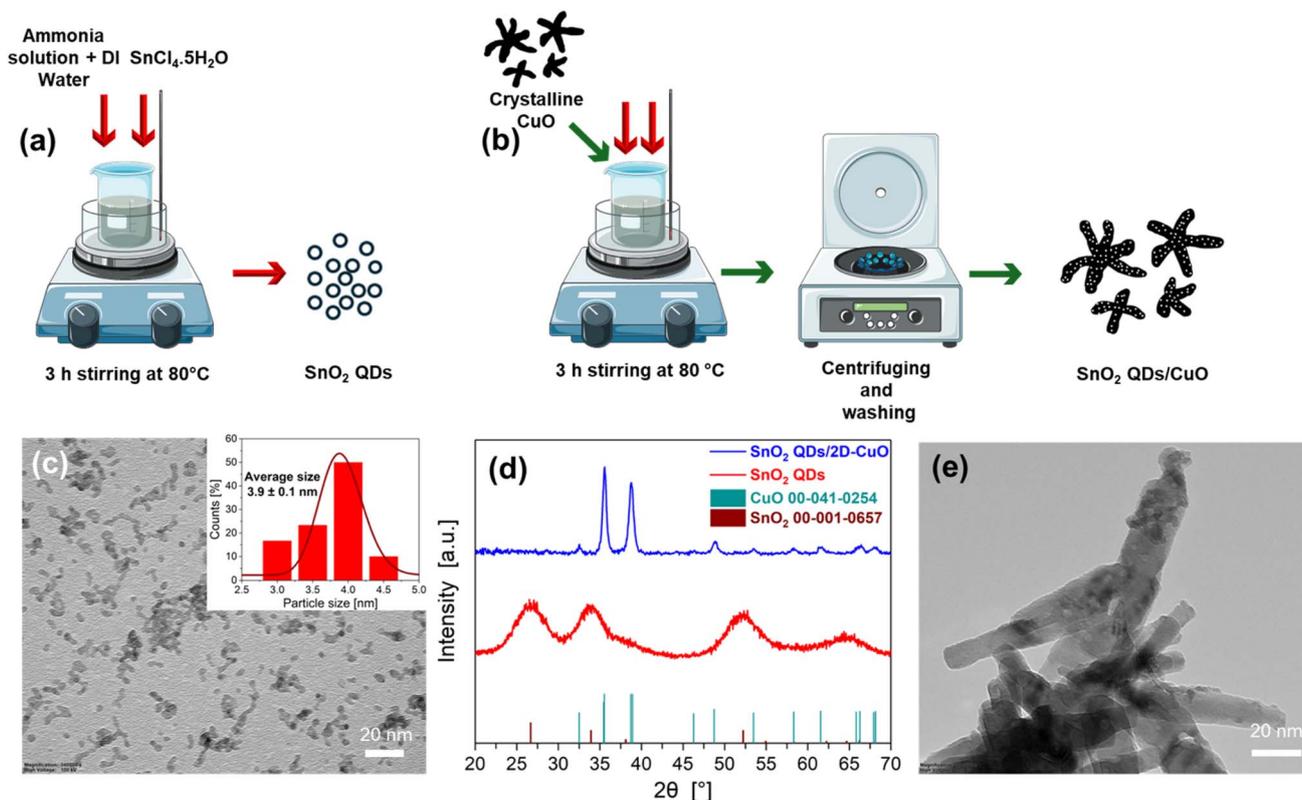

Fig. 2 (a) Synthesis of SnO_2 QDs and (b) SnO_2 -QDs/CuO; (c) TEM image of SnO_2 QDs with inset reporting particle size distribution; (d) XRD spectra of SnO_2 QDs and SnO_2 -QDs/CuO with associated JCPDS cards; (e) TEM image of SnO_2 -QDs/CuO.

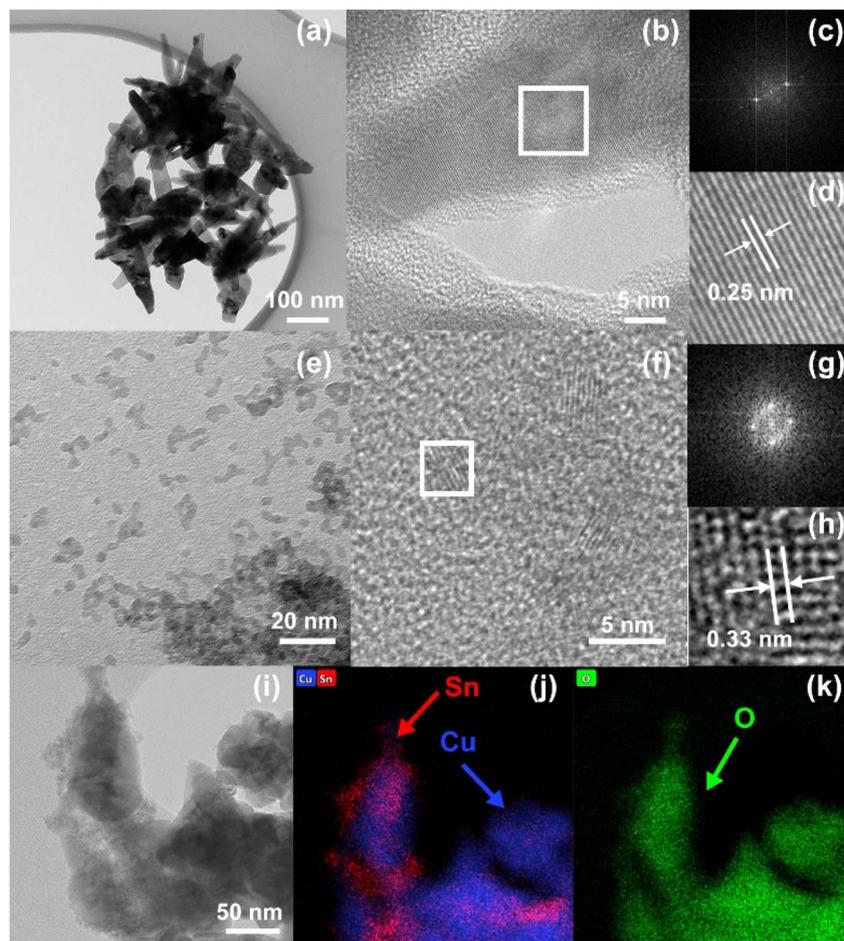

Fig. 3 (a)–(d) TEM characterization of not decorated needle-like CuO: (a) low resolution TEM showing CuO microstructure, (b)–(d) high resolution TEM showing well-ordered crystalline structure (e)–(h) TEM characterization of as synthesized SnO₂ QDs: (e) low resolution TEM showing dots microstructure, (f)–(h) high resolution TEM showing the small crystalline domains of SnO₂ QDs; (i) high resolution TEM of SnO₂-QDs/CuO and EDX maps (j) and (k) with indicated the elemental composition.

synthesized SnO₂-QDs nanoparticles, exhibits the formation of low-crystalline SnO₂ structures, as demonstrated by the presence of broad diffraction peaks in the red curve of Fig. 2d, matching rutile phase of tetragonal tin oxide (JCPDS Card No. 00-001-0657). According to this procedure, we successfully synthesized SnO₂ nanoparticles, with average radii ($R = 1.9 \pm 0.1$ nm) smaller than Bohr's exciton radius (2.7 nm) in SnO₂-QDs,^{34,36} attesting the capability of the synthesized SnO₂-QDs to yield quantum confinements effects.

The SnO₂-QDs decoration of the CuO needle-like nanoparticles to yield SnO₂-QD/CuO, was carried out according to an optimized procedure (Fig. 2b and SI S1, S2) by mixing previously prepared needle-like CuO in 20 ml DI water with 2.6 mg SnCl₄·5H₂O and 0.3 ml of 0.05 M ammonia solution (Fig. 2b) to yield, after centrifugation and washing, decorated SnO₂-QDs/CuO. TEM analysis of the SnO₂-QDs/CuO, shown in Fig. 2e, exhibits the formation of small spherical SnO₂ QDs nanoparticles of ≈ 4 nm size over the edge of the CuO needle-like structures. The XRD pattern of the SnO₂-QD/CuO (blue line of Fig. 2d) confirms the presence of crystalline CuO phase, but it does not display any discernible reflections belonging to SnO₂-

QDs, possibly on account of a limited quantity of the SnO₂-QDs phase as respect to the CuO matrix. HRTEM characterizations of the CuO needle-like, SnO₂-QDs and SnO₂-QDs/CuO, shown in Fig. 3, highlight that CuO needle-like nanoparticles are highly crystalline (Fig. 3a–d), comprising well-ordered lattice fringes with interplanar spacing of 0.25 nm (Fig. 3d), corresponding to the (002) plane of monoclinic CuO.³³

In a similar way, HRTEM of SnO₂ QDs (Fig. 3e–h), display the occurrence of crystalline domains (*i.e.* inside the white box of Fig. 3f), with average diameter's size smaller than 5 nm and interplanar spacing of 0.33 nm (Fig. 3h), consistent with the (110) plane of tetragonal SnO₂. The effectiveness of the SnO₂ QDs decoration of CuO needle-like nanoparticles is finally confirmed by HRTEM of Fig. 3i and by the associated EDX elemental map of the SnO₂-QDs/CuO composite (Fig. 3j and k), attesting a congruent distribution of Cu (cyan), Sn (red) and O (green) elements over the CuO needle-like scaffold.

Finally in Fig. 4 we have reported a schematization of the SnO₂-QDs/CuO model structure. Congruently with HRTEM characterization (see Fig. 3), SnO₂-QDs (white) are discretely distributed as isolated spots over the CuO underlying surface

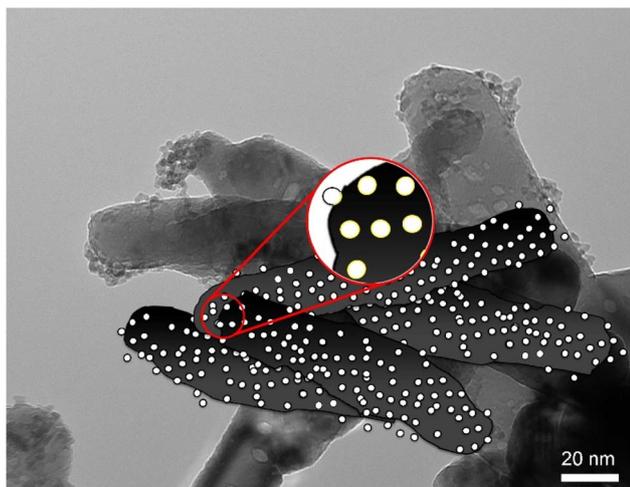

Fig. 4 TEM image with superimposed a schematic illustration of the SnO₂-QDs/CuO model structure. The SnO₂ quantum dots (white) are evenly dispersed as isolated spots on the CuO surface (black). The overall structure consists of a network-like arrangement of needle-shaped CuO nanoparticles, which are decorated with SnO₂ quantum dots.

(black). The whole structure comprises a network morphology of needle like CuO nanoparticles decorated with SnO₂-QDs.

3.2 Optical properties characterization

The optical absorbance of CuO needle-like nanoparticles, SnO₂-QDs and SnO₂-QDs/CuO was measured by UV-vis-near-infrared spectrophotometer as shown in Fig. 5a. Associated bandgaps, reported in Fig. 5b, were determined by DRS applying the Kubelka–Munk method.³⁷ The CuO needle-like nanoparticles absorption curve (green line of Fig. 5a), exhibits a maximum located at ≈ 380 nm, attributed to electrons band-gap excitation in CuO.³⁸ SnO₂-QDs (red line), on the other hand, highlight an absorption edge at ≈ 280 nm, blue shifted compared to that of bulk SnO₂ (345 nm).³⁹ According to literature,⁴⁰ the blue shift may represent the quantum confinement effect associated to the synthesized SnO₂-QDs. Finally, the absorption of SnO₂-QDs/CuO represented by the blue line in Fig. 5a, does not show any

change in the wavelength position compared to that of CuO, but its absorbance is increased considerably. This behavior can be associated to the change in CuO band gap due to SnO₂ decoration and to the formation of surface defects.²⁵

The bandgaps of CuO needle-like nanoparticles, SnO₂-QDs and SnO₂-QDs/CuO displayed in Fig. 5b were extrapolated by Tauc's plot⁴¹ using Kubelka–Munk³⁷ function from diffuse reflectance spectra (E1):

$$(F(R)hv)^{1/\gamma} = B(hv - E_g) \quad (E1)$$

here h [kg m² s⁻¹] is Planck's constant, ν [s⁻¹] is the frequency of the incident electromagnetic radiation, E_g [eV] is the optical bandgap energy, B is a constant and $\gamma = 1/2$, corresponding to a direct band transition for CuO, SnO₂-QDs and SnO₂-QDs/CuO. The measured bandgap (BG) of 1.8 eV found for CuO needle-like nanoparticles (green line of Fig. 5b), is different from that of bulk CuO (1.24 eV) and closer to the reported BG value of 1.73 eV of CuO nanopetals.⁴² The 4.1 eV measured bandgap of SnO₂-QDs (red line of Fig. 5b), which is consistently higher than that of bulk SnO₂ (3.6 eV),³⁴ can be possibly explained considering the QDs nature of the synthesized SnO₂-QDs nanoparticles as respect to bulk SnO₂. To better clarify the nature of this mismatch, we estimated the SnO₂-QDs bandgap using Brus's variational method,⁴³ according to eqn (E2),

$$E_g^{\text{eff}} = E_g + \frac{\hbar^2 \pi^2}{2\mu R^2} - \frac{1.8e^2}{\epsilon R} \quad (E2)$$

where E_g is the bulk band gap energy (3.6 eV), \hbar is reduced Planck's constant, μ is the effective reduced mass expressed as $\left(\frac{1}{m_e^*} - \frac{1}{m_h^*}\right)$ and μ may be replaced by the electron effective mass ($m_e^* = 0.275m_0$), since $m_e^* \ll m_h^*$ (m_e^* and m_h^* are the electron and hole effective masses, respectively).⁴⁴ R is the radius of QDs, e is a charge of an electron (1.602×10^{-19} C) and ϵ is the dielectric constant (for SnO₂, $\epsilon = 14$). Hence, the calculated band gap energy using eqn (E2) is ~ 4.0 eV, which is close to the measured band gap of 4.1 eV (Fig. 5b), confirming the quantum confinement effect occurring in the synthesized SnO₂ QDs.³⁴ Finally, the bandgap of SnO₂-QDs/CuO is determined as 2.0 eV,

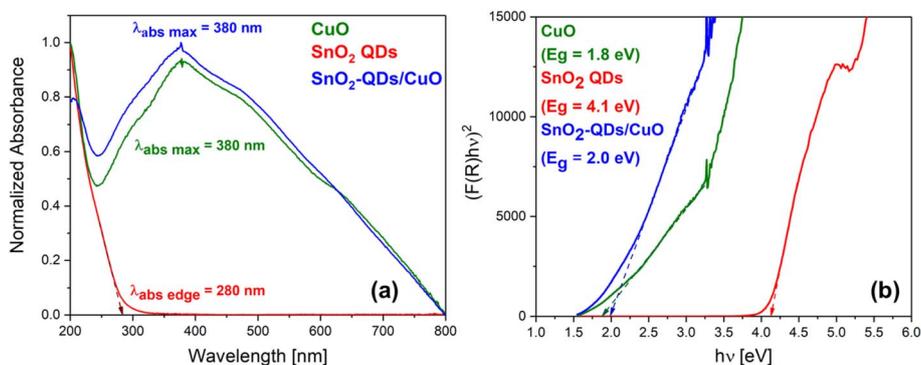

Fig. 5 Optical characterization of CuO, SnO₂ QDs and SnO₂-QDs/CuO. (a) UV-vis absorption spectra (0.5 mg ml⁻¹ in ethanol) and (b) Tauc plot with highlighted the measured bandgaps determination, respectively.

which is higher than that of CuO needle-like nanoparticles ($E_g = 1.8$ eV), with this increment again related to the presence of SnO₂-QDs,²⁴ as previously discussed.

3.3 Gas sensing characterization

The semiconducting nature of the CuO needle-like nanoparticles, SnO₂-QDs and SnO₂-QDs/CuO heterojunction is attested by the decrease/increase of the baseline resistance (*i.e.* BLR – the resistance at equilibrium in dry air), when increasing/decreasing the operating temperature (OT) between 25 °C and 150 °C, as shown in Fig. 6a. CuO nanoparticles and SnO₂-QDs/CuO (green and blue lines) show higher baseline resistances compared to pristine SnO₂-QDs (red line). The BLR of CuO nanoparticles is displayed departing from 75 °C, since at $T < 75$ °C the material's resistance exceeds the instrumental

capabilities. Oppositely, the base line resistance (BLR) of SnO₂-QDs is smaller than the others with BLR's modulation limited in the range 4–20 k Ω . The lower BLR of the SnO₂-QDs film can be related to a size quantization effect, which has recently been demonstrated to be responsible for the increase in conductivity, when the size of the SnO₂ nanoparticles is lowered within the nanometer scale.⁴⁵ The SnO₂-QDs/CuO shows BLR values that are in between those of CuO nanoparticles and SnO₂-QDs, demonstrating the effectiveness of the SnO₂ decoration to tune the film conductivity.

To evaluate the gas sensing properties, concentration ranges of 0.020–1 ppm for NO₂ and 10–250 ppm for H₂, were selected. This choice reflects the significantly higher electron affinity of NO₂ (2.3 eV) compared to H₂ (0.18 eV),^{46,47} which leads to a more pronounced sensor signal variation for NO₂ at equivalent concentrations.

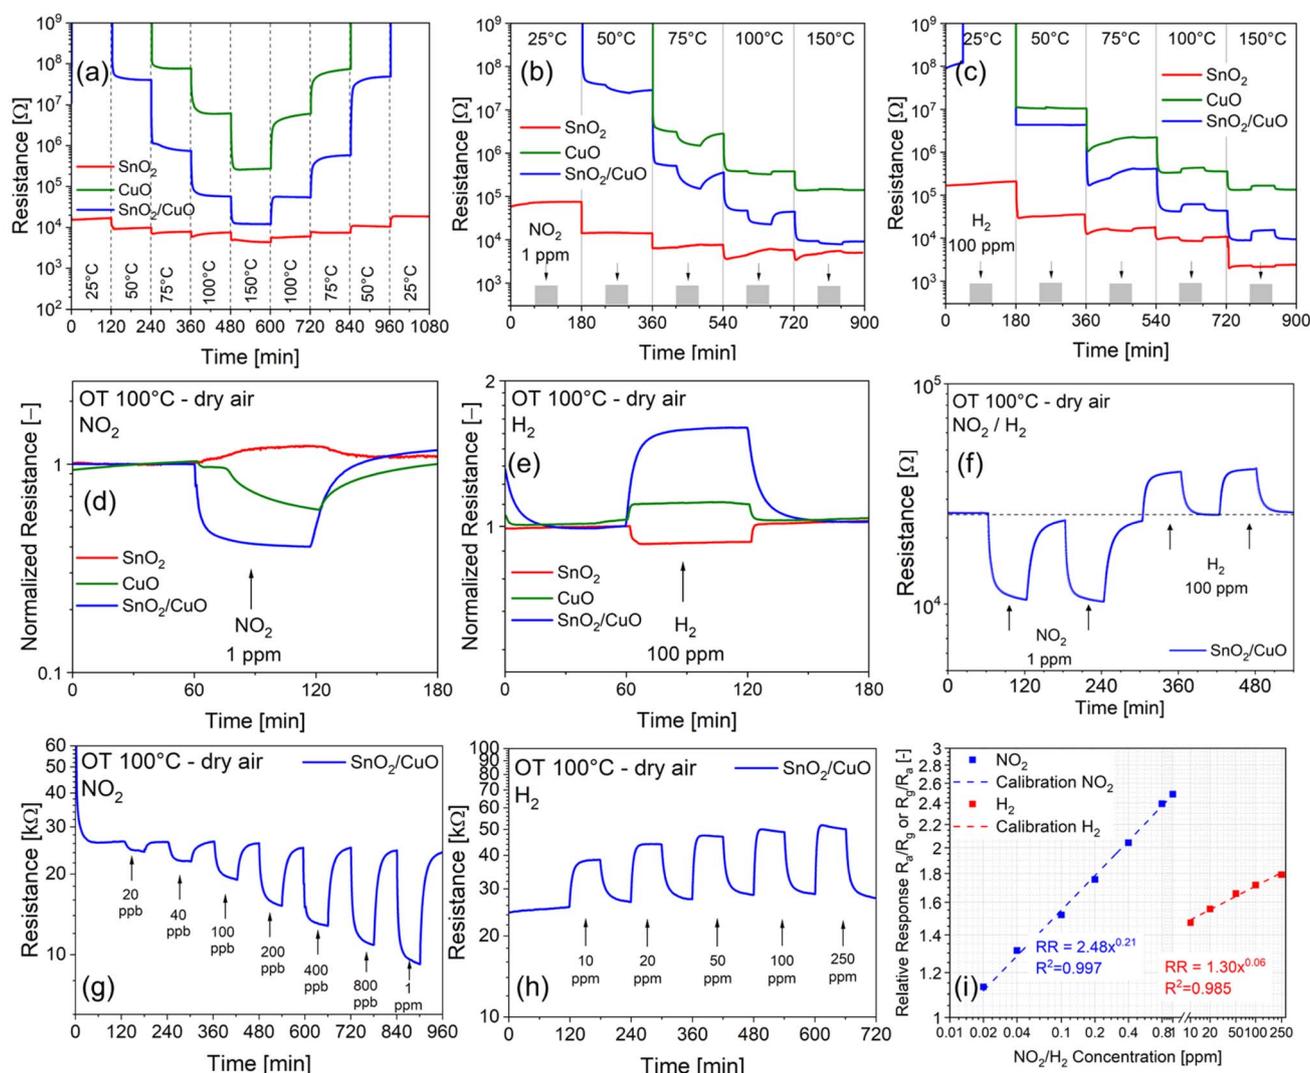

Fig. 6 (a) BLR modulation of CuO (green), SnO₂ (red) and SnO₂-QDs/CuO (blue) measured in dry air under increasing/decreasing the OT in the 25–150–25 °C range; (b) gas sensing response to 1 ppm NO₂ and 100 ppm H₂ at different OTs (25–150 °C); (d) and (e) comparison of the normalized gas response to 1 ppm NO₂ and 100 ppm H₂ at 100 °C OT; (f) SnO₂-QDs/CuO reproducibility response to NO₂ (1 ppm) and H₂ (100 ppm) at 100 °C OT; (g) and (h) dynamic electrical responses of the SnO₂-QDs/CuO in dry air at an OT of 100 °C to NO₂ (20 ppb to 1 ppm) and H₂ (10 ppm to 250 ppm); (i) SnO₂-QDs/CuO log/log calibration plots at 100 °C OT of the sensor's signal (*i.e.*, $RR = R_a/R_g$ or R_g/R_a) vs. NO₂ and H₂ gas concentrations.

To evaluate the optimal operating temperature (OT) of each sensor, films were exposed to low concentrations of NO₂ (1 ppm) and H₂ (100 ppm) in dry air by varying the temperature in the range of 25–150 °C, as shown in Fig. 6b and c. At 25 °C OT, the base line resistance moves beyond 10⁹ Ω exceeding the instrumental capabilities. By stepwise increasing the operating temperature from 25 °C to 150 °C (Fig. 6b and c) the base line resistance of all sensors decreases, consistent with their semi-conducting nature (see also Fig. 6a). Specifically, as shown in Fig. 6b, starting from 75 °C the introduction of 1 ppm NO₂ into the test chamber (indicated by the grey rectangle at the bottom), causes a noticeable decrease of the resistance for both the CuO (green) and SnO₂-QDs/CuO (blue) sensors. Opposedly, base line resistance of SnO₂ remains largely unaffected upon exposure to NO₂. Conversely, as indicated in Fig. 6c, when 100 ppm H₂ is introduced into the chamber, the resistance of both CuO (green) and SnO₂-QDs/CuO (blue) increases. It turns out that both CuO nanoparticles and SnO₂-QDs/CuO exhibit p-type behavior, associated to a decrease/increase of the resistance upon NO₂/H₂ exposure, congruently with previous studies on CuO⁴⁸ and CuO-based heterostructure sensors.^{49,50} Opposedly, SnO₂ quantum dots (QDs) demonstrate typical n-type response, characteristic of SnO₂ metal oxide sensors,⁵¹ with a negligible resistance increase/decrease to NO₂/H₂.

Considering now that the onset gas sensing temperature to NO₂/H₂ of the SnO₂-QDs/CuO heterojunction is 50/100 °C, while that of SnO₂-QD and CuO is 100 °C (Fig. 6b and c), we set the operating temperature (OT) at 100 °C, as a balance between the sensor's signal amplitude (here referred as the relative response, RR) and a fast and reversible baseline recovery. Specifically, sensors' electrical responses at 100 °C to 1 ppm NO₂ and 100 ppm H₂ in dry air are shown in Fig. 6d and e. We found that at 1 ppm NO₂, the RRs values (R_a/R_g or R_g/R_a , depending on the p/n nature of the sensor) are 1.6, 2.5, and 1.2 for CuO, SnO₂-QDs/CuO and SnO₂-QDs (with an estimated standard deviation of ±0.1 calculated over a set of 5 identical measurements). RRs to 100 ppm H₂ are slightly smaller: 1.2, 1.7,

and 1.1, confirming the superior performances of the SnO₂-QDs/CuO to detect both NO₂ and H₂. As a concluding remark, the SnO₂-QD/CuO shows excellent reverse capability to measure NO₂ and H₂ with fast and reversible base line recovery, as displayed in Fig. 6f.

Fig. 6g and h show the dynamic resistance changes of the SnO₂-QDs/CuO to NO₂ in the range 20 ppb to 1 ppm and H₂ (10–250 ppm) in dry air background at 100 °C OT. SnO₂-QDs/CuO shows a remarkable modulation of the sensor's signal to increasing NO₂ and H₂ gas concentrations, with excellent recovery of the BLR following each step of gas/dry air purge. The log–log calibration plots of the sensor's signal (*i.e.*, $RR = R_a/R_g$ or R_g/R_a) vs. NO₂ and H₂ gas concentrations shown in Fig. 6i, yield gas sensitivities (*S*), as represented by the slope of the calibration lines, $S_{NO_2} = (0.21 \pm 0.01) [ppm]^{-1}$ and $S_{H_2} = (0.06 \pm 0.01) [ppm]^{-1}$. The limits of detections (LOD) for NO₂ and H₂ were determined by extrapolating the calibration lines in Fig. 6i to the point where the response ratio (RR) equals 1, yielding $LOD_{(NO_2)} = 12$ ppb and $LOD_{(H_2)} = 15$ ppb respectively. The better NO₂ dynamic responses (RRs) and sensitivities (*S*) with respect to H₂, confirm the stronger tendency of NO₂ molecules to interact with the SnO₂-QD/CuO surface as respect to less electronegative H₂, as it will be discussed in the next paragraph.

Retrieving from literature data, Table 1 compares normalized relative responses – to 1 ppm NO₂ and 100 ppm H₂ (when available) of recently published CuO-based composites for gas sensing. Apart from Pd–CuO/rGO interfaces operating at 25 °C, our SnO₂-QD/CuO yields comparable performances, eventually obtained at lower operating temperature as respect to the others.

In addition, SnO₂-QDs/CuO sensor's adsorption/desorption times (τ_{ads}/τ_{des}) to H₂ are faster with respect to NO₂. Comparing τ_{ads}/τ_{des} to NO₂ (Fig. 7a) and H₂ (Fig. 7d), NO₂ adsorption/desorption times are approximately two-fold those of H₂, with desorption times always bigger than adsorption for both gases. Cross sensitivity tests were carried out to investigate the effect of humidity as interfering gas to the NO₂ and H₂

Table 1 Comparison of the NO₂ and H₂ gas sensing response of CuO based composites normalized at 1 ppm NO₂ and 100 ppm H₂ (where applicable). Relative Response (RRs) indicated as: R_g/R_a if $R_g > R_a$; R_a/R_g if $R_g < R_a$

Sensing material	Gas concentration	Relative response RR [—]	OT [°C]	Ref.

SnO ₂ -QDs/CuO	100 ppm	1.7	100	This work

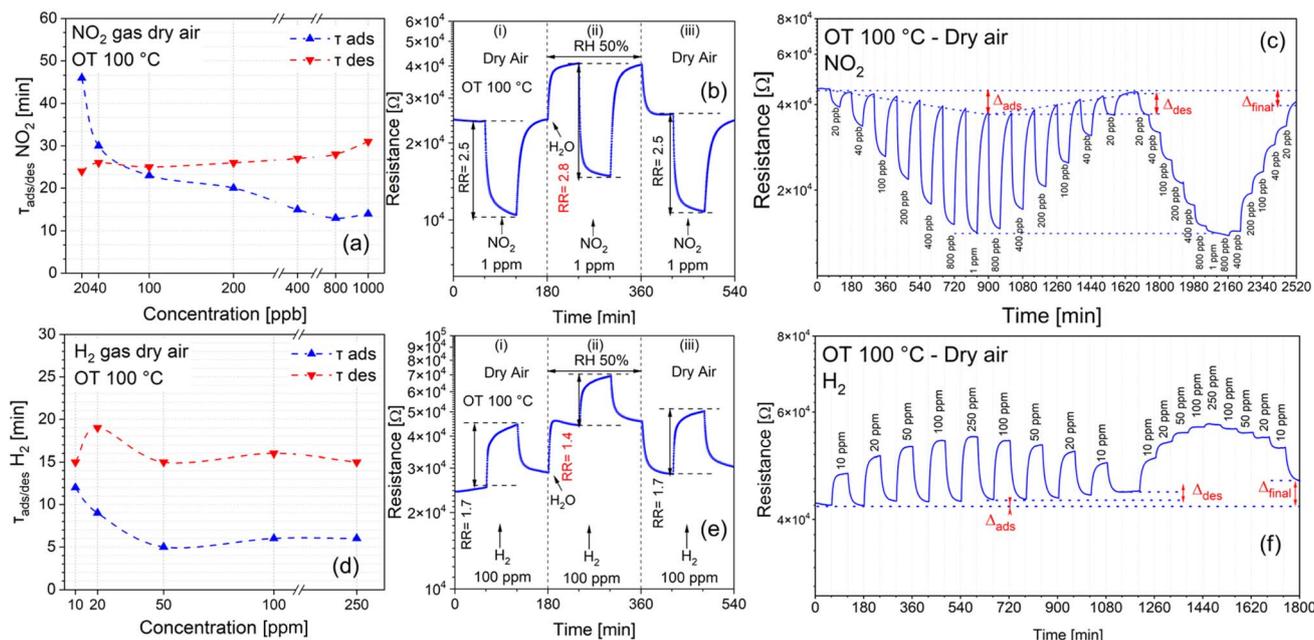

Fig. 7 (a) and (d) Adsorption and desorption times of the SnO₂-QD/CuO in dry air at an OT of 100 °C to NO₂ (20 ppb to 1 ppm) and H₂ (10 ppm to 250 ppm); (b) NO₂ and (e) H₂ cross-sensitivity to 50% relative humidity (RH). Each panel of figures (b)–(e) comprises: first panel (i), the response to 1 ppm NO₂ (100 ppm H₂) in dry air, second panel (ii), response 1 ppm NO₂ (100 ppm H₂) in 50% RH background, third panel (iii), response to 1 ppm NO₂ (100 ppm H₂), as to first panel, to check repeatability; (c) and (f) reproducibility and baseline recovery measured by exposing the SnO₂-QDs/CuO to both pulse and cumulative NO₂ (20 ppb to 1 ppm) and H₂ (10–250 ppm) concentrations.

response, as shown in Fig. 7b and e. The standardized cross-sensitivity procedure comprises three steps. In a first step (panel i) SnO₂-QD/CuO is exposed to 1 ppm NO₂ and 100 ppm H₂ in dry air; in a second step (panel ii) dry air background is replaced by 50% Relative Humidity (RH) humid-air while exposing the sensor to 1 ppm NO₂ and 100 ppm H₂, finally a third step (panel iii) is carried out in the same conditions of (panel i) to check for short term reproducibility. According to Fig. 7b and e, BLR of the SnO₂-QD/CuO rapidly increases as soon as 50% RH is introduced, in line with p-type sensors response to humidity at operating at temperature higher than 25 °C.^{58–60} Significantly, relative response to 1 ppm NO₂ increases from 2.5 ± 0.1 in dry air, to 2.8 ± 0.1 in 50% RH. That to 100 ppm H₂ decreases from 1.7 ± 0.1 to 1.4 ± 0.1 respectively. This behavior is consistent with previous findings about a possible synergistic/antisynergistic effect of water vapor in the presence of oxidizing/reducing gases.^{23,51} Selectivity response (SR) shown in SI Fig. S3, highlights the superior ability of SnO₂-QDs/CuO sensor to detect NO₂ and H₂ compared to 100 ppm NH₃, 1% ethanol and 1% acetone. Notably, SR differs from humidity cross response (Fig. 7b and e), since it compares the sensor's ability to preferentially respond to a specific gas (*i.e.* 1 ppm NO₂ target gas) while ignoring other gases or organic vapours under similar experimental conditions.

Finally, the short term reproducibility of the electrical response to NO₂ and H₂ to both pulsed (on/off) and cumulative (increasing/decreasing) concentration modes is shown in Fig. 7c and f. Specifically, under pulsed conditions, the baseline resistance (BLR) overall recovers its initial value after each

desorption cycle in dry air, with a slight displacement from the BLR (as highlighted by Δ_{ads} for both gases), corresponding to higher gases' concentration. In a similar way, under cumulative stepwise adsorption/desorption modes, the NO₂/H₂ gases resistances taken at 1 ppm/100 ppm, perfectly matches the corresponding ones in pulse mode.

4. Gas sensing mechanism

The SnO₂-QDs/CuO exhibits improved sensing performances with respect to its single counterparts, showing a prevailing p-type response. Apart from the formation of p–n junctions, indeed SnO₂ quantum dots significantly enhance the reacting surface area, increasing the number of available adsorption sites.

The formation of p–n heterojunctions, as tentatively shown in Fig. 8, improves the gas sensing response of the SnO₂-QD/CuO.^{26,49,50} Taking into account that CuO and SnO₂ QDs yield band gaps (BG) of ≈ 1.8 eV and ≈ 4.1 eV (Fig. 5b), and assuming that CuO valence (VB) and conduction (CB) bands potentials are higher than those of SnO₂,^{49,50} when the two materials are brought into contact, Fermi levels align and a typical Z-scheme heterojunction is built up.⁵⁰ Specifically, electrons from SnO₂ diffuse into CuO, and holes from CuO migrate into SnO₂, forming a depletion region at the interface. Such charge redistribution leads to the establishment of an internal electric field, directed from SnO₂ to CuO. As a result, a built-in potential barrier forms, causing an accumulation of electrons in the SnO₂ conduction band and holes in the CuO valence band.

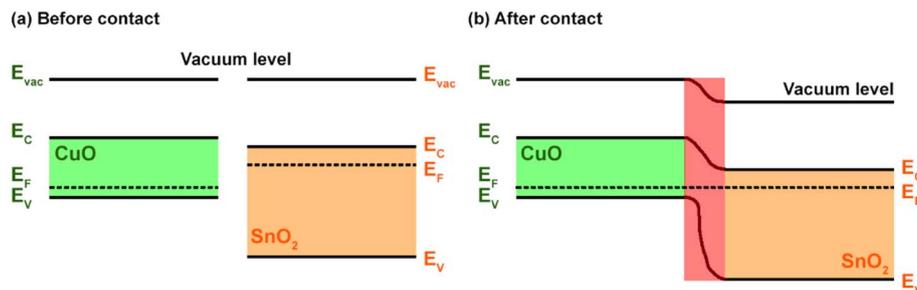

Fig. 8 Schematization of the p-n heterojunction at the interface of CuO and SnO₂ (a) before and (b) after contact.

Consequently, a majority of charge carriers (electrons for SnO₂ and holes for CuO) are available to participate in the gas-surface reactions, yielding a stronger modulation of the electrical resistance in the presence of a target gas.

It turns out that the larger extension of the p-type CuO surface as respect to that of n-type SnO₂-QDs, explains the overall p-type response of the SnO₂/CuO. Given that, we may also estimate that the CuO surface of the heterojunction is the primarily reacting surface to NO₂, H₂ and H₂O adsorbing molecules. Under these conditions at operating temperatures below 150 °C, the adsorption of oxygen on a doubly positively-charged oxygen vacancy V_O^{••} leads to an increase of the holes h[•] concentration in p-type CuO (R1), resulting in a resistance decrease.

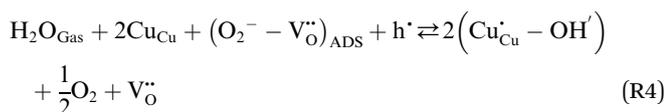

NO₂ molecules, on the other hand, interacts with CuO by direct adsorption on free vacancy sites (R2).²³ Being NO₂ a strong electron-acceptor, electrons are released from the surface, leading to an increase of the h[•] concentration in the material, eventually decreasing the resistance (Fig. 6d).

When a reducing gas like H₂ is introduced, it generally reacts with adsorbed oxygen,⁵³ decreasing h[•] concentration (R3), leading to a resistance increase (Fig. 6e).

Regarding water interaction with CuO, a mechanism involving pre-adsorbed oxygen and Cu lattice atoms has been proposed,^{58,61} which yields a depletion of h[•] concentration (R4) and an increase of the sensor's resistance (Fig. 7b – panel (ii)).

These mechanisms also provide a coherent explanation for the synergistic/antisynergistic effects induced by humidity in the presence of oxidizing or reducing gases. Specifically in

Fig. 7b and e – panel (ii), we demonstrated that sensor's relative responses (RRs) to NO₂/H₂ gases in presence of 50% RH increases/decreases as respect to dry air background (see Fig. 7b and e – panel (i)), following a synergistic/antisynergistic response. In case of NO₂, the synergistic response in 50% RH can be explained considering that as soon as 50% RH interacts with the sensor's surface (Fig. 7b – panel (ii)), reaction (R4) increases the concentration of V_O^{••}, boosting NO₂ adsorption according to reaction (R2). Conversely, the antisynergistic response to H₂ in the presence of 50% RH, can be described taking into account that as soon as 50% RH interacts with the sensor's surface (Fig. 7e – panel (ii)), reaction (R4) decreases the concentration of (O₂⁻ - V_O^{••})_{ADS}, therefore hampering H₂ reduction according to reaction (R3). DFT atomistic simulations of NO₂, H₂ gases and H₂O molecules adsorption over CuO and SnO₂ metal oxides, highlight a substantial agreement with the ionosorption mechanism discussed in this paragraph. Specifically, it was confirmed the stronger oxidizing attitude of NO₂ molecules to form NO₂⁻ with oxygen-vacancy sites V_O^{••}.^{62,63} Furthermore, while H₂ adsorption on SnO₂ is characterized by physisorption,⁶⁴ its interaction with CuO follows a dissociative adsorption pathway.⁶⁵ Accordingly, the weak interaction of H₂ molecules predicted by DFT calculations, is congruent with the smaller sensor's signal variation to H₂ compared to NO₂, as illustrated in Fig. 6i. Finally, H₂O vapor is reported to chemisorb on SnO₂, forming two hydroxyl groups.⁵¹ On CuO, H₂O adsorbs either chemically at Cu sites or dissociatively at oxygen-deficient regions.⁶⁶ Both DFT models of H₂O adsorption predict a decrease/increase of the electrical resistance for n-type SnO₂ or p-type CuO, in agreement with experimental observations.

5. Conclusions

In this work, we have successfully demonstrated a simple and scalable synthesis of a novel heterojunction based on needle-like CuO decorated with SnO₂ quantum dots (QDs, *d* = 3.9 nm) for NO₂ and H₂ gas sensing applications.

The composite exhibits markedly enhanced gas sensing performance compared to the individual components, with higher sensitivity toward the investigated species and excellent stability and reproducibility of the response. Notably, sensor operates efficiently at 100 °C OT, a significantly lower temperature compared to conventional metal oxide sensors, addressing a key limitation of to date gas sensing technologies.

Ultimately, we studied a possible sensing mechanism explaining the role of the heterojunctions and possible gas–surface interaction, tentatively describing also the synergistic/antisnergistic effect played by relative humidity acting as interfering gas over the NO₂/H₂ responses.

In conclusion, these results point out the improving effect of the CuO and SnO₂ QDs coupling, associated to efficient charge transfer and modulation the electronic structure of the sensing interface. Overall, this study provides a promising pathway toward the development of high-performance, low-temperature gas sensors based on engineered oxide.
