DiIcZ MR-TADF emitters as potent energy transfer photocatalysts

Lea Hämmerling,¹ David Hall, Elliott Blin,² Tabea Heil¹ and Eli Zysman-Colman¹*

Photoinduced energy transfer (PEN_T) reactions are a subset of photochemical reactions that involve the indirect photoactivation of substrates following an energy transfer from a photoexcited sensitizer/photocatalyst. Examples of PEN_T reactions include *E/Z* isomerizations, [2 + 2] cycloadditions, and sigmatropic shifts. Here we introduce a family of diindolocarbazole (DiIcZ) multi-resonant thermally activated delayed fluorescent (MR-TADF) photocatalysts (PCs), DiIcZtBu₄, DiIcZMes₄, DiIcZtBuCz₄, and DiIcZtBuDPA₄, which have relatively high triplet energies (E_T). We cross-compare their photocatalytic behavior and that of relevant literature reference PCs¹ in five distinct PEN_T reactions. We demonstrate that the use of the DiIcZ PCs consistently leads to more rapid reaction rates and higher yields compared to the widely used 4CzIPN. DiIcZtBu₄, DiIcZMes₄, and DiIcZtBuCz₄ possess similar E_T but decreasing singlet–triplet energy gaps, ΔE_{ST} , enabling for the first time a comparison of the dependency of both the reaction kinetics and the final yield on this photophysical parameter. We observed that when the reaction kinetics are fast, there is little sensitivity to quenching of the excited PC by oxygen, implying that Dexter Energy Transfer (DET) to the substrate is competitive with DET to oxygen. Importantly, this means that some of the DET reactions using these PCs can be performed in air without adversely affecting reaction yield.

Introduction

One major class of photochemical reactions consists of those that proceed *via* a photoinduced energy transfer (PEN_T) mechanism, which typically involves an electronically excited photocatalyst (PC*) transferring its energy to a substrate (sub). The substrate in its electronically excited state (sub*) then undergoes a photochemical transformation.^{1–3} The majority of PEN_T reactions proceed *via* Dexter Energy Transfer (DET) reactions. DET involves the simultaneous double electron exchange between the PC* and the sub to generate a PC in its S₀ state and a sub*. This can take place from the singlet state of the ¹PC* to generate ¹sub* or more commonly from the triplet state of ³PC* to generate ³sub* (Fig. S1) and does not involve a change in the overall multiplicity.¹ DET processes occur over shorter distances, typically less than 10 Å,⁴ as orbital overlap between the PC and the sub is required, which implies a collisional interaction is needed for DET to occur intermolecularly.

In cases where DET occurs from the ³PC* to ³sub, it is the spectral overlap of the phosphorescence of the ³PC* and the spin-forbidden absorption of the substrate that is relevant to generate ³sub*. Notably, as the spin-forbidden absorption spectrum is of negligible intensity in most organic substrates,

the low-energy onset of the low-temperature phosphorescence spectrum of the sub is used as a surrogate estimation of the energy at which spectral overlap no longer occurs, which is none other than the energy of the T₁ state (E_T) of the sub. It is generally accepted that DET will occur when $E_T(\text{PC}^*) > E_T(\text{sub}^*)$, and the closer these two values are, the more likely DET is to occur.⁵ Given that the ³sub* has a biradical-like character, this enables a diversity of reactions such as *E/Z* isomerization,^{2,6–8} cycloadditions such as [2 + 2],^{9–11} sensitization of metal complexes,^{12–14} homolytic bond cleavages such as N₂ release from benzoyl azides, scission of S–S bonds, and N–O dissociation of oxime esters to instigate the formation of carbon-centered and nitrogen-centered radicals in concert with the loss of CO₂.^{15–17}

Of the PCs typically employed in PEN_T reactions, organic carbonyl-based photosensitizers have the highest E_T . For instance, xanthone and acetophenone (Fig. 1) have similar E_T values of 3.22 eV (74.2 kcal mol⁻¹, 310.5 kJ mol⁻¹) and 3.21 eV (74.0 kcal mol⁻¹, 309.6 kJ mol⁻¹).^{1,2,18} Organometallic PCs are particularly popular for PEN_T reactions in part because the presence of the heavy metal center ensures an essentially quantitative triplet yield as a result of fast intersystem crossing (ISC) mediated by its large spin–orbit coupling (SOC).^{19,20} Two of the most commonly used organometallic PCs for PEN_T reactions include [Ir(dF(CF₃)ppy)₂(dtbbpy)](PF₆) ($E_T = 2.68$ eV)⁵ for

Fig. 1 Chemical structures and E_T for selected literature PCs used for DET reactions and for the four TADF PCs investigated in this work. Quoted E_T values for 4CzIPN, DiIcztBu₄, DiIcztMes₄, DiIcztBuCz₄ and DiIcztBuDPA₄ were estimated from $E_T = E_S - \Delta E_{ST}$, with E_S being the onset of the steady-state emission in DCM at room temperature and ΔE_{ST} determined in 2-MeTHF glass at 77 K. E_T for *fac*-Ir(ppy)₃ was taken from the onset of the room temperature emission in 2-MeTHF. E_T for [Ru(bpy)₃](PF₆)₂ was taken from the emission maximum at 77 K in 4 : 1 MeOH/EtOH glass.²² E_T for [Ir(dF(CF₃)ppy)₂(dtbbpy)]PF₆ was taken from the room temperature emission maximum in MeCN.²³ For the organic PCs, E_T is measured from the phosphorescence spectra at 77 K.⁵

reactions requiring a relatively high E_T and [Ru(bpy)₃](PF₆)₂ ($E_T = 2.12$ eV)²¹ for those that do not (Fig. 1).

Over the last decade or so, organic thermally activated delayed fluorescence (TADF) compounds have been increasingly used in the academic community as alternatives to organometallic complexes, initially as emissive materials for organic light-emitting diodes (OLEDs),²⁴ and later, as PCs.^{25,26} This is because TADF compounds have accessible triplet states owing to the small energy gap (ΔE_{ST}) between their lowest excited singlet (S_1) and triplet (T_1) states, which allows for relatively fast ISC and reverse ISC (RISC) to take place, despite the small SOC between these states in the absence of heavy atoms.^{27,28} Molecules with small ΔE_{ST} are those where the donor (D) and acceptor (A) moieties are sufficiently electronically decoupled such that there is minimal orbital overlap between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO), *i.e.*, the exchange energy is small. This spatial separation also produces an emissive excited state having charge transfer (CT) character. The most widely employed molecular design is one that adopts a strongly twisted D–A structure, exemplified in 4CzIPN and 4DPAIPN (Fig. S2).²⁶ Owing to the distance between D and A units, the emissive S_1 state possesses long-range charge transfer (LRCT) character.²⁹ D–A TADF PCs based on carbazolyl dicyanobenzenes (CDCBs) have been extensively employed in myriad

photocatalytic reactions. Examples from this family of TADF PCs cover a broad range of E_T . For example, the E_T values of 4DPAIPN, 4CzTPN, 2CzIPN, 4CzIPN, and 3,5-2CzBN increase from 2.30 eV³⁰ to 2.34,³¹ 2.72,³¹ 2.73,³² and 3.03 eV,³¹ respectively. These values overlap with those of, for example, [Ir(dF(CF₃)ppy)₂(dtbbpy)]PF₆ ($E_T = 2.64$ eV²³) and benzophenone ($E_T = 3.00$ eV³³). Beyond CDCBs, other D–A TADF PCnT PCs include pDTCz-DPmS³⁴ and DI-PF³⁵ (Fig. S2). pDTCz-DPmS ($E_T = 2.93$ eV) possesses a suitable E_T to photocatalyze the *E/Z* isomerization of diisopropyl fumarate ($E_T = 2.7$ eV),³⁶ producing 81% of diisopropyl maleate while 4CzIPN only yields 6%, owing to its lower E_T of 2.68 eV.³⁷ DI-PF ($E_T = 2.38$ eV) yielded 66% *Z*-stilbene in the *E/Z* isomerization of *E*-stilbene ($E_T = 2.2$ eV) despite its lower triplet energy, while 4CzIPN affords 87% of the desired product.³⁵ Another class of TADF PCs contains an imidazo-phenothiazine (IPTZ) acceptor unit connected with different donor groups. The PCs ACR-IMAC, ACR-IPTZ, and SACR-IPTZ have similar triplet energies of $E_T = 2.76$ eV,³⁸ 2.76 eV,³⁹ and 2.77 eV,³⁹ respectively. Their use in a range of reactions, such as the [2 + 2] cycloaddition of an indole and dimethylphenylvinylsilane, afforded near quantitative product yields.^{38,39} A second class of TADF compounds is the so-called multi-resonant TADF (MR-TADF) emitters. These are rigid polycyclic aromatic hydrocarbons that are typically doped with both electron-rich and electron-deficient groups. Suitable

regiochemistry of these p- and n-dopants produces an alternating pattern of increasing and decreasing electron density in the excited state as compared to the ground state, leading to the necessary small exchange energy that turns on TADF. Given the short distance between D and A motifs, the emissive excited state is of short-range CT (SRCT) character.⁴⁰ Compared to D–A TADF compounds, MR-TADF emitters have more intense low energy absorption bands, narrower emission spectra, smaller Stokes shifts, and their emission spectra show only minimal positive solvatochromism—all potentially attractive properties for their use as PCs.⁴⁰ Our group has demonstrated the broad utility of two families of MR-TADF PCs in a range of photoinduced electron transfer (PET) and PenT reactions.^{41,42} These two families contain nitrogen donor atoms and either boron or carbonyl groups as n-dopants within the polycyclic aromatic hydrocarbon framework.

We, as well as Lee and co-workers, recently showed that the acceptor moiety is not required in MR-TADF emitter design for OLEDs.^{43–47} Indeed, when the nitrogen atoms in diindolocarbazoles are *para*-disposed, there is very weak TADF as ΔE_{ST} is moderately large, resulting in slow k_{RISC} . **DiICztBu₄** and **DiICzMes₄** have similar E_T of 2.55 (in DCM)⁴³ and 2.57 eV (in toluene),⁴⁴ respectively, while their reported ΔE_{ST} values are 0.29 and 0.26 eV. Recognizing their potential as PCs, herein we investigated a series of four structurally related DiICz-based

TADF PCs, **DiICztBu₄**, **DiICzMes₄**, **DiICztBuCz₄**, and **DiICztBuDPA₄**, in DET reactions (Fig. 2); the first two have previously been reported, while **DiICztBuCz₄** and **DiICztBuDPA₄** were, coincident with this work, recently reported by Lee and co-workers.⁴⁸ Across the first three compounds in this series, there is a progressive stabilization of the S_1 state, while the T_1 energy is largely unaffected; both S_1 and T_1 are stabilized in **DiICztBuDPA₄**. Thus, the impact of ΔE_{ST} on the performance in DET is probed for the first time. While we did not observe a dependency of the efficiency of the PenT reactions as a function of the ΔE_{ST} of the PC across five different PenT reactions, four involving direct DET to the substrate and one nickel-sensitized dual photocatalysis reaction, we did discover that these PCs initiate fast PenT reactions that show remarkably little sensitivity to the presence of O₂, despite it being a competitive triplet quencher. In the four PenT reactions with direct energy transfer to the substrate, **DiICztBu₄**, **DiICzMes₄**, and **DiICztBuCz₄** consistently outperform **4CzIPN** both in terms of NMR yield and reaction rate.

Results and discussion

The syntheses of **DiICztBu₄**, **DiICzMes₄**, **DiICztBuCz₄**, and **DiICztBuDPA₄** are detailed in the SI. The UV-vis absorption spectra of these compounds in DCM, along with that of the

Fig. 2 Chemical structures of **DiICztBu₄**, **DiICzMes₄**, **DiICztBuCz₄**, and **DiICztBuDPA₄**.

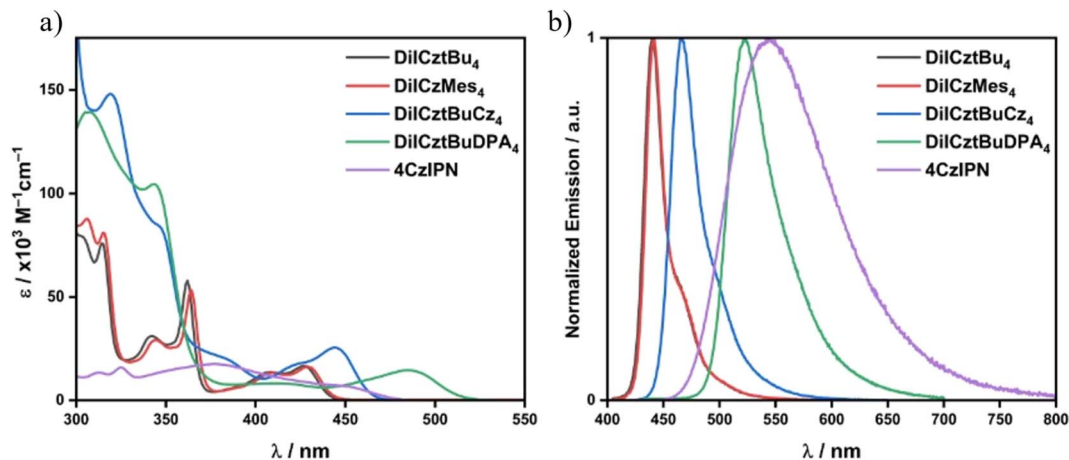

Fig. 3 (a) Absorption and (b) steady-state PL spectra in DCM of DiICztBu₄ ($\lambda_{\text{exc}} = 340$ nm), DiICzMes₄ ($\lambda_{\text{exc}} = 380$ nm), DiICztBuCz₄ ($\lambda_{\text{exc}} = 340$ nm), DiICztBuDPA₄ ($\lambda_{\text{exc}} = 400$ nm), and 4CzIPN ($\lambda_{\text{exc}} = 378$ nm).

reference PC 4CzIPN, are shown in Fig. 3a. DiICztBu₄, DiICzMes₄, DiICztBuCz₄, and DiICztBuDPA₄ all exhibit low-energy absorption bands in the visible region that are more intense than that of 4CzIPN. The presence of the mesityl (Mes) groups in DiICzMes₄ leads to a very slight red shift in the absorption spectrum compared to DiICztBu₄, while the substitution of the diindolocarbazole with progressively stronger carbazole (Cz) and diarylamine donors results in a larger red shift of these bands (Fig. 3a and S37). A similar trend is observed in their photoluminescence (PL) spectra (Fig. 3b), where the PL maximum in DCM shifts from λ_{PL} of 440 to 442, 466, and 532 nm for DiICztBu₄, DiICzMes₄, DiICztBuCz₄, and DiICztBuDPA₄, respectively (Fig. 3b and Table 2). Their emission is more narrowband compared to the broad PL of 4CzIPN, reflecting their more rigid structures.

The S₁ and T₁ energies were determined from the onsets of the steady-state PL and delayed emission (gate time: 1–9 ms) spectra in 2-MeTHF glass at 77 K, respectively (Fig. S40); the ΔE_{ST} value is the difference in energy between these two (Fig. S40 and Table 1). DiICztBu₄, DiICzMes₄, and DiICztBuCz₄ have very similar E_{T} of 2.58, 2.57, and 2.55 eV, respectively. As their emission profiles are similar, so too will be their spectral overlap with the sub, and thus the k_{DET} should be comparable across these three PCs. The S₁ energy, E_{S} , however, progressively decreases from 2.91 to 2.84 and 2.77 eV (measured at 77 K in 2-MeTHF); thus, the ΔE_{ST} likewise narrows from 0.33 to 0.27 and 0.22 eV. The E_{S} and E_{T} for DiICztBuDPA₄ are 2.54 and 2.41 eV, resulting in the smallest ΔE_{ST} of 0.13 eV. The E_{T} values determined at cryogenic temperatures of these four derivatives are all lower than the 2.73 eV of 4CzIPN (Fig. S40e). DiICztBu₄ and DiICzMes₄ have previously been reported as MR-TADF emitters, and given the similar photophysical properties of DiICztBuCz₄ and DiICztBuDPA₄ to these two, the high molar absorptivity of the low-energy absorption band, the minimal positive PL solvatochromism, the narrowband emission and the small ΔE_{ST} , they can also be classified as MR-TADF (Table 2).

While the low temperature (LT) measurements, at 77 K, permit a robust estimation of ΔE_{ST} , noting that in the vast

majority of TADF compounds the S₁ state has greater CT character than T₁, this measurement will not accurately capture E_{S} at room temperature (RT) in solution. This is because CT states are stabilized as a function of solvent polarity, and the greater the CT character, the stronger the stabilization of the state.⁵⁰ As triplet states tend to show lesser CT character than singlets, the estimated $E_{\text{T}} = E_{\text{S}}(\text{RT}) - \Delta E_{\text{ST}}(\text{LT})$ represents the outer bound value for what E_{T} may be at room temperature. Thus, given the LRCT character of the S₁ state of 4CzIPN, the change in E_{T} at room temperature is more pronounced than for the four DiICz MR-TADF compounds (Table 1). This implies that in DET reactions, the spectral overlap between the PC* and the sub may change significantly, especially when the T₁ state possesses some CT character. For MR-TADF compounds, this stabilization effect is small given the SRCT character of the S₁ and T₁ states. So, at low temperature, the E_{T} values are 2.58, 2.57, 2.55, and 2.41 eV in 2-MeTHF for DiICztBu₄, DiICzMes₄, DiICztBuCz₄, and DiICztBuDPA₄, respectively, while in DCM at room

Table 1 Excited-state energies for DiICztBu₄, DiICzMes₄, DiICztBuCz₄, DiICztBuDPA₄, and 4CzIPN

Compound	77 K values ^a			Room temperature $E_{\text{T}}^{\text{b}}/\text{eV}$

^a In DCM at 77 K, taken from the onset of steady-state PL spectrum for E_{S} and the onset of the gated emission spectrum (1–9 ms) for E_{T} . ^b In 2-MeTHF at 77 K, taken from the onset of steady-state PL spectrum for E_{S} and the onset of the gated emission spectrum (1–9 ms) for E_{T} . ^c Under degassed conditions, excited-state lifetimes in air in parentheses. ^d Lifetime is the average lifetime of 4CzIPN calculated as $\tau_{\text{avg}} = \tau_1 \times w_1 + \tau_2 \times w_2$.

temperature, the E_{T} values remain essentially the same at 2.60, 2.65, 2.58, and 2.40 eV, respectively (Table 1). This contrasts with the effect on the T_1 energy of 4CzIPN ($E_{\text{T}}(\text{LT}) = 2.73 \text{ eV}$ vs. $E_{\text{T}}(\text{RT}) = 2.56 \text{ eV}$; where LT is low temperature, 77 K, and RT is room temperature). This is illustrated in a comparison between the T_1 energies in 2-MeTHF glass and DCM solutions, $\Delta E_{\text{T-T}}$, which is 0.08 eV for DiICzMes₄ and 0.17 eV for 4CzIPN. Thus, these four MR-TADF compounds maintain their E_{T} in polar solvents, while for 4CzIPN, the E_{T} is much more stabilized. The time-resolved PL decays of DiICztBu₄, DiICzMes₄, DiICztBuCz₄, and DiICztBuDPA₄ in DCM are shown in Fig. S40 and S41 and are listed in Table 2. There is no delayed emission, and PL lifetimes range from 9–16 ns. Given the moderately large ΔE_{ST} , it is not uncommon for MR-TADF emitters to not show delayed emission in solution as non-radiative decay competes with RISC, while in the solid state, this is largely suppressed, and delayed emission becomes apparent.

DET reactions

We began by studying intramolecular DET reactions with photocatalysts of increasing triplet energy to focus on the interaction between the PC and a single molecule. We first investigated the *E/Z* isomerization of an alkene, *E*-cinnamyl acetate, with a T_1 energy similar to those of the MR-TADF emitters; notably, the structurally similar *E*-methyl cinnamate has a $E_{\text{T}} = 2.38 \text{ eV}$ ⁵¹ (Table S7). We expect the triplet energy of *E*-cinnamyl acetate, which contains a methylene group between the styrenyl moiety and the ester group, to be slightly higher compared to *E*-methyl cinnamate, which has a larger conjugation length. The geometric isomerization does not take place in the absence of an irradiated PC (Table 3, entries 1 and 2). After 24 h of irradiation under N₂, the use of DiICztBu₄, DiICzMes₄, and DiICztBuCz₄ as PCs yielded comparable *E/Z* ratios of 18/82, 19/81, and 19/81, respectively (Table 3, entries 4, 6, and 8), performing as well in this reaction as 4CzIPN (*E/Z* ratio of 14/86, Table 3, entry 12). Similar *E/Z* ratios are observed under air (*E/Z* = 19/81, 17/84, 20/80, and 15/85 for DiICztBu₄, DiICzMes₄, DiICztBuCz₄, and 4CzIPN, respectively, Table 3, entries 3, 5, 7, and 11). Amazingly, the end ratio obtained for this DET reaction

is unaffected despite O₂ being a competitive triplet quencher. This is, however, not the case with DiICztBuDPA₄, which under N₂ yielded an *E/Z* ratio of 28/72, a lower ratio than those obtained with the other PCs, while there is effectively no isomerization observed in air (Table 3, entries 9 and 10).

Fig. 4 shows the reaction progression for the *E/Z* isomerization of cinnamyl acetate in air at short times, while for DiICztBuDPA₄, the reaction under N₂ is shown. The conversion saturates after 30 min for DiICztBu₄, DiICzMes₄, and DiICztBuCz₄, with these PCs having similar reaction rates. There is no correlation observed between ΔE_{ST} and either the *E/Z* ratio or reaction rate for this transformation. The absence of any substantive change in the post-reaction absorption spectra of DiICztBu₄, DiICzMes₄, and DiICztBuCz₄ revealed that these compounds are photochemically stable to O₂ under the reaction conditions (Fig. S46a–c). Given that O₂ does not affect the *E/Z*

Table 3 *E/Z* isomerization of cinnamyl acetate^a

^a Cinnamyl acetate (0.2 mmol) in DCM (0.2 M) with 1 mol% PC loading. *E/Z* ratios were determined via ¹H NMR spectroscopy. Reported yields are the mean from at least two reactions with associated standard deviations.

Fig. 4 Reaction progression for the *E/Z* isomerization of cinnamyl acetate in air unless otherwise noted. *E/Z* ratios are given in % *Z* isomer after *x* minutes ($\lambda_{\text{exc}} = 440 \text{ nm}$). Cinnamyl acetate (0.2 mmol) in DCM (0.2 M) and PC (1 mol%). *E/Z* ratios were determined by ^1H NMR spectroscopy. Reactions with **DiICztBuDPA₄** as the PC were performed under N_2 .

ratio, we investigated the effect on the reaction kinetics as a function of the presence/absence of O_2 by comparing the *E/Z* ratios after 5 min. The reaction rates slightly increase in the absence of O_2 , leading to slightly improved *E/Z* ratios of 48/52, 51/49, and 49/51 for **DiICztBu₄**, **DiICzMes₄**, and **DiICztBuCz₄**, respectively, from those in air (53/47, 61/39, and 56/44, respectively); it is not clear why the change is more dramatic with **DiICzMes₄**. Hence, O_2 acts as an ineffective yet competitive quencher of the triplet excited state of these PCs, as the change in the *E/Z* ratio at early times is marginal. The contrasting results with **DiICztBuDPA₄** are discussed in the SI.

The isomerization reaction with **4CzIPN** is significantly slower than with **DiICztBu₄**, **DiICzMes₄**, and **DiICztBuCz₄**, only producing a 39/61 *E/Z* ratio after 60 min (Fig. 4). Thus, despite similar thermodynamic driving forces (*i.e.*, similar E_{T}), the origin of the higher yields of the *Z* isomer and faster reaction kinetics could be due to either the higher molar absorptivity of these three MR-TADF compounds at the photoexcitation wavelength and/or an increased spectral overlap of the phosphorescence of the MR-TADF emitters with the spin-forbidden absorption of the sub. **4CzIPN** is mostly photostable; however, a slight decrease in the absorbance of the CT band is observed in air, suggesting that some degradation is taking place if the reaction is carried out when O_2 is present (Fig. S46e). Furthermore, there is a significant dependency of the kinetics of the reaction with respect to the presence/absence of O_2 . After 5 min, the *E/Z* ratios are 80/20 and 94/6 under N_2 and air, respectively. These results reveal that **4CzIPN** photocatalyzes this reaction much more slowly than **DiICztBu₄**, **DiICzMes₄**, and **DiICztBuCz₄** and that its triplet excited state is also more strongly quenched by O_2 . The excited-state lifetimes of the PCs under aerated conditions are 8, 8, 8, and 13 ns for **DiICztBu₄**, **DiICzMes₄**, **DiICztBuCz₄**, and **DiICztBuDPA₄**, respectively. These are not

affected by the presence of *E*-cinnamyl acetate (τ_{PL} of 8, 8, 8, and 12 ns for **DiICztBu₄**, **DiICzMes₄**, **DiICztBuCz₄**, and **DiICztBuDPA₄**, respectively, Fig. S47).

We had previously assessed MR-TADF compounds **DABNA-1**, **tDABNA**, **CzBN**, and **DtBuCzB** as photocatalysts in the *E/Z* isomerization of cinnamyl acetate. Of these, **CzBN** produced the highest conversion to the *Z* isomer in a ratio of 19/81 after two hours in air (in THF); the ratio remained the same after 24 hours.⁴² In our previous study, we did not monitor the reaction kinetics at shorter times. Thus, **CzBN** yields a similar *E/Z* ratio as the DiCz photocatalysts (19/81 for **CzBN** after 2 h and 18/82 for **DiICztBu₄** after 1 h). This is consistent with their comparable E_{T} values (2.58 eV for **CzBN** and 2.58 eV for **DiICztBu₄**, respectively, in 2-MeTHF at 77 K).⁴²

We next investigated the *E/Z* isomerization of diisopropyl fumarate, which has a higher E_{T} of 2.7 eV,³¹ to produce the corresponding maleate ($E_{\text{T}} = 3.1 \text{ eV}$)³¹ (Table S8). Despite the E_{T} s of the PCs being lower than 2.7 eV (Table 2), both **DiICztBu₄** ($E_{\text{T}} = 2.60$ in DCM) and **DiICzMes₄** ($E_{\text{T}} = 2.65$ in DCM) photocatalyzed the reaction, producing identical *E/Z* ratios of 13/87 after 24 h (Table 4, entries 4 and 6). **DiICztBuCz₄** and **4CzIPN** were less effective, producing *E/Z* ratios of 66/34 and 69/31, respectively (Table 4, entries 8 and 12). Surprisingly, it seems that the slightly lower E_{T} of **DiICztBuCz₄** (2.58 eV in DCM) compared to **DiICzMes₄** ($E_{\text{T}} = 2.65$ eV in DCM) and **DiICztBu₄** ($E_{\text{T}} = 2.60$ eV in DCM) is responsible for these large changes in *E/Z* ratios; notably, **DiICztBuCz₄** is unstable under the reaction conditions (Fig. S46c). These results also clearly illustrate the effect of solvent polarity on the magnitude of the spectral overlap between the PC and sub, and the corresponding efficiency to photocatalyze the isomerization. Despite **4CzIPN** having the highest E_{T} of 2.73 eV in 2-MeTHF at 77 K, meaning that if these values were reflective of accessible triplet energies

^a Diisopropyl fumarate (0.2 mmol) in DCM (0.2 M) with 1 mol% PC loading. *E/Z* ratios were determined by ^1H NMR spectroscopy. Reported yields are the mean from at least two reactions with associated standard deviations.

under the reaction conditions, then it should be able to photocatalyze the isomerization to a similar extent as the DiICz PCs. The triplet state of **4CzIPN**, however, shows the greatest stabilization as a function of solvent polarity (E_T in DCM is 2.56 eV at room temperature, Table 1). This accounts for the poorer *E/Z* ratio of 69/31 (Table 4, entry 12). Notably, as **4CzIPN** is photostable under these reaction conditions when performed under N_2 , its poor performance cannot be attributed to PC degradation (Fig. S45e).

In contrast to cinnamyl acetate (Table 3), the *E/Z* isomerization of diisopropyl fumarate essentially does not proceed to any appreciable extent in the presence of O_2 , with *E/Z* ratios of 96/5, 93/8, 88/12, and 91/9 for **DiICztBu₄**, **DiICzMes₄**, **DiICztBuCz₄**, and **4CzIPN**, respectively (Table 4, entries 3, 5, 7, and 11). **DiICztBuDPA₄** could not photocatalyze the reaction (Table 4, entries 9 and 10), given its E_T of 2.41 eV.

To understand the divergence in the behavior of these two isomerization reactions in the presence of O_2 , we interrogated the reaction rates of diisopropyl fumarate under N_2 (Fig. 5). If the rates are slower compared to those with cinnamyl acetate, then the lower *E/Z* ratios may be explained by competitive O_2 quenching of the T_1 state to that of the fumarate. Unlike the reaction with cinnamyl acetate, the reaction rates under N_2 differ between **DiICzMes₄**, **DiICztBu₄**, and **DiICztBuCz₄**, but still are all faster than **4CzIPN**. The fastest conversion to the *Z* isomer uses **DiICzMes₄**, yielding an *E/Z* ratio of 22/79 \pm 3 after 60 min (13 : 87 after 24 h, Table 4, entry 6), while **DiICztBu₄** only produces an *E/Z* ratio of 60/41 \pm 1 after 60 min, yet affords the same *E/Z* ratio after 24 h as **DiICzMes₄** (13 : 87 after 24 h, Table 4, entry 4). The reaction reaches its steady-state *E/Z* ratio after 2 h for **DiICzMes₄** (*E/Z* ratio of 12/88), while for **DiICztBu₄** it takes 4 h to reach the 13/87 *E/Z* ratio. These rates are slower than those with cinnamyl acetate, where the reaction was completed after 30 min. Given that both **DiICzMes₄** and **DiICztBu₄** are stable during the reaction when conducted under

N_2 , photodegradation of the PC can be excluded as the origin of the slower reaction kinetics observed for **DiICztBu₄**. As the phosphorescence of both **DiICztBu₄** and **DiICzMes₄** is the same, the spectral overlap between the phosphorescence spectra of these two PCs and the spin-forbidden absorption spectrum of the sub will therefore be similar. A plausible conclusion is that the *tert*-butyl groups are bulkier than mesityl groups and impede the collisional interaction more, thus adversely affecting the reaction kinetics with **DiICztBu₄**. We observed that these two PCs do photodegrade when the reaction is carried out under air. Thus, there is a divergence in the photochemical outcome wherein the kinetics of the *E/Z* isomerization of cinnamyl acetate outcompetes photodegradation, while this is not the case with the *E/Z* isomerization of diisopropyl fumarate (Fig. S45a and b). Surprisingly, while the initial rate of isomerization using **DiICztBuCz₄** is comparatively as fast as using **DiICzMes₄**, there is a significant off-cycle photodegradation both in air and N_2 that effectively caps the *E/Z* ratio at only 66/34 \pm 4 (Fig. S45c). **DiICztBuDPA₄** is photostable when the reaction is conducted under N_2 , while there are changes in the absorption spectrum when the reaction is conducted in air (Fig. S46d). Hence, the fact that the reaction does not proceed is a consequence of there being no spectral overlap between the phosphorescence of **DiICztBuDPA₄** and the spin-forbidden absorption of the substrate.

4CzIPN is significantly slower and less efficient in this isomerization reaction, producing a steady-state *E/Z* ratio of only 69/31 \pm 4 after 24 h (Table 4, entry 12); indeed, after 4 h, there is only an *E/Z* ratio of 95/5 \pm 1 (Table S8). Under these conditions, **4CzIPN** is photostable under N_2 ; however, in air, photodegradation of **4CzIPN** is observed (Fig. S46e). Thus, the poor performance of **4CzIPN** can be explained by the too-small spectral overlap with the fumarate substrate.

The *E/Z* isomerization of diisopropyl fumarate studies demonstrate that three of these PCs can catalyze PEnT reactions with substrates having E_T of 2.7 eV.³¹ Thus, we next explored the intramolecular [2 + 2] cycloaddition of norbornadiene ($E_T = 2.7$ eV⁵²) to quadricyclane (Table S9). Schmid *et al.* had reported a 99% yield after one hour using an anionic Ir complex having an E_T of 2.99 eV (Table 5, entry 14).

The reaction does not take place in the absence of a PC (Table 5, entries 1 and 2). After 30 min reaction time using **DiICztBu₄**, quadricyclane was obtained in an 89% yield under N_2 (Table 5, entry 5). In contrast to the *E/Z* isomerization of fumarate, **DiICzMes₄** and **DiICztBuCz₄** perform as well as **DiICztBu₄**, yielding 85, 88, and 89%, respectively, after 30 min (Table 5, entries 5, 7, and 9). The reaction is slightly quenched in the presence of O_2 , producing yields of 64, 71, and 75% after 30 min when using **DiICztBu₄**, **DiICzMes₄**, and **DiICztBuCz₄**, respectively (Table 5, entries 3, 6, and 8). Given the fast reaction rates, there is thus significantly less quenching of the $^3PC^*$ by O_2 than what has been observed with diisopropyl fumarate. Again, it is not surprising that **DiICztBuDPA₄** does not photocatalyze the reaction, given its too low E_T (Table 5, entries 10 and 11). Similarly, given that **4CzIPN** did not photoisomerize diisopropyl fumarate to diisopropyl maleate after 30 min to any appreciable extent, this PC did not photocatalyze the [2 + 2]

Fig. 5 Reaction progression for the *E/Z* isomerization of diisopropyl fumarate under N_2 . *E/Z* ratios are given in % *Z* isomer after *x* minutes irradiated at 440 nm. Diisopropyl fumarate (0.2 mmol) in DCM (0.2 M) and PC (1 mol%). *E/Z* ratios were determined by 1H NMR spectroscopy.

^a Norbornadiene (0.2 mmol) and PC (1 mol%) in DCM (2 mL). Yields were determined by ¹H NMR spectroscopy using 1,3,5-trimethoxybenzene as the internal standard. ^b From ref. 52 in CD₃CN, λ_{exc} = 415 nm after 1 h, norbornadiene (0.05 mmol), PC (0.3 mol%), CD₃CN (0.6 mL). Reported yields are the mean from at least two reactions with associated standard deviations.

cycloaddition of norbornadiene within 30 min (Table 5, entries 12 and 13). These results not only demonstrate the value of three of these MR-TADF PCs to photocatalyze a demanding PEnT reaction but also that E_T as a parameter is too coarse when cross-comparing different reactions using substrates with similar E_T . We had previously demonstrated that **DiKtA**, another MR-TADF photocatalyst ($E_T = 2.62$ eV),⁴¹ could efficiently photoisomerize diisopropyl fumarate into diisopropyl maleate in a ratio of 10/90 in MeCN over 16 h, a similar ratio to that using **DiICzMes₄** (8/92); in this earlier study, the reaction progression at shorter reaction times was not analysed.⁴¹

The photostability of the PCs was tested under the reaction conditions under N₂ and in air (Fig. S51). The absorption spectra of **DiICztBu₄**, **DiICzMes₄**, and **DiICztBuCz₄** show only a minimal decrease in intensity under N₂, while there are greater changes with O₂ present that suggest more photodegradation, which is consistent with the less efficient performance when the reaction is carried out in air (Fig. S51a–c). Interestingly, the small degree of photodegradation of the MR-TADF PCs in the [2 + 2] cycloaddition in air contrasts with the significant photodegradation in the *E/Z* isomerization with diisopropyl fumarate in air and the associated absence of product formation, despite both substrates having the same reported E_T .

There is significant photodegradation observed for **4CzIPN** under N₂, and the profile is similar to that in air (Fig. S51e). The absorption band at λ_{abs} = 377 nm and the shoulder at λ_{abs} = 450 nm disappear, while a more red-shifted, less intense band at λ_{abs} = 520 nm appears. These results imply that the substrate reacts with **4CzIPN** and that the [2 + 2] cycloaddition is likely a radical stepwise process as opposed to a concerted mechanism (Table 5, entry 12 and 13).

We then explored a PEnT reaction with a substrate having a higher E_T , the sigmatropic shift of (*S*)-verbenone ($E_T = 3.0$ eV)⁵² to chrysanthenone (Table S10). This rearrangement has been used in the synthesis of the natural product xishacorene B, where verbenone was directly irradiated in the first step with UV light (λ_{exc} = 365 nm), yielding 67% chrysanthenone.⁵³ Schmid *et al.* showed that this transformation can be photocatalyzed using the same iridium isocyanoborato complex as was used in the [2 + 2] cycloaddition of norbornadiene,⁵² whereupon irradiating the solution at 415 nm produced the desired product in 80% yield after 180 min (Table 6, entry 10). With **DiICztBu₄**, **DiICzMes₄**, and **DiICztBuCz₄** as the PCs, the yields were generally low after 24 h at 29, 22, and 18%, respectively, using 1 mol% PC (Table 6, entries 2, 4, and 6); evidently, **DiICztBuDPA₄** cannot photocatalyze this reaction due to its too low E_T (Table 6, entry 8). The yields were improved by increasing the PC loading to 5 mol%, resulting in yields of 37, 38, and 21% for **DiICztBu₄**, **DiICzMes₄**, and **DiICztBuCz₄**, respectively (Table 6, entries 3, 5, and 7). Using **4CzIPN** afforded only 5% product yield at 5 mol% PC loading (Table 6, entry 9).

There is essentially no change in the absorption profiles of **DiICztBu₄**, **DiICzMes₄**, and **DiICztBuCz₄** before and after irradiation, suggesting that any photodegradation of the PCs is not the cause for the low yields in this reaction but rather the too low triplet energy (Fig. S53a–c). **4CzIPN** and **DiICztBuDPA₄** are stable under the reaction conditions (Fig. S53d and e), and the 5% yield for **4CzIPN** and the 0% yield for **DiICztBuDPA₄** can be attributed to each having a T_1 energy that is effectively too low to enable DET with any degree of efficiency.

Thus far, we have explored four intramolecular PEnT reactions. To expand the portfolio of available reactions, we next investigated an example of a bimolecular cross-coupling reaction. This is frequently achieved by combining the photocatalytic cycle with a Ni-mediated cross-coupling reaction. In

^a (*S*)-verbenone (0.2 mmol) in DCM (0.1 M) with given PC loadings. Yields were determined by ¹H NMR spectroscopy using 1,3,5-trimethoxybenzene as the internal standard. ^b From ref. 52 in CD₃CN with *hν* = 415 nm after 3 h. Reported yields are the mean from at least two reactions with associated standard deviations.

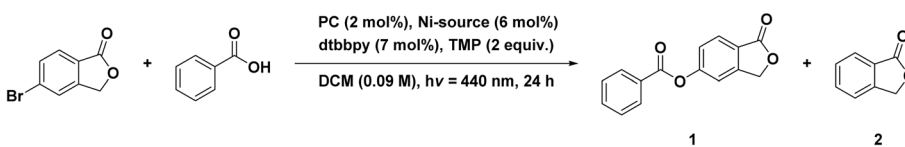

such dual-catalyzed reactions, the PC can either be involved in a PET mechanism, a so-called metallaphotoredox reaction, or in a PenT reaction to sensitize the Ni co-catalyst by DET after it has undergone oxidative addition and transmetallation steps. This photoactivation accelerates the reductive elimination of the product.³¹ One such cross-coupling reaction where the PC is purported to engage in DET is an esterification involving aryl halides being cross-coupled with carboxylic acids, where Welin *et al.* used **fac-Ir(ppy)₃** as the PC ($E_T(\text{fac-Ir(ppy)}_3) = 2.58 \text{ eV}$).¹³ In this cross-coupling reaction, an undesired side product is lactone **2** (Table 7). Several groups have employed organic PCs such as **4DPAPN** or **SACR-IPTZ** for these reactions (Fig. S1).^{31,39} **4DPAPN**, after optimization of the reaction conditions, yielded 91% of 4-(trifluoromethyl)phenyl benzoate in the cross-coupling of benzoic acid with 4-bromobenzotrifluoride as substrates.³¹ With the same substrates but under slightly different conditions, Welin *et al.* reported an 86% yield using **fac-Ir(ppy)₃** as the PC. The reaction photocatalyzed using **SACR-IPTZ** yielded 99% of the coupled product between 5-bromophthalide and benzoic acid, and no protodehalogenated product was observed.³⁹

We first investigated the use of different Ni precursors in the presence of dtbbpy as an ancillary ligand under conditions similar to those reported by Hojo *et al.*³⁹ We changed the solvent from DMF to DCM, as the DiICz PCs are more soluble in the latter.³⁹ We observe a generally higher product yield in DCM when using Ni(COD)₂ than with NiBr₂·glyme, regardless of the choice of PC. The use of **DiICzMes₄** yielded 65% in combination with Ni(COD)₂, while using NiBr₂·glyme only results in a 41% yield (Table 7, entries 5 and 6). In both cases, side product **2** is

observed in 30 and 19% yield (Table 7, entries 5 and 6). **DiICztBu₄**, **DiICzMes₄**, and **DiICztBuCz₄** perform similarly in combination with Ni(COD)₂ with yields of 59, 65, and 60% of **1**, respectively, while **2** formed in 28, 28, and 31% yield, respectively (Table 7, entries 3, 5, and 8). Changing the Ni source to NiBr₂·glyme yielded 31/15 and 41/19% of **1** and **2** using **DiICztBu₄** and **DiICzMes₄**, respectively, implying that the use of NiBr₂·glyme results in more undesired protodehalogenated product for these two complexes, while with **DiICztBuCz₄**, the reaction proceeds less readily, affording 20% of each of **1** and **2**. These PCs produce higher yields of **1** in combination with Ni(COD)₂ than using **4CzIPN** (43%, Table 7, entry 12), and this is correlated to a greater amount of **2** forming (36%) with this latter PC. When **fac-Ir(ppy)₃** is employed as the PC in combination with Ni(COD)₂, 65% of **1** and 15% of **2** form (Table 7, entry 14). A comparable yield is observed with **DiICzMes₄** (68/18% of **1** and **2**, Table 7, entry 7), but the Ni source must be [Ni(dtbbpy)(OH₂)₄]Cl₂, implying that the kinetics of the formation of the active Ni species are suboptimally aligned with the kinetics of DET with this PC. After solvent optimization with the best performing DiICz PC, **DiICzMes₄**, the coupled product **1** was obtained in a 74% yield when using a 1:1 mixture of DMSO:toluene (Table 8, entry 4), while the control experiment with **fac-Ir(ppy)₃** yielded a comparable yield of 77% (Table 8, entry 6). The 1:1 DMSO:toluene solvent system had previously been shown to be optimal with **SACR-IPTZ** as the PC, yielding 99% of **1** (Table 8, entry 8).³⁹ The reaction does not readily proceed in toluene, yielding only 10% product, while in DMSO an increase in the yield (64% of **1**) compared to that in DCM is observed, ostensibly due to a partial suppression of the

^a 5-Bromophthalide (0.188 mmol, 1.0 equiv.), benzoic acid (0.301 mmol, 1.6 equiv.), TMP (0.375 mmol, 2.0 equiv.), Ni-source (0.011 mmol, 6 mol%), dtbbpy (0.013 mmol, 7 mol%) and PC (0.004 mmol, 2 mol%) in the respective solvent (0.09 M). Yields were determined by ¹H NMR spectroscopy using 1,3,5-trimethoxybenzene as the internal standard. ^b Literature yield taken from ref. 39 5-bromophthalide (0.188 mmol, 1.0 equiv.), benzoic acid (0.301 mmol, 1.6 equiv.), TMP (0.375 mmol, 2.0 equiv.), Ni-source (0.011 mmol, 6 mol%), dtbbpy (0.013 mmol, 7 mol%) and PC (0.004 mmol, 2 mol%) in the respective solvent (0.09 M), λ_{exc} = 400 nm.

formation of **2** (Table 8, entry 1–3). Using 1 : 1 DMSO : toluene in combination with the preformed Ni complex [Ni(dtbbpy)(OH₂)₄]Cl₂ and **DiICzMes₄** as the PC resulted in 81% yield of **1** and only 13% of **2** (Table 8, entry 7). Reducing the reaction time from 24 to 3 h resulted in a lower yield of **1** (54%) but not of **2** (13%) (Table 8, entry 5), while with **fac-Ir(ppy)₃** as the PC the product was obtained in 68% yield after 3 h (Table 8, entry 7). While the reaction with **fac-Ir(ppy)₃** is slightly faster than with **DiICzMes₄**, effectively similar yields of 74 and 77% were obtained after 24 h using **DiICzMes₄** and **fac-Ir(ppy)₃**, respectively.

Conclusion

We have investigated four DiICz emitters as fast and efficient DET photocatalysts in five different energy transfer reactions, highlighting their ability to activate high triplet energy substrates and outperform literature reference PCs. There is scant solvent dependency of the T₁ state energies of these four MR-TADF PCs, unlike D–A TADF PCs such as **4CzIPN**. Surprisingly, we observed a dependency of the sensitivity of O₂ quenching as a competitive triplet quencher as a function of the nature of the PENt reaction, even when the E_T of the substrate was the same. Reactions that proceed sufficiently rapidly with these PCs show little to no O₂ dependency on the final yield, which is a benefit of these compounds as photocatalysts. This suggests that the quenching of the excited state by O₂ is not competitive with the DET kinetics to the substrate. Excitingly, DET to substrates with triplet energies as high as 3.0 eV is feasible with **DiICztBu₄** and **DiICzMes₄**, both of which catalyze the sigmatropic shift of (*S*)-verbenone, yielding the product in around 38% yield. We concluded that there is no connection between either the yield or the reaction rate and the ΔE_{ST} of the

PC. This study reveals the particularly valuable and wide utility of **DiICzMes₄** as a PENt photocatalyst for substrates possessing high triplet energies.

Author contributions

E. Z.-C. conceived and managed the project and supervised the work. D. H. synthesized **DiICzMes₄** and **DiICztBuCz₄**, E. B. synthesized **DiICztBuDPA₄** and L. H. synthesized **DiICztBu₄**. D. H. performed the steady-state emission and absorption measurements in toluene, T. H. measured the photoluminescence quantum yields of the four photocatalysts, and the emission lifetimes of the photocatalysts in presence of cinnamyl acetate, and L. H. performed steady-state emission and absorption measurements in DCM, DMF and EtOAc, the time-resolved photoluminescence measurements in DCM, and the determination of ΔE_{ST} in 2-MeTHF. L. H. carried out photocatalysis reactions and photostability studies. L. H., D. H. and E. Z.-C. contributed to the manuscript writing and discussion.

Data availability

The research data supporting this publication can be accessed at <https://doi.org/10.17630/22609279-98d6-4d3c-a1c1-b1f14b04b22d>. Supplementary information: synthetic procedures, UV-vis absorption and photoluminescence spectra (room temperature steady-state, 77 K steady-state, and 77 K gated emission), time-resolved PL decays, photoluminescence

quantum yield data, photocatalysis procedures, and photostability studies. See DOI: <https://doi.org/10.1039/d5sc04014k>.

Acknowledgements

We thank the European Union H2020 research and innovation program for the funding under the Marie S. Curie Grant Agreement (PhotoReAct, No. 956324). We thank Geena Zoubarev for the contribution to the initial photocatalytic assessments. We thank Dr Megan Bryden, Francis Millward, and Violaine Manet for providing samples of **4CzIPN** and **fac-Ir(ppy)₃**. We thank EPSRC for financial support (EP/W522259/1, EP/W007517/1 and EP/M02105X/1).
