Promoting electrocatalytic CO₂ reduction to *n*-propanol over ethanol at Cu step sites†

Yuanyuan Xue, Ximeng Lv,[†] Chao Yang, Lu Song, Lijuan Zhang* and Gengfeng Zheng[†]*

Obtaining valuable C₃₊ products directly from the electrocatalytic reduction of CO₂ or CO is an attractive but challenging task, due to the much more complicated reaction pathways and sluggish kinetics of C₃₊ products than their C₁ and C₂ counterparts. As different C₃₊ products and competitive C₂ side-products may share the common rate-determining step (e.g. the carbon–carbon coupling), the regulation of subsequent selectivity-determining step(s) is critical for promoting the selectivity of C₃₊ products. Herein, we focused on tuning the selectivity competition between *n*-propanol (*n*-C₃H₇OH, an important C₃₊ alcohol) versus ethanol (C₂H₅OH, a major C₂ side product), based on the constant potential computations on the Cu surface with different step sites. The critical selectivity-determining steps for the *n*-C₃H₇OH and C₂H₅OH pathways have been identified, and the impact of Cu step sites on the competitive relation between *n*-C₃H₇OH and C₂H₅OH has been explored. Moreover, a descriptor related closely to the *n*-propanol selectivity has been developed, showing that controlling the competitive hydrogenation of C₂ intermediates and C₁–C₂ coupling processes is vital to differentiate the selectivity of *n*-propanol from ethanol. This work can inspire the screening and rational design of unconventional electrocatalytic sites for generating more value-added C₃₊ products from the electrocatalytic CO₂ reduction.

Introduction

The electrocatalytic CO₂ or CO reduction reaction (CO₂RR/CORR) using renewable electricity has attractive potential for reducing carbon footprint and energy storage in liquid fuel products like alcohols,^{1–4} due to their high energy densities, convenient storage, and facile transportation.^{5,6} C₁ and C₂ alcohols, *i.e.*, methanol (CH₃OH)^{7–9} and ethanol (C₂H₅OH),^{10–12} have relatively high selectivities and activities. In contrast, the selective electroreduction of CO₍₂₎ into C₃₊ alcohols, such as *n*-propanol (*n*-C₃H₇OH), is still challenging versus the competing side reactions of C₁ and C₂ products. As the CO₍₂₎-to-C₃H₇OH involves complicated reaction pathways containing both the C₁–C₁ coupling and subsequent C₁–C₂ coupling,^{13,14} most of the reported faradaic efficiencies (FEs) of *n*-C₃H₇OH in CO₍₂₎ electroreduction are still below 20% to date.^{15–18}

A variety of approaches have been investigated to promote the selectivity of the *n*-propanol product from the CO₍₂₎RR. For instance, doping Au into Cu(100) was reported to decrease the adsorption of CO* (where * refers to the adsorption site) while

retaining the intrinsic Cu(100) active sites at the same time, which facilitated the C₁–C₂ and C₁–C₁ coupling process and presented a peak FE of 18% for *n*-C₃H₇OH.¹⁵ Cu co-doped with Ag and Ru was synthesized for the CO electroreduction to *n*-C₃H₇OH, with a 37% FE and >100 mA cm^{–2} of partial current density.¹⁹ Nonetheless, the production selectivity and yield of *n*-C₃H₇OH by the electrocatalytic CO₍₂₎RR are still much lower than those of the C₁ and C₂ side products and also far from the commercialization requirements.^{20–22}

The selectivity of C₁ and C₂ products in the CO₍₂₎RR can be promoted based on the rate-determining step (RDS) regulation,^{23–29} such as using atomic structure design²³ or microenvironmental tuning.^{24,26} However, as the C₃ formation steps (e.g. the C₁–C₂ coupling and the hydrogenation of C₃ intermediates) are far away from the initial reaction stage and unlikely to serve as the RDS,³⁰ different C₃₊ products and those C₂ side products may share the same RDS. Thus, it is hard to improve the selectivity of C₃₊ products by the RDS tuning strategy. The selectivities of C₃₊ products should mainly be determined by the selectivity-determining steps (SDSs) for the competitive pathways.³¹ Ethanol has been proposed as a major competing side product of *n*-C₃H₇OH.^{32–36} Wang and coworkers analyzed the reported CO₂RR-relevant studies using the machine learning method and found correlation between FEs/ΔFEs of ethanol and *n*-propanol, suggesting that ethanol and *n*-propanol share the common C–C coupling process and compete

with each other.³⁶ In addition, according to our previously reported work,² the pathways to ethanol and *n*-propanol separate with the acetate/acetic acid pathway at an earlier stage (CH_2CO^*). Thus, the FE of acetate is generally low under conditions that are advantageous for the *n*-propanol formation.^{37,38} Thus, the competitive relationship between ethanol and *n*-propanol is more critical for determining the *n*-propanol selectivity in the CO_2 RR. By using differential electrochemical mass spectrometry, it was found that the concentration ratios of acetaldehyde/ethanol and propionaldehyde/*n*-propanol near the cathode surface are higher than those in the bulk electrolyte during CO_2 electroreduction, suggesting that acetaldehyde (CH_3CHO) is the bifurcation point of $\text{C}_2\text{H}_5\text{OH}$ and *n*- $\text{C}_3\text{H}_7\text{OH}$.³² The subsequent coupling of CH_3CHO and CO^* can lead to the formation of *n*- $\text{C}_3\text{H}_7\text{OH}$, while the further hydrogenation of CH_3CHO results in $\text{C}_2\text{H}_5\text{OH}$.³² In addition to acetaldehyde, methylcarbonyl (CH_3CO^*) has also been suggested as another possible branching point for the $\text{C}_2\text{H}_5\text{OH}$ and *n*- $\text{C}_3\text{H}_7\text{OH}$ pathways.³⁴ Nonetheless, despite that they are crucial for the CO_2 RR to *n*- $\text{C}_3\text{H}_7\text{OH}$, the branching intermediates and selectivity-determining steps for the $\text{C}_2\text{H}_5\text{OH}$ and *n*- $\text{C}_3\text{H}_7\text{OH}$ pathways are still ambiguous, precluding the breakthrough of designing efficient electrocatalysts.

In this work, we first conducted constant potential computations to identify the selectivity-determining steps and the critical bifurcation intermediate for the *n*- $\text{C}_3\text{H}_7\text{OH}$ and $\text{C}_2\text{H}_5\text{OH}$ pathways. Then we designed a variety of high-index Cu facets with step sites and theoretically investigated for their catalytic performances on the selectivity competition between the *n*- $\text{C}_3\text{H}_7\text{OH}$ and $\text{C}_2\text{H}_5\text{OH}$ pathways. Finally, a critical descriptor was developed to predict the capabilities of different Cu sites for the CO_2 RR to *n*- $\text{C}_3\text{H}_7\text{OH}$, suggesting the potential of developing new electrocatalysts for more value-added products.

Results and discussion

Selectivity mechanism

As Cu(100) has been widely reported for the CO_2 RR to C_2+ products (mostly C_2 products like ethylene and ethanol though),³⁹ we first conducted constant potential calculations to explore the critical elementary steps regarding the competition between $\text{C}_2\text{H}_5\text{OH}$ and *n*- $\text{C}_3\text{H}_7\text{OH}$ pathways on Cu(100) (computational details in Fig. S1 and Tables S1, S2†). There are two possible bifurcation intermediates (*i.e.*, CH_3CO^* and $\text{CH}_3\text{-CHO}^*$) for the competition pathways between $\text{C}_2\text{H}_5\text{OH}$ and *n*- $\text{C}_3\text{H}_7\text{OH}$,^{32–34} and the possible hydrogenation steps and coupling steps of those two intermediates are schematically displayed (Fig. 1a). Although CH_2CHO^* has also been proposed as a possible precursor to form CH_3CHO^* ,³⁷ the formation of CH_3CO is easier than that of CH_2CHO^* (Fig. S2†). Thus, CH_3CO^* is chosen as the starting point (Fig. 1a). For the hydrogenation of CH_3CO^* , the free energy change (ΔG) to CH_3CHO^* (*i.e.*, $\text{CH}_3\text{CO}^* + \text{H}^+ + \text{e}^- \rightarrow \text{CH}_3\text{CHO}^*$) is more negative than that of CH_3COH^* (*i.e.*, $\text{CH}_3\text{CO}^* + \text{H}^+ + \text{e}^- \rightarrow \text{CH}_3\text{COH}^*$) in the whole potential range and pH range (Fig. S3†), indicating that the carbon atom of the carbonyl group in CH_3CO^* tends to obtain the proton rather than the oxygen atom

Fig. 1 (a) Possible hydrogenation and coupling steps of the two possible branching intermediates (CH_3CO^* and CH_3CHO^*) for $\text{C}_2\text{H}_5\text{OH}$ and *n*- $\text{C}_3\text{H}_7\text{OH}$ pathways. The preferable hydrogenation and coupling steps of CH_3CO^* and CH_3CHO^* are marked with purple arrows. The hydrogen atoms from the hydrogenation of CH_3CO^* are shown in green color, and the hydrogen atoms from the hydrogenation of CH_3CHO^* are shown in blue color. The most possible $\text{C}_2\text{H}_5\text{OH}$ and *n*- $\text{C}_3\text{H}_7\text{OH}$ pathways are highlighted with the dashed boxes. (b) Free energy changes of the hydrogenation and coupling steps of CH_3CO^* on Cu(100) versus the potential and pH. (c) Free energy changes of the hydrogenation and coupling steps of CH_3CHO^* on Cu(100) versus the potential and pH. The circle highlights the dominant potential range (at pH 14) where the coupling step proceeds preferably. The grey planes in (b) and (c) are the planes of the function of $\Delta G = 0$ (eV).

of the carbonyl group. For the subsequent hydrogenation of CH_3CHO^* , the carbon atom of the aldehyde group is also easier to obtain the proton (*i.e.*, $\text{CH}_3\text{CH}_2\text{O}^*$) than the oxygen atom of the aldehyde group (*i.e.*, CH_3CHOH^*) (Fig. S4†), suggesting that $\text{CH}_3\text{CH}_2\text{O}^*$ is more likely to be the key intermediate toward ethanol than CH_3CHOH^* . For the *n*-propanol formation pathway (Fig. S5†), the coupling of CH_3CHO^* with CO^* tends to form $\text{CH}_3\text{COCHO}^*$ on Cu(100) within the whole potential and pH ranges, rather than form the $\text{CH}_3\text{CHOCO}^*$ intermediate.

From the above analysis, the most possible hydrogenation and coupling steps of CH_3CO^* and CH_3CHO^* are determined (purple arrows in Fig. 1a), among which CH_3CHO^* can be obtained from the hydrogenation of CH_3CO^* . As shown in Fig. 1b, the coupling between CH_3CO^* and CO^* (*i.e.*, $\text{CH}_3\text{CO}^* + \text{CO}^* \rightarrow \text{CH}_3\text{COCO}^*$) is preferable under alkaline conditions, as the ΔG of the CH_3CO^* hydrogenation step (*i.e.*, $\text{CH}_3\text{CO}^* + \text{H}^+ + \text{e}^- \rightarrow \text{CH}_3\text{CHO}^*$) is more positive in a higher pH environment. However, when the coupling step becomes spontaneous, ΔG of the CH_3CO^* protonation step is more negative, even at pH 14. Thus, the protonation of CH_3CO^* to CH_3CHO^* is generally advantageous during the CO_2 RR. On the other hand, for

CH_3CHO^* in an alkaline environment (Fig. 1c), the coupling step ($\text{CH}_3\text{CHO}^* + \text{CO}^* \rightarrow \text{CH}_3\text{COCHO}^*$) is more preferable than its protonation step in the potential range of -0.27 to -0.50 V vs. the standard hydrogen electrode (SHE) at pH 14, suggesting that CH_3CHO^* is more likely to be the branching intermediate for $\text{C}_2\text{H}_5\text{OH}$ and $n\text{-C}_3\text{H}_7\text{OH}$ pathways. The corresponding SDS for $\text{C}_2\text{H}_5\text{OH}$ formation is: $\text{CH}_3\text{CHO}^* + \text{H}^+ + \text{e}^- \rightarrow \text{CH}_3\text{CH}_2\text{O}^*$, and the corresponding SDS for $n\text{-C}_3\text{H}_7\text{OH}$ formation is: $\text{CH}_3\text{CHO}^* + \text{CO}^* \rightarrow \text{CH}_3\text{COCHO}^*$. Kastlunger *et al.* conducted microkinetic simulations based on the constant-potential density functional theory (DFT) to explore the formation of C_2 products by the CO_2RR on $\text{Cu}(100)^{40}$ and found that the hydrogenation of CH_3CHO^* to $\text{CH}_3\text{CH}_2\text{O}^*$ led to the formation of $\text{C}_2\text{H}_5\text{OH}$, consistent with our results. Recently, the surface reconstruction of $\text{Cu}(100)$ during the CO_2RR was theoretically explored by the potential-dependent grand canonical Monte Carlo method combined with the environmental kinetic Monte Carlo method and the DFT method, showing that $\text{C}_2\text{H}_5\text{OH}$ can be produced through the hydrogenation of CH_3CHO^* to $\text{CH}_3\text{CH}_2\text{O}^*$.⁴¹ This work also supports that the hydrogenation of CH_3CHO^* is a critical step for the formation of $\text{C}_2\text{H}_5\text{OH}$. The free energy profiles of SDSs for both the $\text{C}_2\text{H}_5\text{OH}$ and $n\text{-C}_3\text{H}_7\text{OH}$ formation pathways at -0.4 V vs. SHE at pH 14 are displayed (Fig. S6†), indicating the feasibility for the CO_2RR to n -propanol *via* the coupling between CH_3CHO^* and CO^* .

When the potential becomes more negative (< -0.50 V vs. SHE, pH 14), the hydrogenation step of $^*\text{CH}_3\text{CHO}$ toward ethanol becomes more dominant than the coupling step on $\text{Cu}(100)$ (Fig. 1c), indicating that the perfect $\text{Cu}(100)$ facet is hard to catalyze the CO_2RR to $n\text{-C}_3\text{H}_7\text{OH}$. In comparison, on Ag-doped Cu, the SDS for the $n\text{-C}_3\text{H}_7\text{OH}$ pathway becomes dominant in the potential range between 0.22 and -0.96 V vs. SHE at pH 14 (see $\Delta G(\text{U}, \text{pH})$ and structures in Fig. S7, computational details in Fig. S8 and Table S3†), in accordance with the experimental observation of the enhanced $n\text{-C}_3\text{H}_7\text{OH}$ selectivity on Ag-doped Cu,⁴² also confirming the branching intermediate (CH_3CHO^*) and SDSs for $\text{C}_2\text{H}_5\text{OH}$ and $n\text{-C}_3\text{H}_7\text{OH}$ pathways.

Step effects

After determining the critical branching intermediate and corresponding SDSs for the $\text{C}_2\text{H}_5\text{OH}$ and $n\text{-C}_3\text{H}_7\text{OH}$ pathways, we further investigated the roles of surface step sites in the competition between $\text{C}_2\text{H}_5\text{OH}$ and $n\text{-C}_3\text{H}_7\text{OH}$. The explicit functions of step sites on the $n\text{-C}_3\text{H}_7\text{OH}$ selectivity were first surveyed by constructing surface steps with different upper terrace widths and lower terrace widths based on the $\text{Cu}(100)$ facet (Fig. 2a–h). The step surfaces were constructed by removing the different numbers of atom row on the top layer of $\text{Cu}(100)$, and the width of one row is the diameter of Cu (1.8 \AA). The formed step surfaces are designated as “Step_u(x)d(y)”, where “u(x)d(y)” refers to the step site unit comprising x rows at the upper terrace and y rows at the lower terrace. It was found that the adsorption of CH_3CHO^* and CO^* competes with each other,³³ while the adsorption of CH_3CHO^* on $\text{Cu}(100)$ is always weaker than that of CO^* in the whole potential range of the

Fig. 2 (a–h) The side views and top views of different step surfaces constructed based on the $\text{Cu}(100)$ facet, including (a) Step_u5d1, (b) Step_u4d2, (c) Step_u3d3, (d) Step_u2d4, (e) Step_u2d2, (f) Step_u1d5, (g) Step_u1d3, and (h) Step_u1d1. The Cu atoms of the uppermost layer are presented with a brown color to clearly display the step sites. These step surfaces were denoted as “Step_u(x)d(y)”, which means that the upper terrace width of the step unit is “ x ” times the diameter of the Cu atom, and the lower terrace width of the step unit is “ y ” times the diameter of the Cu atom. The diameter of the Cu atom is 1.8 \AA .

CO_2RR (Fig. 3a, computational details in Fig. S9 and Table S4†). For the coupling of CH_3CHO^* and CO^* (*i.e.*, the SDS for the n -propanol pathway), the adsorption of both CO^* and CH_3CHO^* should be optimized. Thus, the $\Delta E_{\text{ads}}(\text{CH}_3\text{CHO}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ ratio is used to evaluate the priority of the $n\text{-C}_3\text{H}_7\text{OH}$ pathway, from which the ratio close to 1 suggests an optimal match of both CH_3CHO^* and CO^* adsorption. The $\Delta E_{\text{ads}}(\text{CH}_3\text{CHO}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ ratio reaches the highest value of 0.84 when the width of the lower terrace of the $\text{Cu}(100)$ step is 3.6 \AA (Fig. 3b, computational details in Table S5†). On the other hand, for the protonation of CH_3CHO^* to $\text{CH}_3\text{CH}_2\text{O}^*$ (*i.e.*, the SDS of the $\text{C}_2\text{H}_5\text{OH}$ pathway), when hydrogenated $\text{CH}_3\text{CH}_2\text{O}^*$ is more stable, the possibility for the formation of $\text{C}_2\text{H}_5\text{OH}$ increases. Thus, the $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ ratio is used to represent the protonation capability of the catalyst for C_2+ intermediates, from which the smaller ratio represents that the hydrogenation step is less likely to occur. The $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ ratio reaches the lowest value (2.45) when the width of the upper terrace is 1.8 \AA (Fig. 3c, computational details in Table S5†). Based on the two indicators above, the optimal $\text{Cu}(100)$ step is the Step_u1d2, with a lower terrace width of 3.6 \AA and an upper terrace width of 1.8 \AA (Fig. S10†).

To evaluate the $n\text{-C}_3\text{H}_7\text{OH}$ selectivity of different step sites, we set the $\text{Cu}(100)$ surface as the benchmark, and the $n\text{-C}_3\text{H}_7\text{OH}$ relative selectivity compared to the $\text{Cu}(100)$ surface is defined as: $(K_{\text{C}_2+\text{CO}}/K_{\text{C}_2+\text{H}} \times K_{\text{C}_3+\text{H}})$, where $K = k_{\text{step}}/k_{\text{Cu}(100)}$, k refers to the rate constant of an elementary reaction, “step” refers to the step surfaces, and “ $\text{C}_2 + \text{CO}$ ”, “ $\text{C}_2 + \text{H}$ ”, and “ $\text{C}_3 + \text{H}$ ” represent the coupling of CH_3CHO^* and CO^* to $\text{CH}_3\text{COCHO}^*$, the hydrogenation of CH_3CHO^* to $\text{CH}_3\text{CH}_2\text{O}^*$, and the hydrogenation of $\text{CH}_3\text{COCHO}^*$ to $\text{CH}_3\text{COCHOH}^*$ (Fig. S11†), respectively. The relative $n\text{-C}_3\text{H}_7\text{OH}$ selectivity of the $\text{Cu}(100)$ surface is set as 1. “ $K_{\text{C}_2+\text{CO}}/K_{\text{C}_2+\text{H}}$ ” represents the switching trend of the $\text{C}_2\text{H}_5\text{OH}$ and $n\text{-C}_3\text{H}_7\text{OH}$ pathways, which shows a linear correlation with the $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ value (Fig. 3d). Then the relative selectivity of $n\text{-C}_3\text{H}_7\text{OH}$ on different $\text{Cu}(100)$ steps was

(b) The adsorption energy ratios between CH_3CHO^* and CO^* of the step surfaces constructed based on $\text{Cu}(100)$ against the width of the lower terrace. (c) The adsorption energy ratios between $\text{CH}_3\text{CH}_2\text{O}^*$ and CO^* of the step surfaces constructed based on $\text{Cu}(100)$ against the width of the upper terrace. The data in (b) and (c) are from $\text{Cu}(100)$, Step_u5d1, Step_u4d2, Step_u3d3, Step_u2d4, and Step_u1d5. (d) The relation of the switching trend (defined as $K_{\text{C}_2+\text{CO}}/K_{\text{C}_2+\text{H}}$) against the descriptor $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$. (e) The free energy changes of three reaction steps including the protonation of CH_3CHO^* ($\text{C}_2 + \text{H}$), the protonation of $\text{CH}_3\text{COCHO}^*$ ($\text{C}_3 + \text{H}$), and the coupling between CH_3CHO^* and CO^* ($\text{C}_2 + \text{CO}$), and n -propanol relative selectivity of $\text{Cu}(100)$ and step surfaces constructed based on $\text{Cu}(100)$. (f) The free energy changes of the SDSs for n -propanol and ethanol pathways on Step_u1d2 against the potential and pH. The grey plane is the plane with the function of $\Delta G = 0$ (eV). The highlighted region with blue color shows the potential range at $\text{pH} = 14$ where the n -propanol is preferably produced. (g) The adsorption configurations of $\text{CH}_3\text{CH}_2\text{O}^*$ on $\text{Cu}(100)$ and Step_u1d2 (top), and the atomic charge coloring diagrams of $\text{CH}_3\text{CH}_2\text{O}^*$ on $\text{Cu}(100)$ and Step_u1d2 (bottom), the numbers of electron transferred from the surface adsorption sites to $\text{CH}_3\text{CH}_2\text{O}^*$ are marked.

calculated, among which the Step_u1d2 sites show the highest n - $\text{C}_3\text{H}_7\text{OH}$ relative selectivity of 5.7×10^{10} (Fig. 3e, right y-axis). The SDS of the n - $\text{C}_3\text{H}_7\text{OH}$ pathway on Step_u1d2 is more

dominant than the ethanol pathway in the potential range of -0.41 to -1.03 V vs. SHE at $\text{pH} 14$ (Fig. 3f, computational details in Fig. S12 and Table S6[†]), wider than that of the perfect $\text{Cu}(100)$ surface (Fig. 1c, -0.27 to -0.50 V vs. SHE). By comparing ΔG values of the hydrogenation and coupling steps of CH_3CHO^* and the hydrogenation step of $\text{CH}_3\text{COCHO}^*$ on Step_u1d2 and $\text{Cu}(100)$ (Fig. 3e, left y-axis), the suppression of the CH_3CHO^* protonation contributes the most to the enhanced n - $\text{C}_3\text{H}_7\text{OH}$ relative selectivity of Step_u1d2. The adsorption of $\text{CH}_3\text{CH}_2\text{O}^*$ is switched from a bridged-adsorption mode on the $\text{Cu}(100)$ surface, to a top-adsorption mode on the Step_u1d2 sites due to the confined surface structure (Fig. 3g). This top-adsorption mode leads to the less electron transfer from Cu atoms to $\text{CH}_3\text{CH}_2\text{O}^*$ according to the Bader charge and differential charge density analysis (Fig. 3g and S13[†]), thus decreasing the binding strength of $\text{CH}_3\text{CH}_2\text{O}^*$ on Step_u1d2 (Fig. S14a, computational details in Fig. S12 and Table S6[†]). On the other hand, the adsorption of CH_3CHO^* on Step_u1d2 is stronger than that on $\text{Cu}(100)$ (Fig. S14b, computational details in Fig. S12 and Table S6[†]). The angle between the Cu–O bond (the O atom from CH_3CHO^*) and the surface plane of Step_u1d2 is 64° (Fig. S15[†]), smaller than that of CH_3CHO^* on $\text{Cu}(100)$ (82°), indicating a geometric affinity of Step_u1d2 for the CH_3CHO^* adsorption. Thus, the weak adsorption of $\text{CH}_3\text{CH}_2\text{O}^*$ and the strong adsorption of CH_3CHO^* on Step_u1d2 together contribute to the inhibited protonation of CH_3CHO^* and enhanced n - $\text{C}_3\text{H}_7\text{OH}$ relative selectivity.

Furthermore, the n - $\text{C}_3\text{H}_7\text{OH}$ relative selectivity of $\text{Cu}(100)$ and step sites shows a volcano trend with the $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ value (Fig. 4a), as the adsorption energies of different reaction intermediates are correlated during the reactions.⁴³ When $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ decreases at the right side of the volcano, the hydrogenation step of CH_3CHO^* (*i.e.*, SDS for the $\text{C}_2\text{H}_5\text{OH}$ pathway) is inhibited as the adsorbed $\text{CH}_3\text{CH}_2\text{O}^*$ becomes unstable. This SDS suppression of the $\text{C}_2\text{H}_5\text{OH}$ pathway is beneficial for the n - $\text{C}_3\text{H}_7\text{OH}$ production. When $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ further decreases at the left side of the volcano, not only the protonation of CH_3CHO^* is suppressed, but also the protonation of C_3 intermediates, like $\text{CH}_3\text{COCHO}^*$, is also suppressed. Thus, the n - $\text{C}_3\text{H}_7\text{OH}$ relative selectivity decreases as the $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ further decreases (at the left side of the volcano).

Facet prediction

As the high-index facets of Cu show characteristics of different step sites, we further screened the potential facets for the electroreduction of $\text{CO}_{(2)}$ toward n - $\text{C}_3\text{H}_7\text{OH}$ using the $\Delta E_{\text{ads}}(-\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ descriptor (Fig. 4b). The $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ values of (433), (321), and (310) are located in the optimal range (2.0–3.0 eV). In our work, the high-index facets have been constructed from the primitive cell of Cu, to control the suitable model size for DFT computations. For instance, $\text{Cu}(321)$ studied in this work corresponds to $\text{Cu}(210)$ (Fig. S16[†]), and a distinct experiment performance of the $\text{Cu}(210)$ facets for the CO_2RR to n -propanol was previously

Fig. 4 (a) The volcano plot of *n*-propanol relative selectivity (defined as $K_{C_2+CO}/K_{C_2+H} \times K_{C_3+H}$) versus the descriptor $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$. (b) The contour map showing the $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ values of different Cu facets. (c) The *n*-propanol relative selectivity and $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ values of three efficient Cu facets for the $\text{CO}_{(2)}\text{RR}$ to *n*-propanol. (d) The free energy changes of the SDSs for *n*-propanol and ethanol pathways on Cu(433) against the potential and pH. The grey plane is the plane with the function of $\Delta G = 0$ (eV). The highlighted region with orange color shows the potential range at pH = 14 where the *n*-propanol is preferably produced. (e) The adsorption energies of CH_3CHO^* (top) and $\text{CH}_3\text{CH}_2\text{O}^*$ on Cu(100) and Cu(433) against the potential. The potential range from -0.8 to -1.4 V vs. SHE is where the formation of *n*-propanol is preferable on Cu(433). (f) The adsorption configurations of CH_3CHO^* on Cu(433) and Cu(100). The angles between the Cu–O bond and the surface are marked. (g) The adsorption configurations of $\text{CH}_3\text{CH}_2\text{O}^*$ on Cu(100) and Cu(433) (top) and the atomic charge coloring diagrams of $\text{CH}_3\text{CH}_2\text{O}^*$ on Cu(100) and Cu(433) (bottom), the numbers of electron transferred from the surface adsorption sites to $\text{CH}_3\text{CH}_2\text{O}^*$ are marked. (h) The volcano plot of the *n*-propanol relative selectivity versus the descriptor $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$, including the data of the step surfaces (the Step_u(x)d(y) surfaces and Cu facets), the Cu-based bimetals, and other metals.

reported,⁴⁴ further confirming the practicability of the selectivity descriptor.

Compared to different facets, Cu(433) exhibits the highest relative selectivity ($\sim 10^9$) of *n*-propanol (Fig. 4c). The potential range for *n*-propanol production on Cu(433) was calculated to

be -0.40 to -1.49 V vs. SHE at pH 14 (Fig. 4d, computational details in Fig. S17 and Table S7[†]), which covers the experimentally observed potential range (-1.20 to -1.50 V vs. SHE, at pH 14) for *n*-propanol production,^{15,20} further indicating the great potential of Cu(433) in the $\text{CO}_{(2)}\text{RR}$ to *n*-propanol. Compared to Cu(100), Cu(433) shows a stronger adsorption for CH_3CHO^* and a weaker adsorption for $\text{CH}_3\text{CH}_2\text{O}^*$ in the potential range for *n*-propanol production (Fig. 4e, computational details in Fig. S17 and Table S7[†]). Thus, the hydrogenation of CH_3CHO^* on Cu(433) becomes difficult and the ethanol pathway is inhibited. The strong adsorption of CH_3CHO^* on Cu(433) is attributed to the geometric effect from the step sites. Compared to Cu(100), CH_3CHO^* adsorbed on Cu(433) is closer to the surface (Fig. 4f), allowing a strong interaction between the CH_3CHO^* and the Cu(433) surface. On the other hand, $\text{CH}_3\text{CH}_2\text{O}^*$ is adsorbed at the bridged-sites on Cu(100), and at the top-sites on Cu(433) (Fig. 4g). The less electron transfer from Cu(433) to the adsorbed $\text{CH}_3\text{CH}_2\text{O}^*$ results in the weak adsorption of $\text{CH}_3\text{CH}_2\text{O}^*$ based on the Bader charge and differential charge density analysis (Fig. 4g and S18[†]).

To more clearly show the practicability of the selectivity descriptor $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$, the experimentally reported Cu(321) facet was compared with the Cu(100) and Cu(433) facets. As shown in Fig. S19,[†] the high *n*-propanol relative selectivity of Cu(321) is also mainly from its capability for inhibiting the hydrogenation of CH_3CHO^* . The binding strength of Cu(321) for CH_3CHO^* is stronger than that of Cu(100) and weaker than that of Cu(433) (Fig. S20[†]). The adsorption configuration of CH_3CHO^* adsorbed on Cu(321) was analyzed (Fig. S21[†]). The angle between the Cu–O bond and the surface plane is smaller than that of Cu(100) (82°) and larger than that of Cu(433) (55°), suggesting that the capability of Cu(321) to stabilize the CH_3CHO^* intermediate is superior to that of Cu(100) and inferior to that of Cu(433). On the other hand, the adsorption of $\text{CH}_3\text{CH}_2\text{O}^*$ on Cu(321) is weaker than that on Cu(100) and stronger than that on Cu(433) (Fig. S22[†]). Furthermore, $\text{CH}_3\text{CH}_2\text{O}^*$ is also adsorbed on Cu(321) in a top-adsorption way, and the charge transfer of Cu(321) to the $\text{CH}_3\text{CH}_2\text{O}^*$ intermediate is less than that of Cu(100) and more than that of Cu(433) (Fig. S23[†]), confirming that the capability of Cu(321) to adsorb $\text{CH}_3\text{CH}_2\text{O}^*$ is between that of Cu(100) and Cu(433). Therefore, the *n*-propanol relative selectivity of Cu(321) is higher than that of Cu(100) and lower than that of Cu(433) (Fig. 4c). On Cu(321), the preferable potential range (at pH 14) for the coupling of CH_3CHO^* with CO^* is 0 to -0.75 V vs. SHE according to the constant potential calculations (Fig. S24, computational details in Fig. S25, and Table S8[†]). The overall selectivities of Cu(100), Cu(321), and Cu(433) for *n*-propanol were further calculated by considering the mainly competitive carbon-containing products (methane, methanol, ethylene, and ethanol) in the $\text{CO}_{(2)}\text{RR}$ to *n*-propanol (Fig. S26[†]). Cu(100) was also used as a reference in those calculations. The *n*-propanol overall selectivities (by considering all the possible carbon-containing products) on Cu(433) and Cu(321) are calculated to be $\sim 10^9$ and $\sim 10^6$, respectively (Fig. S27[†]), which are close to the *n*-propanol relative selectivities of the two facets (Fig. 4c). This result confirms that the *n*-propanol relative selectivity is

a reasonable metric to evaluate the *n*-propanol selectivity of different structures.

Finally, the relative selectivities of *n*-propanol of all step surfaces (including the step surfaces based on Cu(100) and different Cu facets), the Cu-based bimetals (structures in Fig. S28†), and other metals (structures in Fig. S29†), with respect to the descriptor $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$, exhibit a volcano correlation (Fig. 4h). This result suggests that the selectivity descriptor $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ is universal in finding the various catalysts for the $\text{CO}_{(2)}\text{RR}$ to *n*-propanol. The Step_u1d2 sites and Cu(433) are located at the top of the volcano plot, suggesting that the capability of those surface Cu catalytic sites toward higher $\text{CO}_{(2)}$ -to-*n*-propanol conversion selectivities. Although the step surfaces may experience reconstruction during the $\text{CO}_{(2)}\text{RR}$ due to the high surface energies and the harsh reaction conditions, there have been some reports those have successfully synthesized the high-index Cu-based facets and retained good reaction stability.^{44–46} For example, by utilizing OH^- anions as the controlling reagents and the ascorbic acid for the slow growth of the nanocrystals, the $\text{Cu}_2\text{O}(211)$ facets were synthesized, showing a $\text{FE}_{\text{C}_2\text{H}_4}$ of 87% in the CO_2RR after being stored in 1 M KOH for one month.⁴⁵ In addition, it has been found that the presence of the low-index facets can help to stabilize the high-index facets under electroreduction conditions.⁴⁶ Those studies can inspire the synthesis of high-index Cu-based facets for the $\text{CO}_{(2)}\text{RR}$ catalysis.

Conclusions

In summary, this work represents a rational theoretical design for the electrocatalytic sites for efficient $\text{CO}_{(2)}$ -to- C_{3+} products based on the constant potential computations. For the formation of *n*-propanol, ethanol shares the common RDS and is a main side product. In our work, CH_3CHO^* has been identified as the critical intermediate for the bifurcation of *n*-propanol and ethanol pathways, and $\Delta E_{\text{ads}}(\text{CH}_3\text{CH}_2\text{O}^*)/\Delta E_{\text{ads}}(\text{CO}^*)$ has been proposed as a key descriptor for the formation of *n*-propanol. Based on this descriptor, different step sites have been screened to select the optimal catalytic sites, and Cu(433) facets have been suggested as the most promising facets for the electrochemical $\text{CO}_{(2)}$ -to-*n*-propanol conversion. Our work highlights the significance of SDS regulation in the $\text{CO}_{(2)}\text{RR}$ and allows understanding the competition mechanism between the C_2 and C_{3+} products.
