rsc.li/chemical-scienceDirect conversion of waste CO₂ over porous polymer catalystsJun-Song Jia,^a Ying Liang^{ID}*^b and Ying-Ming Pan^{ID}*^c

Direct conversion of waste CO₂ avoids CO₂ capture and lowers the cost of CO₂ utilisation; however, this route remains a challenging research topic. Developing catalysts that facilitate the enrichment and conversion of waste CO₂ is therefore essential. Porous polymer catalysts offer unique advantages due to their high surface area and tunable functionality. These materials catalyse the conversion of both simulated waste CO₂ and CO₂ present in industrial waste gases, such as anaerobic fermentation gas, lime kiln waste gas, and coal-fired flue gas. This review summarises recent progress on the direct conversion of waste CO₂ using porous polymer catalysts. It analyses the structural features of these catalysts, their CO₂ adsorption properties, and the associated catalytic mechanisms. A quantitative comparison of catalytic performance—such as turnover frequency, stability, and CO₂ adsorption capacity—is also provided. The findings may support the rational design and synthesis of catalysts for the direct utilisation of waste CO₂, and provide parameters for the industrialisation of porous polymer catalysts.

1. Introduction

Owing to the continuous development of the global economy and the emission of industrial waste gases, the concentration of CO₂ in the atmosphere has been increasing for centuries.^{1–3} As a greenhouse gas, CO₂ can result in many environmental

problems, such as global warming, rising sea levels, the destruction of ecosystems, and extreme weather.^{4–6} In recent years, the annual emission of CO₂ into the atmosphere has reached a concerning level of 3.31 billion tons.⁷ Therefore, capturing and converting CO₂ to reduce its concentration in the atmosphere are urgent tasks.

CO₂ is a low-cost, safe, non-toxic, and abundant C1 source.^{8,9} Its conversion by chemical methods helps reduce CO₂ emissions and yields a range of high value-added products, including synthons, fine chemicals, pharmaceuticals, and hydrocarbon fuels.^{10–13} Many methods have been developed to convert CO₂ into bulk chemicals, such as CO, CH₃OH, and HCOOH.^{14,15} CO₂ can also be introduced into organic structures through catalysis to synthesise carboxylic acids, esters, and

methods and instruments.

Ying Liang is a professor at Guilin University of Electronic Technology. Born on September 11, 1975, in China, she received her BSc degree from Central South University in 1997, followed by an MSc degree from Guangxi University in 2000. She obtained her PhD degree from Xiamen University in 2006. Currently, her research focuses on chemical carbon sequestration and the development of environmental monitoring

Scheme 1 Capture and utilisation of waste CO₂.

carbonyl compounds.^{16–19} However, these reactions require pure CO₂ and generally convert CO₂ under high pressure (Scheme 1A). Currently, the capture of CO₂ from industrial waste gas is usually achieved through liquid or solid adsorption, followed by heating and desorption, and then compression and storage.²⁰ Desorption and compression require a large amount of energy, resulting in high costs. For example, the cost of capturing one tonne of CO₂ by amine washing is \$59.10 for a typical coal-fired power plant.²¹ Therefore, the steps for capture and storage between CO₂ emissions and utilisation must be reduced. If the CO₂ in exhaust gas generated by burning fossil fuels is directly utilised, the steps of capture and storage can be eliminated, thereby reducing the cost of CO₂ utilisation (Scheme 1B).

The exhaust gas emitted from industrial production has a low CO₂ concentration. For example, flue gas contains CO₂ at 10–15 vol%.²⁰ Anaerobic fermentation gas (AFG) typically consists of CH₄, CO₂, N₂, and H₂S, with a CO₂ concentration in the range of 30–35 vol%.^{22,23} Waste gas from lime kilns mainly comprises N₂, O₂, CO₂, CO, SO₂, H₂O, and dust, with a CO₂ concentration of 20–42 vol%.^{24–26} In addition, activated CO₂ can be converted into small molecule compounds such as CO and HCOOH.^{27–29} In catalytic systems that convert CO₂ into high value-added products, these small molecule products are often overlooked. Therefore, the direct conversion of waste CO₂ faces three challenges: (1) the catalyst must have the capacity for *in situ* enrichment of low-concentration CO₂; (2) the catalyst must accurately identify CO₂ in exhaust gases without interference from other gas molecules; and (3) selective conversion of CO₂. Hence, a new catalytic system with enrichment and conversion effects for low-concentration CO₂ must be developed.

Ying-Ming Pan

Ying-Ming Pan is a professor at Guangxi Normal University. He was born in Jiangxi, China. He received his BSc degree from Gannan Normal University and MSc degree from Guangxi University (China). He obtained his PhD degree from Xiamen University in 2010. He was awarded the Mingde Teacher Award in 2018. His present research interests focus on electrochemical synthesis and heterogeneous catalysis.

Porous polymer catalysts are a new class of porous materials with the advantages of high specific surface area, diverse pore structures, low skeleton density, and facile functionalisation.^{30–32} They have become versatile hard ligands and carriers for converting many homogeneous catalysts into heterogeneous nano or single-site active-centre catalysts with unique catalytic activity and stability.^{33–35} Compared to metal-organic framework (MOF) and covalent organic framework (COF)-based catalysts, polymer catalysts present several advantages: (1) the structure of polymer catalysts is characterised by weak pore uniformity and topological ordering.^{36–38} The hierarchical pore structure promotes the physical adsorption of CO₂. (2) Polymer catalysts are more thermally stable. They are also more stable in water, acid, and base, which broadens their applicability.^{37,39} (3) After the loading of metal onto polymer catalysts, the metal is distributed on the surface, facilitating its contact with reactants. The metals within MOFs are typically positioned at the core of the crystal structure, reducing the accessibility of the substrate.^{40,41} In addition, porous polymer catalysts have advantages over non-porous catalytic systems: (1) the porous 3D structure increases the catalyst's surface area and allows more active sites to be loaded per unit volume, increasing the probability of CO₂ coming in contact with the catalyst.^{30,39} (2) The hierarchical pore structure, especially micropores, contributes to CO₂ enrichment.⁴² (3) The swelling properties of porous structures can create a “quasi-homogeneous” catalytic system that accelerates mass transfer and improves catalytic efficiency.⁴³

Porous polymer catalysts include porous organic polymers (POPs), porous ionic liquid polymers (PILs), porous organic ligand polymers (POLs), and hypercrosslinked polymers (HCPs).³⁹ Incorporating active sites that can activate or enrich CO₂ into the framework of porous polymers creates an ideal platform for heterogeneous catalytic CO₂ conversion. Chemists have reviewed the use of porous catalysts for the conversion of pure CO₂. In 2018, Huang, Liu, and co-workers reviewed the design and synthesis progress of POPs for catalytic CO₂ conversion.²¹ The design strategies of these catalysts include nitrogen doping, metallisation, and ionic functionalisation of POPs. In 2022, Wang, Zhou, and co-workers summarised the synthesis of porous PILs and the catalytic details for achieving cycloaddition between pure CO₂ and epoxides.⁴² However, only a few reports are available on the enrichment and conversion of CO₂ in exhaust gas catalysed by porous polymers.

In this review, the most recent advances in the design and synthesis of porous polymer catalysts for the conversion of low-concentration CO₂ are summarised. The discussion highlights the synthesis strategies of porous polymers with enrichment effects for low CO₂ concentration and the accurate identification of CO₂ molecules in exhaust gas (simulated exhaust gas). Problems in this field are analysed and future development directions are outlined. This review is divided into two sections: the first addresses simulation of waste CO₂, and the second addresses real waste CO₂. Within each section, further categorisation distinguishes waste CO₂ conversion with metal catalysis from that without metal catalysis.

2. Direct conversion of simulated waste CO₂

Simulated waste CO₂ gas is prepared by mixing pure CO₂ with other gases, such as N₂ or air. This mixing process is straightforward and generates a low-concentration CO₂ atmosphere under experimental conditions, facilitating the study of simulated waste CO₂. Existing reports generally indicate a volume concentration of simulated waste CO₂ of 15–20 vol%, which can represent the CO₂ concentration in actual exhaust gases, such as flue gas or lime kiln gas.^{20,24} However, the presence of other gases in waste CO₂ gas cannot be fully replicated by simulating the waste CO₂ gas alone.

2.1 Direct conversion of simulated waste CO₂ involving metals

Porous polymer catalysts used to convert waste CO₂ typically contain alkaline sites, which can be loaded with metals to produce metal-loaded porous polymer catalysts. The alkaline sites in these catalysts can alter the electron distribution in CO₂, facilitating acid–base reactions and thereby activating CO₂.²¹ Additionally, metals loaded onto the catalyst can effectively activate other reaction substrates. The reaction between CO₂ and epoxides to form cyclic carbonates, which achieves 100% atom economy, has received broad attention.^{44,45} Numerous heterogeneous catalysts have been developed for the reaction of CO₂ with epoxides to generate cyclic carbonates; however, these catalysts often have drawbacks, such as harsh reaction conditions, catalyst loss, and the need to add large quantities of soluble cocatalysts.⁴⁶

Porphyrins are a class of conjugated macrocyclic structures with 18 π electron systems, which enable strong interactions with CO₂.⁴⁷ Furthermore, the cavity structure of porphyrin-based polymers can coordinate with metals to facilitate their loading. Therefore, many porphyrin-based porous materials have been used to convert pure CO₂. In 2016, Xiao, Meng, and co-workers utilised porphyrin POP loaded with Co³⁺ to synthesise a heterogeneous catalyst, Co/POP-TPP, which enabled the reaction of low-concentration CO₂ (15 vol%) with epichlorohydrin **1** by cycloaddition, yielding cyclic carbonates **2** with a 45.4% conversion rate and 88.7% selectivity (Scheme 2a).⁴⁸ The catalytic system required the addition of tetrabutylammonium bromide (TBAB) as a cocatalyst. The study found that the activity of the heterogeneous Co/POP-TPP catalyst exceeded that of the corresponding homogeneous Co/TPP catalyst. This difference can be attributed to the strong adsorption capacity of Co/POP-TPP for 15 vol% CO₂ (adsorption capacity of 8 cm³ g^{−1}), whereas the nonporous Co/TPP showed negligible CO₂ adsorption. Activation of the adsorbed CO₂ can be attributed to two factors: the acid–base interaction between nitrogen atoms in porphyrins and CO₂, and the strong interaction between the porphyrin π system and CO₂. This catalyst can convert low concentrations of CO₂ at 1 atm and room temperature, which is relevant for utilising CO₂ generated during industrial processes. Although the catalyst successfully

Scheme 2 Co and Mg/porphyrin ligand polymers catalyse the conversion of low-concentration CO₂.

enabled the conversion of simulated waste CO₂, the product yield remained relatively low.

In the cycloaddition reaction between epoxides and CO₂, it is customary to add metal ions or halide anions, both of which serve to activate the substrate.²¹ Therefore, the design and synthesis of porous polymer catalysts containing both metal ions and halogen anions will contribute to the conversion of waste CO₂. In 2021, Xiao's group continued to investigate and synthesise heterogeneous catalysts with multiple synergistic active sites to address the challenge of adding large quantities of soluble cocatalyst TBAB, as shown in Scheme 2a.⁴⁶ They prepared a porous organic catalyst, POP-PBnCl-TPPMg-*x*, containing both Lewis acidic and Lewis basic active sites, by copolymerising different proportions of Mg–porphyrin monomers and phosphonium salt monomers (Scheme 2b). Among these, the catalyst POP-PBnCl-TPPMg-12 catalysed the cycloaddition of 15 vol% CO₂ with epoxides to form cyclic carbonates with a 95.1% conversion rate and 73.8% selectivity.

In general, increasing the surface area of polymer catalysts is considered beneficial for enhancing reactant accessibility to

active sites.²¹ However, the results from the Co/POM-TPP and POP-PBnCl-TPPMg-12 studies suggest that the Brunauer–Emmett–Teller (BET) surface area and pore volume are not the determining factors in waste CO₂ conversion. Halogen anions integrated onto polymers provide improved cocatalytic effects, likely owing to better dispersion of halogens on the polymer. Additionally, POP-PBnCl-TPPMg-12 does not require cocatalysts and offers a broad range of parameters for converting low-concentration CO₂. The use of MeCN as a solvent in the catalytic system significantly increased the cyclic carbonate yield, although the mechanism underlying this enhancement was not explained by the authors.

The disordered hierarchical pore structure is a prominent feature of porous polymer catalysts. Pore structures of varying volumes in polymers may serve different functions in the conversion of waste CO₂. In 2016, Yang, Li, and co-workers prepared a hierarchical meso/microporous polymer catalyst containing a 2,2'-bipyridine Zn(II) coordination structure, Bp-Zn@MA (Scheme 3).⁴⁹ When TBAB was used as a cocatalyst,

Bp-Zn@MA catalysed the cycloaddition reaction of simulated flue gas (20 vol% CO₂) and epoxide to produce cyclic carbonates 2. The N₂ adsorption test showed that the micropore volume of Bp-Zn@MA was 0.002 cm³ g⁻¹, representing 0.198% of the total pore volume. The authors verified, using Henry's law and ideal adsorption solution theory, that Bp-Zn@MA exhibits higher adsorption selectivity for CO₂ than N₂ in mixed gases. Notably, the micropores and abundant N sites in Bp-Zn@MA show selective adsorption for CO₂ in CO₂/N₂ mixed gases, whereas the role of mesopores is to facilitate the rapid diffusion of reactants and products. Therefore, micropores exert a more pronounced enrichment effect on waste CO₂. However, the "division of labour" mechanism between micropores and mesopores in catalysis requires further investigation.

In parallel, the authors proposed a mechanism for this reaction. The catalytic cycle begins with the coordination of epoxyethane compounds with zinc to produce compound 3. Bromide anions then perform a nucleophilic attack on epoxyethane to generate Zn-coordinated ring-opening intermediate 4, which combines with CO₂ to afford zinc carbonate species 5. Finally, the intramolecular cyclisation of zinc carbonate species generates the final product 2 and releases bromide anions and regenerated catalyst Bp-Zn@MA, thus completing the catalytic cycle. In this process, zinc activates epoxides, whereas the activation of CO₂ is mainly due to the acid–base interaction between the alkaline N site and CO₂. Unfortunately, the reaction conditions are harsh (high temperature and pressure) and not suitable for large-scale catalyst application. In addition, the catalytic efficiency decreases when the reaction is carried out in a mixed gas at atmospheric pressure.

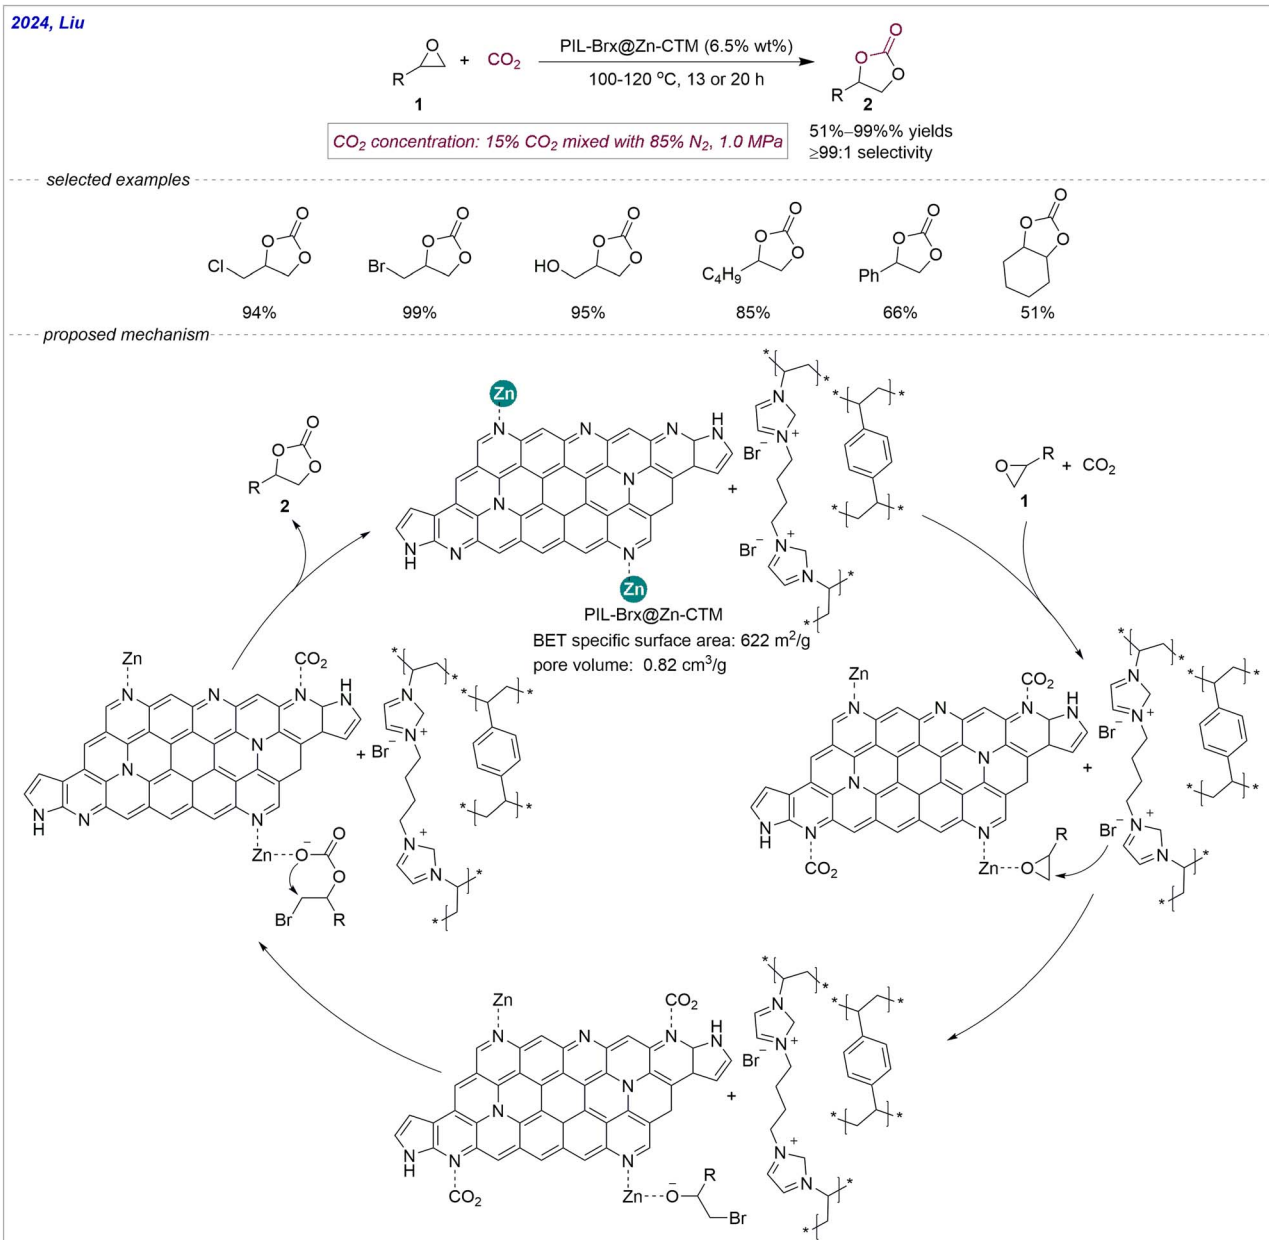

Nitrogen heterocyclic carbene (NHC) ligands contain multiple nitrogen atoms that can interact with the carbon in CO₂ to activate it. NHC polymer catalysts also exhibit stronger alkalinity than N-doped polymers, facilitating acid–base interactions with CO₂.²¹ PILs combine the advantages of porous materials, polymers, and ionic liquids, and have shown promise in CO₂ fixation by cycloaddition.⁴² PILs synthesised from NHC ligand polymers demonstrate excellent catalytic performance in the conversion of low-concentration CO₂.^{50–54} In 2024, the Liu group prepared a poly(ionic liquid)@porous carbon nanocomposite (PIL-Br_x@Zn-CTM) through the pyrolysis of fluid precursors and *in situ* polymerisation (Scheme 4).⁵⁵ PIL-Br_x@Zn-CTM contains Lewis acidic (Zn²⁺) and Lewis basic (N) sites and a nucleophilic anion Br⁻. PIL-Br_{1.0}@Zn-CTM can absorb low concentrations of CO₂ and catalyse its reaction with epoxides to produce cyclic carbonates 2. The catalytic system does not require cocatalysts or solvents, making it a green approach. In this heterogeneous catalyst, zinc has strong coordination ability, whereas bromide anions have high nucleophilicity. Therefore, the presence of zinc and bromide anions activates epoxides. In addition to the alkaline NHC and N-doped sites, the strong interaction between the large conjugated structure of carbon nanocomposites and CO₂ may also benefit CO₂ adsorption and conversion. However, this catalytic reaction requires a high temperature, which limits its industrial application.

Scheme 3 Bp-Zn@MA catalyzes the conversion of low-concentration CO₂.

2024, Liu

Scheme 4 Poly(ionic liquid)@porous carbon nanocomposites for the capture and *in situ* conversion of low-concentration CO₂.

The process of PIL-Br_{1.0}@Zn-CTM adsorbing and converting low-concentration CO₂ is illustrated in Scheme 4. The alkaline N sites on the catalyst surface adsorb and activate low-concentration CO₂. Simultaneously, Zn²⁺ coordinates with the epoxides **1** and induces C–O bond polarisation. The nucleophilic Br[−] attacks the β-C of epoxyethane, which has minimal steric hindrance, to generate the ring-opening intermediate, which undergoes nucleophilic addition with the CO₂ adsorbed by the catalyst to form alkyl carbonate compounds. Finally, intramolecular cyclisation occurs to generate the final product **2** and release PIL-Br_{1.0}@Zn-CTM.

Due to the disorder of the polymer structure, its BET surface area, pore volume, and pore size are difficult to control during preparation. The development of methodologies capable of

precisely modulating the surface area and pore volume of polymers remains a significant challenge in this field. In 2017, Wang, Zhou, and co-workers described the selective capture and conversion of CO₂ from simulated flue gas (15 vol% CO₂) under mild conditions using imidazolinium-based porous hypercrosslinked ionic polymers (HIPs) with cocatalyst ZnBr₂ (Scheme 5).⁵⁶ Notably, the authors adjusted the porosity of HIPs by modifying the initial gel composition. The catalytic effect of this heterogeneous catalyst is substantially better than that of homogeneous ionic liquid monomers and post-modified analogues. The halogen anions in HIPs show high nucleophilicity and high leaving ability, which promote the selective adsorption of CO₂. Furthermore, the authors propose that HCP exhibits advantages for CO₂ capture and utilisation due to its

Scheme 5 HIP-Br-2 catalyses the conversion of low-concentration CO₂.

high surface area and narrowly dispersed micropores. The CO₂ conversion mechanism is the same as for Scheme 3. In addition to halide anions, the alkalinity of NHCs contributes to CO₂ activation. Zn²⁺ assists in epoxide activation.

2.2 Direct conversion of simulated waste CO₂ without metals

As previously stated, metals and halogens primarily facilitate the activation of epoxides in the conversion of waste CO₂. The enrichment and transformation of CO₂ depend mainly on the pore structure and alkaline sites of porous polymers. Therefore, within heterogeneous catalytic systems, the reaction between waste CO₂ and epoxides can be achieved without the involvement of metals. In 2020, Wang, Zhou, and co-workers prepared HCPs through Friedel-Crafts alkylation and the conjugate crosslinking of benzyl imidazolite and α,α' -dichloro-*p*-xylene (DCX) (Scheme 6).⁵⁷ Altering the IL : DCX : FeCl₃ ratio changes the BET surface area and total pore volume of the polymer. Notably, the microporous structure and the ionic liquid enhance the enrichment of CO₂ at the active sites. At 273 K and 1 bar, the CO₂ adsorption capacity of HCP is 3.05 mmol g⁻¹. HCP can achieve the adsorption and conversion of CO₂ from simulated flue gas (15 vol% CO₂) without additives or solvents, yielding cyclic carbonates with a turnover number (TON) of 4250–4800. However, this catalytic system requires high temperatures and pressures, which limits its industrial application.

As depicted in Scheme 6, the mechanism of this transformation begins with the formation of hydrogen bonds between the epoxyethane compound 1 and imidazolium salts to afford 6, followed by Br⁻ nucleophilic attack on epoxyethane to generate ring-opening products 7. CO₂ insertion into O⁻...H then produces opening carbonates 8, which undergo nucleophilic attack to form ring-closing products 2 and release the

Scheme 6 HCP catalyses the conversion of low-concentration CO₂.

catalysts. It can be inferred from the mechanism that NHC monomers also activate epoxides. However, the mechanisms of CO₂ adsorption and activation were not clarified by the authors.

Progress has been made in enriching and converting simulated waste CO₂ using porous polymer catalysts. Some catalysts can achieve the conversion of low-concentration CO₂ at room temperature, atmospheric pressure, and without co-catalysts, confirming the potential of polymer catalysts for industrial waste CO₂ conversion. However, further research is required into the underlying mechanisms of CO₂ enrichment by porous polymer catalysts. In addition, the above waste CO₂ reactions are carried out in closed reactors. Given the fluidity of industrial waste gases, studying the conversion of CO₂ in flowing gases will provide more relevant reference data.

selected examples

proposed mechanism

Scheme 7 Cu@NHC-1 catalyses CO₂ conversion in lime kiln waste gas.

3. Direct conversion of real waste CO₂

The flue gas released from industrial production comprises not only waste CO₂ but also other gases, including O₂, SO₂, and NO₂. The presence of these other gases may affect the ability of porous polymer catalysts to capture and convert CO₂.⁵⁸ Therefore, the study of polymer catalysts for the identification and conversion of real waste CO₂ has greater academic and industrial significance. In this section, we review the progress of research into the enrichment and conversion of real waste CO₂ using porous polymer catalysts. The conversion of CO₂ is no longer limited to the cycloaddition with epoxides to form cyclic carbonates, but can also generate a wider range of molecules, such as formamide and oxazolidinone.

3.1 Direct conversion of real waste CO₂ involving metals

Currently, the enrichment and conversion of CO₂ in exhaust gas are mostly conducted in fixed reaction equipment, so the exhaust gas must first be collected. Directly introducing the exhaust gas into the reaction equipment for the continuous conversion of CO₂ will simplify the production process. In 2023, Liang's group developed the heterogeneous catalyst Cu@NHC-1 for the continuous conversion of CO₂ in lime kiln exhaust gas (30 vol%) using a continuous flow device (Scheme 7).⁵⁹ They polymerised a bidentate NHC monomer with divinylbenzene (DVB) to obtain NHC-1, which was coordinated with Cu(OAc)₂ to form Cu@NHC-1 under alkaline conditions. Without co-catalysts, the cyclisation of propargylamine **9** with CO₂ in lime kiln exhaust gas produces oxazolidinones **10**. The catalytic system can also achieve gram-scale conversion (15 mmol). As depicted in Scheme 7, the first step in the reaction mechanism is to use the pore effect of the catalyst and the nucleophilic effect of nitrogen to enrich CO₂. Meanwhile, propargylamine **9** is captured by the N sites of the catalyst and interacts with the copper centre to form intermediate **11**. The activated CO₂ and propargylamine are converted by cation **12** into aminofornate intermediate **13**, which then undergoes intramolecular cyclisation to form intermediate **14**. Lastly, **14** is protonated by cation **12** to yield the final product oxazolidinone **10**, regenerating the catalyst Cu@NHC-1. Therefore, the NHC in Cu@NHC-1 activates and enriches CO₂, while copper activates propargylamine. However, the authors did not examine the effects of O₂, CO, and SO₂ on the enrichment of CO₂ by the polymer.

Scheme 8 Schematic diagram of the bubbling device for continuous gas flow.

As shown in Scheme 8, a continuous flow device introduces 30 vol% CO₂ into a heterogeneous catalytic system *via* bubbling. Under analogous conditions, the continuous flow apparatus achieves a product yield of 96%, whereas the fixed reactor yields 72%. The authors suggest that the observed difference in yield results from more effective contact between the waste CO₂, the catalyst, and the substrate in the continuous flow device. This finding highlights the potential application of the catalyst for CO₂ enrichment and conversion in industrial waste gas. However, the authors did not explore the mechanism of

Scheme 9 Ag@POP-NL-3 catalyses CO₂ conversion in lime kiln waste gas.

selective adsorption and enrichment of CO₂ in lime kiln exhaust gas by the hierarchical pore structure of the catalyst.

Increasing the number of NHC and metal sites in the monomer enhances the probability of CO₂ contacting active sites, thereby improving the conversion efficiency. In 2023, Liang, Pan and co-workers synthesised the nanocatalyst Ag@POP-NL-3 by pre-coordination and polymerisation of a tridentate NHC monomer with AgNO₃ (Scheme 9).⁶⁰ Coordinating before polymerising ensures uniform distribution of Ag on POP-NL-3 and improves catalytic efficiency. The hierarchical pore structure and abundant nitrogen sites of the catalyst guarantee the adsorption and conversion of CO₂. Using Ag@POP-NL-3 as the heterogeneous catalyst and 0.6 equivalent of DBU as an additive, CO₂ (30 vol%) in lime kiln waste gas reacts with propargyl alcohol **15** to form cyclic carbonates **16**. Raman spectroscopy detected the stretching vibration (1183 cm⁻¹) and antisymmetric stretching (2211 cm⁻¹) of the N-CO₂ structure. This result confirms the adsorption and activation of CO₂ by N species within the polymer.

Following the addition of Ag@POP-NL-3 to propargylic alcohol, the ¹H nuclear magnetic resonance absorption peak signal of propargylic alcohol decreased, indicating that Ag@POP-NL-3 exerts an adsorption effect on the substrate. The mechanism of this reaction is shown in Scheme 9. First, the hierarchical pore structure and abundant nitrogen sites of the catalyst enrich the low-concentration CO₂ to a locally high concentration. DBU and propargylic alcohol **15** then interact through hydrogen bonding, and Ag coordinates with C≡C to form intermediate **17**. The oxygen atom of propargylic alcohol attacks CO₂, inserting CO₂ and providing intermediate **18** while releasing DBU-H⁺ **19**. Intermediate **18** undergoes intramolecular cyclisation with carbonate and C≡C to form intermediate **20**, followed by reaction with **19** to produce cyclic carbonate **16**. Through controlled experiments, the authors demonstrated that DBU activates propargylic alcohol. It is speculated that, as an organic base, DBU may also activate CO₂. Therefore, exploring the catalytic effect of DBU on this reaction in the absence of polymer catalysts would improve the accuracy of the proposed mechanism.

The addition of nitrogen-containing components and copolymerisation with NHC monomers can effectively increase the alkaline nitrogen sites in the polymer. In 2024, Pan, Liang and co-workers added copolymer allyl aniline to the bidentate NHC ligand to synthesise polymer POP-6 with abundant nitrogen sites, and then loaded it with Ag₂O to form POP-6@Ag₂O (Scheme 10).⁶¹ This polymer catalyst enables the cyclisation between CO₂ in coal-fired flue gas (8 vol%) and propargylamides **21** to produce oxazolidine-2,4-diones **22**. The amine groups in the polymer selectively absorb CO₂ from coal-fired flue gas, and imidazole and silver nanoparticles activate CO₂ and propargylamides.

The mechanism of POP-6@Ag₂O adsorbing and converting waste CO₂ is shown in Scheme 10. The CO₂ in coal-fired flue gas is first adsorbed in the hierarchical pores of the polymer and then onto the amino group. The CO₂ adsorbed by the amine group is transferred to the carbene nitrogen for activation. The nitrogen in propargylamine attacks activated CO₂, and Ag

Scheme 10 POP-6@Ag₂O catalyzes CO₂ conversion in coal-fired flue gas.

activates alkynes. Finally, intermediate **23** undergoes intramolecular cyclisation to generate the target product **22**. The enrichment and activation of waste CO₂ with a concentration below 10 vol% in the presence of other gases is a challenging process. The hierarchical porous structure of polymer catalysts facilitates the enrichment of CO₂ and other gases. Therefore, the selectivity of polymers towards waste CO₂ is predominantly attributed to the interaction between the alkaline sites of the polymer and CO₂. Notably, the stronger alkalinity of aliphatic amines compared to aromatic amines means that integrating alkyl amines into polymer catalysts could improve their ability to enrich and activate waste CO₂.

More importantly, the authors demonstrated through controlled experiments that neither SO₂ nor NO₂ affects the

cyclisation reaction. This reaction is unaffected by SO_2 , NO_x and volatile organic compounds in actual coal-fired flue gas. Therefore, it can be deduced that the presence of other gases in the mixed gas does not affect the catalytic performance of the polymer catalyst. However, the efficiency of the polymer catalyst may decrease as the reaction progresses if the metal loaded on it is sensitive to water and oxygen.

Compared with the two-component reaction involving waste CO_2 , the three-component reaction is more challenging. In 2025, Pan, Liang and co-workers copolymerised a six-membered NHC monomer with DVB to generate POP-1, which was then loaded with $\text{Pd}(\text{PPh}_3)_4$ to form the catalyst POP-1-Pd (Scheme 11).⁶² At 298.15 K, the CO_2 adsorption capacity of POP-1-Pd is $11.62 \text{ m}^3 \text{ g}^{-1}$. Under the action of NaO^tBu , POP-1-Pd catalyses a three-component reaction of CO_2 from lime kiln exhaust gas with propargylamine **9** and aryl iodide **24** to produce oxazolidinone **25**. When $\text{NHC} : \text{DVB} = 1 : 4$, the catalyst has the best effect on CO_2 adsorption and conversion. This finding indicates that the specific surface area of the catalyst has a significant effect on the utilisation of CO_2 . Moreover, this

catalytic system can be applied to the gram-level synthesis of oxazolidinone ($100 \text{ vol}\% \text{ CO}_2$, 1.72 g).

CO_2 is enriched near the catalytic sites through the adsorption of imidazolium salts. In parallel, Pd^0 undergoes oxidative addition with aryl iodide **24** and coordinates with the $\text{C}\equiv\text{C}$ of propargylamine **9** to form intermediate **26**. CO_2 is then integrated into intermediate **27** via the imidazole structure. The N^- in propargylamine attacks CO_2 to produce intermediate **28**, which undergoes intramolecular cyclisation to generate intermediate **29**. Finally, **29** undergoes reductive elimination to yield the desired product **25** and regenerate the catalyst. The hierarchical pores of POP-1-Pd provide a microenvironment with increased concentration after adsorbing CO_2 and substrates. According to the mechanism proposed by the authors, NHC adsorbs and activates waste CO_2 , while palladium activates iodobenzene and propargylamine. There is no direct interaction between palladium and CO_2 . Furthermore, the addition of stoichiometric strong base NaO^tBu renders the reaction conditions harsh.

Interestingly, the anions in the imidazole polymer can be exchanged with other anions, thereby enhancing the ability of

Scheme 11 POP-1-Pd catalyses CO_2 conversion in lime kiln exhaust gas.

Scheme 12 Ag@POP-HCO₃ catalyses CO_2 conversion in coal-fired flue gas.

the polymer to enrich and convert waste CO₂. In 2025, Pan, Liang and co-workers developed an Ag@POP-HCO₃ catalysed reaction of propargylamine **30** with CO₂ in coal-fired flue gas (8 vol%), producing oxazolidinones **31** (Scheme 12).⁶³ Ag@NHC-HCO₃ can be obtained by modifying the Ag@NHC ligand with HCO₃[−], which enhances the catalyst's ability to adsorb CO₂. The specific surface area and micropore volume of the catalyst can be controlled by changing the NHC:HCO₃[−]:DVB ratio. Moreover, the authors designed simulated flue gas with different SO₂ and NO₂ contents. Subsequent controlled experimentation confirmed that SO₂ and NO₂ have no significant effect on the activity of the catalyst.

The mechanism of this conversion is shown in Scheme 12. CO₂ is enriched by the porous structure of polymers and free HCO₃[−] to give **32**. The N-nucleophile of propargylamine then attacks the activated CO₂, and Ag interacts with C≡C through π electrons to form the carbamate intermediate **33**, followed by intramolecular cyclisation to generate vinyl-silver **34**. Finally, **34** is converted into the final product **31**, and the catalyst Ag@NHC-HCO₃ is regenerated. HCO₃[−] may promote the conversion of waste CO₂ in two ways: (1) as the HCO₃[−] content increases, the specific surface area and microporosity of the catalyst increase, which favours CO₂ adsorption; (2) HCO₃[−] contributes to the formation of the NHC-CO₂ structure between CO₂ and NHC under alkaline conditions.^{64,65} According to this mechanism, CO₂ may be converted into other small-molecule compounds, such as H₂CO₃. Further analysis of these compounds could clarify the issue of selective CO₂ conversion.

3.2 Direct conversion of real waste CO₂ without metals

As demonstrated in the preceding discussion, imidazole polymers and metallised imidazole polymers offer unique advantages in the catalytic conversion of waste CO₂.⁵⁷ CO₂ can undergo C=O bond cleavage, resulting in the formation of CHO fragments. In 2023, Liang, Pan and co-workers reported the enrichment and conversion of CO₂ in AFG (46 vol%) using an ionic NHC ligand polymer, IPOP-3, through metal-free catalysis (Scheme 13).⁶⁶ The hydroxide anions, nitrogen sites, and porous structure in IPOP-3 act synergistically to promote the enrichment and conversion of CO₂. With IPOP-3 as the catalyst and PhSiH₃ as the additive, the primary amines **35** react with the CO₂ present in AFG to produce the corresponding formamide **36**. In addition, this reaction can convert the CO₂ in AFG gas on the gram scale (1.27 g).

As illustrated in Scheme 13, the authors proposed the catalytic cycle. Initially, CO₂ in AFG gas is selectively adsorbed onto IPOP-3 through the combined effect of hydroxide ions, nitrogen sites, and pore channels, creating a local atmosphere of high CO₂ concentration. PhSiH₃ is activated *via* nucleophilic interaction with the OH[−] groups in IPOP-3, forming a high-valence silicon centre **37** that reduces CO₂ to formate anions and intermediate **38**. The formate anion undergoes nucleophilic substitution with intermediate **38** to generate intermediate **39** and regenerate the IPOP-3 catalyst. Finally, amine **35** undergoes nucleophilic substitution with **39** to yield the formamide product **36** and byproduct phenylsilanol. It is evident that waste

Scheme 13 IPOP-3 catalyzes CO₂ conversion in AFG.

CO₂ is also activated by NHC, whereas the reactant amine is not activated by any species. Nevertheless, the use of stoichiometric phenylsilane and the low atomic utilisation rate of CO₂ reduce the atomic economy of this method.

Real waste CO₂ can be directly converted into various high-value-added products using porous polymer catalysis, providing a solution to the environmental problems caused by industrial CO₂ emissions. Although this process is currently at the pilot stage, it provides important information for potential industrial applications. Additionally, the Liang group⁵⁹ designed a prototype continuous-flow device for converting waste CO₂, demonstrating the possibility of directly introducing emitted exhaust gas into a porous polymer catalytic system to achieve selective adsorption and conversion of CO₂. Designing a comprehensive flow catalytic system and exploring further parameters—including exhaust gas introduction, product separation, catalyst regeneration and circulation, and exhaust gas treatment—will help porous polymer catalysts achieve continuous conversion of waste CO₂ on a large scale. However, there remains a paucity of discussion regarding selectivity in real CO₂ conversion processes.

Table 1 Activities of different catalysts for waste CO₂ conversion

Catalysts	Preparation method	TOF ^a	Stability/°C	CO ₂ adsorption capacity ^b	Pore sizes/nm
Co/POP-TPP	Radical polymerization	4.4	350	8 cm ³ g ⁻¹ (15% CO ₂)	0.4–2, 12–150

^a TOF = $[n(\text{product})]/[n(\text{ionic or metal sites}) \times (\text{reaction time})]$. ^b Unless indicated otherwise, the term refers to the adsorption capacity for pure CO₂ and 25 °C.

4. Summary and outlook

Porous polymer catalysts offer unique advantages for the enrichment and catalytic conversion of waste CO₂. This review summarises research on the catalytic conversion of waste CO₂

using porous polymer catalysts. The catalytic efficiency and reaction conditions of different heterogeneous polymer catalysts vary. For clarity, Table 1 provides a summary of the turn-over frequency (TOF), stability, CO₂ adsorption capacity, and reaction conditions involved in the conversion of waste CO₂. To

Porous polymer catalyst without metal loading

distinguish between “simulated” and “real” waste CO₂, we have summarised the gas composition and experimental conditions for each type in Table 2. Table 3 summarises the characteristics of the porous polymer catalysts described in this review, including functional groups, metal incorporation, and mechanistic features such as CO₂ activation modes. Moreover, Table 4 summarises the performance of different polymer catalysts in generating the same products (*e.g.* cyclic carbonates, formamides and oxazolidinones), including yield, TOF and selectivity. Our outlook is as follows:

(1) The mechanism of enrichment and activation of waste CO₂ by porous polymer catalysts is as follows: (i) acid–base interactions between active sites and CO₂ can alter the electron distribution of CO₂; (ii) interactions between specific polymer structures and CO₂, such as strong interactions observed between conjugated macrocyclic structures and CO₂; (iii) the hierarchical pore structure of the polymer (primarily micropores) enables CO₂ enrichment, increasing its concentration near catalytic active sites. However, the mechanism of CO₂ enrichment by the pore structure of polymers remains unclear. For mixed gases, the hierarchical pore structure of polymers may enrich each gas molecule. Therefore, further research is required to elucidate the enrichment mechanism of waste CO₂ by the pore structure.

Table 4 A comparison of the catalytic performance when synthesising the same product

<p>(d) </p>				
IPOP-3	62–90	—	0.3–0.4	66

(2) The BET surface area and total pore volume can be modulated by adjusting the ratio of crosslinking agent to ligand. However, no direct relationship is observed between the BET surface area or total pore volume of the polymer and the conversion of low-concentration CO₂ catalysed by the polymer. Accurately preparing polymer catalysts with specific surface area and pore volume tailored to the size of CO₂ would be more effective for enriching and converting waste CO₂. In addition, the principle underlying the regulation of BET surface area and total pore volume through the addition of anions requires further investigation.

(3) Some reports using gram-scale reactions indicate that porous polymer catalysts may catalyse the large-scale conversion of waste CO₂. The development of continuous flow devices demonstrates the feasibility of introducing industrial waste gas directly into the catalytic system for enrichment and conversion of waste CO₂. To our knowledge, no published studies have demonstrated the use of polymeric catalysts for industrial-scale CO₂ separation and conversion, nor have the economic viability and technical feasibility of such processes been systematically evaluated. Therefore, further research is required to transition catalysts from laboratory to industrial production. Further development of milder and more efficient porous polymer catalysts is required. Sufficient attention should also be given to reactor design and optimisation.

(4) Traditionally, the discovery of catalysts for CO₂ absorption and conversion involves a sequential process of polymer synthesis, catalyst optimisation and extensive data collection. Nevertheless, this empirical trial-and-error approach is not only labour-intensive, but also inherently inefficient. In the context of the rapid advancement of artificial intelligence, data-driven machine learning (ML) approaches can now be used to discover high-performance catalysts through computational prediction, thus eliminating the need for extensive experimental procedures.⁶⁷ Therefore, implementing ML-based predictive modelling for catalyst optimisation can significantly reduce the time taken to develop porous polymer catalysts, while ensuring enhanced catalytic efficacy. On the other hand, ML shows great promise in characterising the surface architectures of heterogeneous catalysts using computational modelling techniques such as density functional theory, molecular dynamics and Monte Carlo simulations.⁶⁸ As previously established, microstructural parameters of porous polymer catalysts, including pore size distribution, total pore volume and BET-specific surface area, affect the performance of CO₂ capture and enrichment. Consequently, compiling a comprehensive database of these surface characteristics from catalysts reported in the literature is essential for the ML-driven optimisation of porous polymer parameters.

(5) The adsorption outcomes of porous polymer catalysts on waste CO₂ have been detected using FT-IR and Raman spectroscopy.⁶⁹ Nevertheless, the dynamic adsorption and conversion process of CO₂ on polymer surfaces remains to be elucidated. In order to facilitate more intuitive detection of the conversion process of low concentration CO₂, there is a critical research frontier in the development of advanced *in situ*

spectroscopic methodologies capable of real-time monitoring of both selective adsorption and activation phenomena.

(6) In recent years, the development of bifunctional materials (BFMs) for capturing and converting CO₂ has emerged as a significant research area. Typically, BFMs comprise two phases: a catalyst phase and a high-temperature adsorbent phase. Meanwhile, porous polymer catalysts have excellent thermal stability (300–750 °C, Table 1), making them compatible with high-temperature adsorption.⁷⁰ Therefore, the integration of porous polymer catalysts with high-temperature adsorption phases, such as CaO, to prepare novel BFMs for CO₂ adsorption and conversion is also worth studying. The good adsorption capabilities of porous polymers for waste CO₂ may facilitate the capture and conversion of CO₂ by BFMs, obviating the necessity for elevated temperature conditions.

(7) Polymer-based membranes exhibit significant advantages in manufacturability and functional versatility, enabling their widespread adoption in liquid/gas separation processes.⁷¹ Notably, porous organic polymers offer superior design flexibility due to their tunable wettability, chemical stability, and facile modification capabilities.⁷² These attributes position porous polymer catalysts as promising alternatives to conventional membrane materials—including polydimethylsiloxane, polyvinylidene fluoride, poly(vinyl alcohol), and polyethylene glycol laurate—with demonstrated potential to enhance performance metrics in critical applications ranging from gas separation and osmotic processes to advanced filtration and solvent recovery systems. On the other hand, millimetre-sized composite beads are prepared using a double cross-linking strategy, combining powdered, porous polymer catalysts with additives such as polyacrylic acid, CaCl₂ and sodium alginate.⁷³ The assembly of fixed-bed catalytic systems utilizing these composite beads as structured packing media has evolved into a burgeoning research focus, particularly for enabling continuous-flow transformation of reactants with enhanced mass transfer efficiency. For gas-phase reaction systems targeting waste CO₂ valorization, continuous gas feeding into the flow reactor configuration enables simultaneous concentration enhancement and catalytic conversion through optimized gas-liquid-solid interfacial contact.

We hope that this review provides a new perspective on the enrichment and conversion of waste CO₂ using porous polymer catalysts and offers direction for the design and synthesis of heterogeneous catalysts that can facilitate more efficient conversion of waste CO₂.

Author contributions

All authors contributed to the conceptualization and literature search. J.-S. Jia wrote the first draft and made all schemes. All authors were involved in revising, editing, and proofreading.

Conflicts of interest

There are no conflicts to declare.

Data availability

No primary research results, software or code have been included and no new data were generated or analysed as part of this review.
