## Interface morphodynamics in living tissues

Cheng-Lin Lv<sup>a</sup> and Bo Li<sup>id</sup> \*<sup>abc</sup>

Interfaces between distinct tissues or between tissues and environments are common in multicellular organisms. The evolution and stability of these interfaces are essential for tissue development, and their dysfunction can lead to diseases such as cancer. Mounting efforts, either theoretical or experimental, have been devoted to uncovering the morphodynamics of tissue interfaces. Here, we review the recent progress of studies on interface morphodynamics. The regulatory mechanisms governing interface evolution are dissected, with a focus on adhesion, cortical tension, cell activity, extracellular matrix, and microenvironment. We examine the methodologies used to study morphodynamics, emphasizing the characteristics of experimental techniques and theoretical models. Finally, we explore the broader implications of interface morphodynamics in tissue morphogenesis and diseases, offering a comprehensive perspective on this rapidly developing field.

### 1 Introduction

Tissue interfaces define the boundaries between different tissue types or between a tissue and its external environment. They are present throughout all stages of life, including in vertebrate embryos,<sup>1–3</sup> skin layers,<sup>4</sup> and blood vessels<sup>5</sup> (Fig. 1). These interfaces play critical roles in signal transmission,<sup>6</sup>

material transport,<sup>7</sup> structural support,<sup>8,9</sup> and responses to external stimuli.<sup>10</sup> Their fundamental importance makes them highly relevant for applications in biomedicine and bioengineering.

The study of tissue interfaces focuses on their topological and physical properties, as well as their evolution over time. This field, known as interface morphodynamics, examines the continuous remodeling and adaptation of tissue interfaces in response to both internal and external factors. The morphodynamics of tissue interfaces plays a crucial role in various biological processes, such as development,<sup>13,14</sup> tumor invasion,<sup>12,15</sup> and wound healing.<sup>16,17</sup> For instance, coordinated cell movements and interface morphology are fundamental in the formation of tissue layers and organ structures,<sup>13</sup> while tumor progression depends on the evolving interface

between tumors and adjacent healthy tissues.<sup>18</sup> In recent years, significant research has focused on understanding the regulatory mechanisms driving interface evolution, with particular attention to factors such as adhesion,<sup>19–21</sup> tension,<sup>22,23</sup> cell activity,<sup>24,25</sup> and the extracellular matrix.<sup>15</sup>

The study of tissue evolution faces several challenges due to its complex, multifactorial, and multiscale nature. However, advancements in experimental techniques and theoretical models have helped address these challenges. State-of-the-art experimental equipment allows for the dynamic tracking of interface evolution across multiple scales.<sup>26,27</sup> Additionally, the application of models such as the vertex model,<sup>28,29</sup> deformable polygons (DP) model,<sup>30</sup> and active liquid crystal model,<sup>31,32</sup> along with other theoretical frameworks, have shed light on the multifactorial interactions governing interface dynamics.

In this review, we examine recent experimental and theoretical advancements in the morphodynamics of tissue interfaces. We begin by classifying tissue interfaces and then explore the key regulators of interface morphodynamics, including adhesion, cortical tension, cell migration, cell activity, extracellular matrix (ECM) composition, and the surrounding microenvironments. We also summarize the experimental approaches and theoretical models used to study these interfaces. Additionally, we discuss the biological significance and potential applications of interface morphodynamics. Finally, we offer perspectives on future research directions in this field.

## 2 Classification of tissue interfaces

To study the morphology and dynamics of tissue interfaces, it is essential to choose suitable experimental and theoretical

models based on the interface characteristics, as well as appropriate parameters for describing the interface. We classify interfaces according to their dimensions and components, and provide an overview of the common parameters used to characterize interface morphology and dynamics.

### 2.1 Classification by interface dimensions

**2.1.1 Two-dimensional interfaces.** The two-dimensional (2D) interfaces, typically studied in 2D systems, are among the most extensively researched in both experiments and simulations.<sup>10</sup> Topologically, a 2D interface can be viewed as a line on a plane or surface. Since 2D cell culture has been developed for over a century,<sup>33</sup> experimental models for 2D interfaces are well-established, with various preparation methods available. These include creating interfaces through mechanical scratches<sup>34,35</sup> or generating tissue encounter interfaces using topological constraints<sup>36</sup> (Fig. 2(a)). Compared to three-dimensional (3D) interfaces, 2D interfaces allow for simpler imaging and higher-resolution acquisition without transparency processing. These advantages make 2D interface experiments an effective tool for studying interface morphodynamics.

Recently, a wealth of theories and simulation models have been developed to explore the evolution of 2D interfaces.<sup>32,38–40</sup> These models simplify the analysis by confining both endogenous factors (such as cellular interactions, migration, proliferation, and signaling) and exogenous factors (such as biochemical molecules and substrates) to two dimensions, while still retaining key biological relevance. When solving a 3D problem, discretizing the governing equation in space results in a computational complexity of  $S(n^3)$ . By introducing a reasonable simplification and employing a 2D model, the complexity is reduced to  $S(n^2)$ , significantly enhancing computational efficiency. Additionally, in theories such as vertex models, 2D simplifications streamline the handling of topological transformations. While 2D models provide a coarse-grained representation of real systems, these advantages make them a valuable analytical tool. For example, the evolution of tissue interfaces during wound healing<sup>16,17</sup> can be conceptualized as a 2D interface problem, providing *in vivo* examples that can be tested against *in vitro* models of interface dynamics.

**2.1.2 Three-dimensional interfaces.** In 2D systems, the presence of a substrate significantly influences various properties of collective cell behavior, including deformation, topology, and dynamics, which are affected by factors such as substrate stiffness and surface structure.<sup>41,42</sup> However, substrates of this kind are rarely found in real environments, limiting the consistency between results from 2D systems and *in vivo* conditions. To overcome these limitations, researchers have developed a range of 3D cellular systems that more accurately replicate the *in vivo* environment. As shown in Fig. 2(b), materials such as matrix gels,<sup>43,44</sup> hydrogels,<sup>45,46</sup> microfluidic chips,<sup>47,48</sup> and biopolymer scaffolds<sup>49</sup> are used to construct 3D cell systems. Over the past decade, there has been increasing interest in developing 3D multicellular interfaces, both between tissues and between tissues and their extracellular

Fig. 2 2D interfaces and 3D interfaces. (a) Experiments of 2D epithelial–cancer interface and its evolution over time. Reprinted from ref. 36 with permission. matrix (Fig. 2(b)), to better mimic *in vivo* conditions.<sup>33</sup> Compared to 2D interfaces, 3D interface experiments and simulations more accurately represent interface evolution in living organisms. Notably, 3D interfaces enable the investigation of local curvature effects and topological properties, whereas 2D interfaces are restricted to analyzing average curvature and cannot fully capture the complexity of curvature-driven dynamics in 3D biological systems. For example, 3D interfaces and their morphological and dynamic properties have been extensively studied in areas such as mouse neural tube development,<sup>50</sup> epithelial cell invasion,<sup>51</sup> and tumor invasion.<sup>52–54</sup> Despite challenges in imaging accuracy, quantitative analysis, and model complexity, these studies demonstrate the potential of 3D interface systems in revealing interface evolution and its mechanisms *in vivo*.

## 2.2 Classification by components

**2.2.1 Single-tissue interfaces.** Tissues and the ECM, which represents the external environment, are the primary components of tissue interfaces. Based on the number of tissue components on both sides of the interface, they can be classified into single-tissue and double-tissue interfaces. Single-tissue interfaces are formed between a tissue and the external environment, such as the advancing front of spreading cell monolayers<sup>55,56</sup> and the outer boundary of 3D tumor spheroids.<sup>15,52,57</sup> *In vitro*, the formation of single-tissue interfaces can result from spontaneous tissue growth<sup>58</sup> or controlled destructive methods like barrier removal<sup>59,60</sup> and laser ablation.<sup>61</sup> In simulations, the evolution of single-tissue interfaces is often studied using single-phase theory.<sup>62</sup> However, since both tissue properties<sup>63,64</sup> and external environmental factors<sup>15</sup> jointly govern the morphological dynamics of single-tissue interfaces, some models incorporate viscoelastic or

similar characteristics of the external environment, effectively describing single-tissue interfaces using a quasi-biphasic model.<sup>65</sup> Single-tissue interfaces provide a valuable platform for studying tissue responses to changes in the external environment, advancing our understanding of tissue integrity<sup>58</sup> (Fig. 3(a)) and lumen formation<sup>66</sup> (Fig. 3(b)).

**2.2.2 Double-tissue interface.** The double-tissue interface forms between two distinct types of tissues, such as the interlayer interface between different germ layers<sup>1–3</sup> or the interface between tumor and normal tissue<sup>12,18,69</sup> (Fig. 3(c)). Cell sorting is a key mechanism in the formation of double-tissue interfaces.<sup>70–72</sup> This process often involves differences in characteristic properties, such as adhesion<sup>73–75</sup> and cortical

Fig. 3 Single-tissue interface and double-tissue interface. Wound healing (a) and hole nucleation (b) are typical models of single-tissue interface evolution. tension,<sup>22</sup> which contribute to the interface formation (Fig. 3(d)). Additionally, specific topological constraints can promote the free spreading of tissues, leading to the development of double-tissue interfaces.<sup>76–78</sup> Theories like the differential adhesion hypothesis (DAH),<sup>19,71</sup> differential surface contraction hypothesis (DSCH),<sup>79,80</sup> and differential interfacial tension hypothesis (DITH)<sup>81,82</sup> have been pivotal in explaining the mechanisms behind double-tissue interface formation and evolution. For instance, Guan *et al.* constructed an epithelial–cancerous interface and demonstrated that the competition between cancerous and epithelial tissues governed the evolution of the double-tissue interface, highlighting the critical role of DAH.<sup>36</sup>

### 2.3 Quantification of interface morphodynamics

Following the classification of tissue interfaces, it is essential to quantify their topography and dynamics in order to accurately capture their properties. As shown in Table 1, this subsection reviews the commonly used parameters for quantifying interface morphodynamics, focusing on geometric, dynamic, and mechanical aspects.

**2.3.1 Curvature, roundness and fractal dimension.** Geometrical parameters, including curvature, roundness, and fractal dimension, are essential for quantifying the morphology of interfaces. Curvature intuitively measures the deviation of an interface from being a straight line or a plane.<sup>83</sup> For a 2D interface, the curvature ( $\kappa$ ) at a point  $B$  is the reciprocal of the radius ( $R$ ) of the osculating circle:

$$\kappa(B) = 1/R \quad (1)$$

with the sign determined by the circle's position relative to the interface. For 3D interfaces, curvature is defined by the curvature of the common curve of any plane containing a normal vector at point  $B$ . The principal curvature,  $\kappa_1$  and  $\kappa_2$ , represent the maximum and minimum values, respectively, while the mean curvature

$$\kappa_H = (\kappa_1 + \kappa_2)/2 \quad (2)$$

and the Gaussian curvature

$$\kappa_K = \kappa_1\kappa_2 \quad (3)$$

are also commonly used. Experimental and computational studies of embryonic development have shown a correlation between interface curvature and the emergence of branching morphologies.<sup>84,85</sup>

While curvature characterizes local topological features, roundness quantifies how closely the shape of a 2D interface approximates a perfect circle, capturing its global topological properties.<sup>25,86</sup> Roundness is typically defined as

$$\text{Roundness} = 4\pi A/P^2 \quad (4)$$

where  $A$  is the area enclosed by the interface and  $P$  is its perimeter. In three dimensions, this concept is extended by introducing sphericity. In contrast to curvature and roundness, the fractal dimension offers a more comprehensive measure of the complexity and self-similarity of the interface.<sup>87</sup> The fractal dimension is defined as

$$D = \log N/\log(1/\varepsilon) \quad (5)$$

where  $N$  is the number of self-similar pieces and  $\varepsilon$  is the scaling factor. As illustrated in Fig. 4(a),<sup>32</sup> fractal dimension values are obtained by box-counting method. The stable interface presents the lowest fractal dimension values, while the finger-like interface displays a larger dimension value and the largest one corresponds to the mixing interface. In addition to the aforementioned ones, other parameters, such as roughness,<sup>88</sup> local characteristic length, angle,<sup>51</sup> and genus,<sup>50</sup> are also used to describe the morphology of interfaces.

**2.3.2 Displacement, trajectory and velocity.** Dynamic parameters such as displacement, trajectory, and velocity are essential for describing the temporal evolution of interfaces. Displacement, one of the most fundamental quantities in dynamics, characterizes the movement of an interface over time.<sup>25,89,91</sup> The displacement of an interface  $\mathbf{u}$  at a point  $\mathbf{X}$  and time  $t$  is defined as

$$\mathbf{u}(\mathbf{X}, t) = \mathbf{x}(\mathbf{X}, t) - \mathbf{X} \quad (6)$$

where  $\mathbf{X}$  is the initial position of the interface,  $\mathbf{x}$  is the current position. For clearer representation, the interface morphology at different time points can be plotted on a single diagram to generate an interface trajectory diagram<sup>36,66,89</sup> (Fig. 4(b)). By

**Table 1** Parameters of morphodynamics

| Parameters        | Description  | Formula  |
|-------------------|--|--|
| Curvature         | The degree of a surface or a curve deviating from a flat one       | 2D, $\kappa = 1/R$<br>3D principal curvature, $\kappa_1 = 1/R_1$ , $\kappa_2 = 1/R_2$<br>3D mean curvature, $\kappa_H = (\kappa_1 + \kappa_2)/2$<br>3D Gaussian curvature, $\kappa_K = \kappa_1\kappa_2$ |
| Roundness         | The degree to which the shape deviates from the perfect circle     | Roundness = $4\pi A/P^2$   |
| Fractal dimension | The degree of self-similarity of the interface                     | $D = \log N/\log(1/\varepsilon)$   |
| Displacement      | The evolution of interface position with time                      | $\mathbf{u}(\mathbf{X}, t) = \mathbf{x}(\mathbf{X}, t) - \mathbf{X}$   |
| Velocity          | The degree of interface evolution                                  | $\mathbf{v}$   |
| Anchoring angle   | Cell orientation at the interface                                  | $\Delta\theta(x, y) = \theta - \theta_t$ , $\theta(x, y) = \frac{1}{2} \arctan\left(\frac{2\tilde{I}_{xy}}{\tilde{I}_{xx} - \tilde{I}_{yy}}\right)$  |
| Stress tensor     | Stress at the interface  | $\boldsymbol{\sigma}$  |
| Modulus           | The ability of the tissue near the interface to resist deformation | $E = E' + iE''$  |

analyzing this trajectory, the dynamic nature of the interface can be revealed.<sup>25</sup>

The intensity of the interface's evolution is further characterized by the velocity  $\mathbf{v}$  and trajectory of the cells near the interface.<sup>55,64,66,89,92</sup> As illustrated in Fig. 4(d), velocity can be obtained through particle image velocimetry analysis of phase-difference time-lapse images.<sup>55,93</sup> In this method, the system is treated as a continuous fluid, and the instantaneous velocity of each point is calculated *via* cross-correlation.<sup>94,95</sup> The cell trajectories are determined using a tracking algorithm that iteratively screens distances to establish the correspondence of cells at different time points.<sup>36,54</sup> Quantitative analysis of the velocity field and cell trajectories near the interface has revealed phenomena such as coherent flow<sup>25</sup> and global rotation<sup>44,54</sup> (Fig. 4(e)), highlighting the distinctive collective behaviors of cells near the interface. The fluctuating nature of the interface can also be captured by plotting the kymograph of displacement or velocity.<sup>89,91</sup> As shown in Fig. 4(c), the band structure in the kymograph reflects deformation waves propagating along the interface.<sup>89</sup> These fluctuations can be quantitatively described using parameters such as dynamic structure factors.<sup>91</sup>

**2.3.3 Orientation and interfacial anchoring.** In certain situations, cells or cytoskeletons adopt elongated shapes, similar to the configuration of liquid crystal molecules.<sup>31,96</sup> The orientation field of cells and cytoskeletons near the interfaces can be analyzed using principles from liquid crystal theory.<sup>32,97,98</sup> For the phase contrast image matrix  $I$  of the cells near the interfaces, the local structure tensor  $J$  is formulated by<sup>99,100</sup>

$$J = \begin{bmatrix} I_x I_x & I_x I_y \\ I_x I_y & I_y I_y \end{bmatrix}, \quad (7)$$

where  $I_x$  and  $I_y$  are the gradient of  $I$  along  $x$  and  $y$ -directions. A smoother structure tensor  $\tilde{J}$  is obtained by Gaussian filtering:

$$\tilde{J} = \begin{bmatrix} \tilde{J}_{xx} & \tilde{J}_{xy} \\ \tilde{J}_{xy} & \tilde{J}_{yy} \end{bmatrix}. \quad (8)$$

The orientation angle  $\theta(x,y)$  is computed by:

$$\theta(x,y) = \frac{1}{2} \arctan \left( \frac{2\tilde{J}_{xy}}{\tilde{J}_{xx} - \tilde{J}_{yy}} \right). \quad (9)$$

As shown in Fig. 4(f), the color map represents the distribution of organizational order, with short line segments indicating local tissue orientation and the closed curve delineating the interface between two phases. To quantify cellular arrangement at the interface, the interfacial anchoring angle is introduced as

$$\Delta\theta(x,y) = \theta - \theta_t, \quad (10)$$

where  $\theta_t$  represents the angle of the tangent vector.<sup>101</sup> This parameter defines the relative angle between the orientation of the cells near the interface and the tangential direction of the interface. Interfacial anchoring has a profound effect on the movement of cells near the interface and in the generation of interfacial tension.<sup>90,102</sup> Tangential anchoring, where  $\Delta\theta = 0$ , is the most common configuration in interface problems.<sup>32</sup> In some scenarios, normal anchoring ( $\Delta\theta = \pi/2$ ) can emerge over time, especially as the system transitions from two-dimensional to three-dimensional structures.<sup>103,104</sup> Due to the effects of adhesion, anisotropy in cell shape, and dynamic interactions, chiral anchoring may also arise, with angles between 0 and  $\pi/2$ ,<sup>105–107</sup> which can mediate global rotation<sup>108</sup> or local fluctuations at the interface.<sup>106</sup>

**2.3.4 Force, stress and elasticity.** The mechanical properties of interfaces are characterized by the distribution of forces, stress, and elasticity near the interface. Traction force  $\mathbf{T}$  describes the interaction between the tissue and the substrate near the interface.<sup>66,109</sup> By measuring the force exerted by the tissue on the soft substrate and applying Newton's third law, the external force on the interface can be inferred. Interface tension  $F_\sigma$  is an internal force that represents the macroscopic effect of cytoskeletal contraction forces in cells near the interface.

In 2D situation, stress tensor  $\boldsymbol{\sigma}$  can be simplified as:

$$\boldsymbol{\sigma} = \begin{bmatrix} \sigma_{xx} & \sigma_{xy} \\ \sigma_{xy} & \sigma_{yy} \end{bmatrix} \quad (11)$$

where  $\sigma_{xx}$ ,  $\sigma_{yy}$  and  $\sigma_{xy}$  are the components of the stress tensor. Under reasonable assumptions, the stress at the interface can be derived using equilibrium equations and the Cauchy formula.<sup>76</sup> The stress tensor contains both the extreme values of stress and directional information, expressed as:

$$\sigma_1 = \frac{\sigma_{xx} + \sigma_{yy}}{2} \pm \sqrt{\frac{(\sigma_{xx} - \sigma_{yy})^2}{4} + \sigma_{xy}^2} \quad (12)$$

$$\tan \theta_{1,2} = \frac{\sigma_{xx} - \sigma_1}{-\sigma_{xy}} \quad (13)$$

where  $\sigma_1$  and  $\sigma_2$  represent the principal stresses.<sup>36</sup> The forces and stress at the interface can directly drive its evolution<sup>110,111</sup> or interact with biochemical signals, resulting in wave-like signal propagation tangentially or normally to the interface.<sup>112</sup>

The modulus  $E$  quantifies the tissue's resistance to deformation near the interface. Since biological tissue is generally viscoelastic, the complex modulus is introduced for a more accurate description,<sup>113</sup> given by  $E = E' + iE''$ , where  $E'$  is the elastic modulus,  $E''$  is the loss modulus. The measurement and study of interface and tissue moduli provide valuable insights into the formation of spatial heterogeneity during development<sup>52</sup> (Fig. 4(g)).

### 3 Regulatory mechanisms of interface morphodynamics

The morphological evolution of interfaces is influenced by a variety of factors, such as adhesion, cortical tension, cell migration, cellular activity, ECM interactions, and microenvironmental conditions. In the following sections, we will explore how these factors, both individually and in combination, shape the dynamics of the interface, affecting its stability, adaptability, and overall morphology.

#### 3.1 Adhesion

Adhesion plays a pivotal role in the interactions between cells and between cells and ECM.<sup>114</sup> Intercellular adhesion is primarily mediated by cadherins<sup>115</sup> and nectins,<sup>116</sup> while cell-ECM adhesion is largely driven by integrins.<sup>117</sup> These adhesion

mechanisms are crucial in the formation and evolution of tissue interfaces.<sup>118</sup> According to the DAH,<sup>71,119,120</sup> in hybrid systems, cells with weaker intercellular adhesion tend to form a shell around cells with stronger adhesion. Based on this concept, the self-organization of complex structures and interfaces can be realized by designing synthetic adhesion molecules<sup>118</sup> (Fig. 5(a)). Changes in adhesion significantly impact the morphodynamic properties of interfaces. For instance, during the epithelial-to-mesenchymal transition (EMT), epithelial cells transition into mesenchymal cells with reduced adhesion and increased motility, which in turn intensifies the dynamics of interface evolution.<sup>121,122</sup> In cancer-normal tissue interface models (Fig. 5(b)), the downregulation of E-cadherin in normal cells smooths the interface, while the downregulation of P-cadherin enhances the invasive potential of cancerous tissues.<sup>36</sup> This differential regulation provides valuable insights for developing strategies to prevent cancer metastasis. Furthermore, adhesion plays a critical role in regulating *in vivo* interface development. For example, in mouse embryonic salivary glands, strong cell-matrix and weak intercellular adhesion synergize to drive epithelial budding, initiating branching morphogenesis<sup>123</sup> (Fig. 5(c)). Similarly, in *C. elegans* gonadal morphogenesis, asymmetric adhesion regulates interface elongation and directional turning.<sup>124</sup>

#### 3.2 Cortical tension

Cortical tension, which is the contractile force generated by the cell cortex,<sup>125</sup> plays a critical role in maintaining the stability of tissue interfaces.<sup>110</sup> As shown in Fig. 6(a), an increase in cortical tension reduces the roughness of the interface between the dorsal and ventral compartments in the *Drosophila* wing.<sup>88</sup>

**Fig. 5** Effects of cell adhesion on tissue interfaces. (a) By designing synthetic cell adhesion molecules, various 3D structures and interfaces can be induced. (b) Down-regulating the expression of specific E-cadherin molecules can change the morphology of the epithelial-cancer interface. Reprinted from ref. 36 with permission. Copyright 2023, American Chemical Society. (c) Morphogenesis of a mouse salivary gland. Reprinted from ref. 123 with permission. Copyright 2021, Elsevier.

**Fig. 6** Effects of cortical tension on tissue interfaces. (a) Increased cortical tension smooths the tissue interface. Reprinted from ref. 88 with permission. Copyright 2012, Elsevier. (b) Characterization of purse-strings at the leading edge of epithelial cell sheets. Reprinted from ref. 126 with permission. Copyright 2012, National Academy of Sciences.

In wound healing, one of the driving force behind interfacial evolution arises from the formation of purse-string structures composed of actomyosin in cells near the interface<sup>126</sup> (Fig. 6(b)). Theoretical studies also show that when neighbor exchange occurs at double-tissue interfaces, differences in cortical tension cause resilience and help maintain the interface's integrity.<sup>29</sup> Given the structural linkage between the cytoskeleton and adhesion proteins, cortical tension and adhesion can synergistically regulate interface morphology in certain contexts.<sup>115</sup> Studies have shown that cadherins interact with actomyosin under the regulation of extracellular biochemical signals, resulting in changes in contractility, skeletal rearrangement, and cortical tension.<sup>127,128</sup> This process is considered a form of mechanical polarization, which shapes both tissue–tissue and tissue–ECM interfaces.<sup>129</sup> For example, during zebrafish gastrulation, cortical tension controls the expansion of cell–cell contacts, while cell adhesion provides a scaffold for cortical tension, driving cell sorting.<sup>22</sup>

### 3.3 Cell migration

Cell migration underpins the self-organization of cellular populations and plays a crucial role in interface evolution. At tissue interfaces, migration occurs in both collective and individual modes. Collective migration, prevalent in epithelial tissues, enables large-scale movement while preserving tissue integrity and is a key driver of interface evolution in wound healing.<sup>34</sup> Some studies indicate that collective migration and the purse-string mechanism mentioned above interact dynamically during wound healing. Brugués *et al.*<sup>130</sup> demonstrated that collective migration dominates the early healing phase (Fig. 7(a)), while the purse-string mechanism becomes prominent once stable intercellular connections form. Curvature further

modulates their interplay: negative curvature aligns migration with contractile forces, enhancing healing efficiency, whereas positive curvature creates antagonism, reducing efficiency.<sup>58</sup> In contrast, individual migration, typical of cancer and mesenchymal cells, contributes to interface instability.<sup>15</sup> EMT facilitates the shift from collective to individual migration, accelerating interface evolution.<sup>131</sup> Moreover, variations in migration rates and specific collective movement patterns (Fig. 7(b)) can induce interfacial instabilities, such as the fingering instability observed in both developmental and cancerous tissues.<sup>132</sup>

### 3.4 Cell activity

Living tissues can be considered as active matter, undergoing continuous movement and deformation driven by cellular activity.<sup>31,133,134</sup> Due to the contraction of actomyosin, individual cells behave as contractile force dipoles.<sup>135</sup> In cellular monolayers, active behaviors vary: contractile cells (*e.g.* C2C12, NIH 3T3) exhibit contractile activity,<sup>136,137</sup> while MDCK and neural progenitor cell monolayers display extensile activity, with net forces elongating cells along their long axis.<sup>97,98</sup> In recent years, cellular activity has garnered increasing attention in explaining the evolution of tissue interfaces. Zhang *et al.*<sup>32</sup> investigated how activity differences between two tissues influence interface stability, finding that the movement of topological defects excited by cellular activity can drive morphological changes at the interface (Fig. 8(a)). Balasubramaniam *et al.*<sup>24</sup> revealed how MDCK monolayers transition from extensile to contractile activity, uncovering the mechanisms behind interface formation and stability during morphogenesis (Fig. 8(b)). Beyond the nature of cellular activity, the strength of activity can also drive the transition of an interface from static to dynamic<sup>25</sup> (Fig. 8(c)), influencing its topological complexity and dynamic properties.<sup>38,138</sup> In some cases, specialized forms of activity can lead to intriguing morphological evolution at the interface. A notable example is chiral activity, which involves spontaneous symmetry breaking in cell–cell interactions.<sup>139</sup> As shown in Fig. 8(d), chiral activity induces oscillatory patterns that propagate along the interface within tissues, such as those found in starfish embryos.<sup>140</sup> When chiral activity is present on both sides of the interface, traveling waves can emerge, and topological defects may form in a sandwich-like arrangement.<sup>141</sup>

### 3.5 Extracellular matrix

The ECM is composed of a complex network of components, such as collagen, elastin, and laminins, which provide structural support and mediate biochemical signaling.<sup>142,143</sup> The concentration and composition of ECM components can significantly influence the morphology of tissue interfaces. For instance, increased structural protein concentration can mediate the transition to an invasive phenotype in tumor spheroids, resulting in smoother 3D interfaces (Fig. 9(a)).<sup>15</sup> The mechanical properties of the ECM, such as stiffness, also play a crucial role in shaping interface morphology and its adaptability.<sup>114</sup> Cancer cells, for example, exhibit more aggressive metastasis on stiffer ECM substrates,<sup>144</sup> which may lead to

rougher interfaces that facilitate cancer cell invasion and migration. Additionally, ECM stiffness gradients can induce cell durotaxis, promoting asymmetric evolution of the interface morphology (Fig. 9(b)).<sup>42,145</sup> In these processes, integrins mediate cellular force perception of the ECM by linking ECM ligands to the cytoskeleton.<sup>146</sup> Through integrin signaling, extracellular mechanical cues activate proteins such as focal adhesion kinase (FAK), Rho, and Rho-associated protein kinase (ROCK), facilitating adhesion plaque maturation and stress fiber formation.<sup>143</sup> This mechanotransduction extends to the nucleus, where intracellular forces alter nuclear membrane

tension, open nuclear pores, and enable YAP nuclear translocation, driving phenotypic changes. This coupling mechanism underlies the diverse morphologies and evolution of tissue interfaces in different ECM environments. Tissue cells remodel the ECM during interface evolution, with matrix metalloproteinases (MMPs) and other enzymes degrading ECM components to facilitate cell migration and interface rearrangement.<sup>37</sup> As shown in Fig. 9(c), the regulation of tissue interface morphology can be modulated by promoting or inhibiting MMP activity.<sup>51</sup>

### 3.6 Microenvironment

The tissue microenvironment comprises a variety of chemical, physical, and biological factors that influence cellular behavior.<sup>110,147</sup> Gradients of morphogens and growth factors play a crucial role in directing the organization of tissue boundaries. For instance, under hypoxic conditions, the upregulation of vascular endothelial growth factor stimulates endothelial cells in existing blood vessels to become active, promoting sprouting of new vessels and the formation of dynamic interfaces.<sup>148,149</sup> As illustrated in Fig. 10(a), hepatocyte

growth factor (HGF) can drive the evolution of 3D epithelial-ECM interfaces into branching structures.<sup>150–152</sup> Similarly, retinoic acid (RA) supports the formation of neural tubes<sup>153</sup> and enhances the topological complexity of neuroepithelial organoid interfaces in mice<sup>50</sup> (Fig. 10(b)). Tumor tissues can also stimulate the formation of vascular networks and tissue-tissue interfaces, depending on nutrient availability within the microenvironment.<sup>154–156</sup>

## 4 Methods for studying interface evolution

Experimental techniques and theoretical simulations are the two main approaches used to investigate tissue interface dynamics. Experimental methods enable direct observation and manipulation of tissue interfaces, while theoretical models provide predictive insights and a deeper understanding of the underlying principles governing interface behaviors. In the following, we review the key experimental methodologies and techniques, along with theoretical modeling approaches.

### 4.1 Experimental approaches

**4.1.1 Live cell imaging and immunofluorescence staining imaging.** Experimental techniques for studying tissue interface dynamics include live imaging, biochemical assays, and biophysical measurements. As early as the 1980s, light and transmission electron microscopy were employed to investigate interface morphology,<sup>157</sup> highlighting the long history of interface research. Optical imaging remains a key method for studying the evolution of interface morphodynamics, encompassing live cell imaging and immunofluorescence staining. Live cell imaging, utilizing advanced microscopy techniques such as confocal and light sheet microscopy, captures high-resolution images of cell movements and interface changes over time.<sup>36,66</sup> Immunofluorescence employs antigen-antibody interactions to identify subcellular structures, with fluorescent markers for specific proteins (*e.g.* actin for cytoskeletal dynamics and cadherins for adhesion sites) enabling precise tracking of cellular factors<sup>158</sup> (Fig. 11(a)). Coupled with image recognition and processing techniques, morphodynamic parameters such as curvature, displacement fields, velocity fields, and orientation fields can be extracted.

**4.1.2 Atomic force microscopy and traction force microscopy.** Measurement techniques such as atomic force

microscopy (AFM) and traction force microscopy (TFM) are widely utilized to assess interface mechanics. AFM operates by pressing a probe into the cell surface and extracting the Young's modulus of cells and tissues based on the relationship between pressing depth and applied load<sup>160</sup> (Fig. 11(b)). The pressing depth is defined as the displacement of the cantilever minus its deformation, while the load is determined from the cantilever's deformation.<sup>161,162</sup> Data processing methods, such as those based on Hertz theory, are commonly applied to AFM data to calculate the Young's modulus.<sup>163–165</sup> More recently, techniques like optical tweezers<sup>166</sup> and magnetic tweezers<sup>167</sup> have been developed and applied. For instance, optical tweezers enable the characterization of the Young's modulus at or near the interface of 3D tumor spheroids, bridging a gap in 3D mechanical measurements.<sup>52</sup>

TFM is a powerful technique for characterizing the traction forces at tissue interfaces.<sup>168</sup> This method involves using a light microscope to directly capture the position of fluorescent particles embedded in a substrate, computing the displacement field following the application of traction forces. By applying elasticity theory, the traction field can then be reconstructed<sup>168–171</sup> (Fig. 11(c)). Building on this, advanced technologies such as ultra-high-resolution traction microscopy, which offers enhanced spatial resolution,<sup>172,173</sup> 3D traction microscopy, capable of measuring forces in three dimensions,<sup>174,175</sup> and cell monolayer stress microscopy, which enables the calculation of interfacial stress, have been developed.<sup>36,176</sup>

**4.1.3 Pharmacological manipulation.** While the experimental techniques and measurement methods discussed above can effectively describe the topological and dynamic properties of tissue interfaces, they do not capture the biochemical factors that influence interface dynamics. In particular, biochemical signaling pathways, which regulate cellular processes such as adhesion, motility, and force generation, play a critical role in modulating interface stability and dynamics. Pharmacological manipulation enables researchers to selectively modify cellular behaviors with specific agents, providing insights into how biochemical signals influence tissue interface morphodynamics. As an illustration, Y27632 can inhibit ROCK and thus disrupts actomyosin contractility.<sup>24</sup> Similarly, Blebbistatin is a myosin II inhibitor that also specifically blocks actomyosin contractility.<sup>24</sup> These agents are frequently employed in studies exploring the impact of cortical tension or cellular activity on the evolution of tissue interfaces. Additionally, GM6001, an MMP inhibitor that interferes with extracellular matrix remodeling,<sup>51</sup> can modify the interaction between cell tissue and ECM. These targeted modulations of cellular behavior allow researchers to investigate the underlying biochemical regulation of tissue interface dynamics more comprehensively, providing a valuable approach to better understanding the cellular and molecular mechanisms that govern tissue organization and adaptation during development, homeostasis, and disease.

### 4.2 Theoretical approaches

Theoretical approaches, such as discrete and continuum models, provide a framework for modeling tissue morphodynamics under

**Fig. 11** Experimental methods of interface morphodynamics. (a) Actin labeling during embryonic dorsal closure. Reprinted from ref. 159 with permission. Copyright 2005, Elsevier. (b) The ECM stiffness near the 3D interface is measured by AFM. Reprinted from ref. 51 with permission. Copyright 2011, Oxford University Press. (c) The traction force near the hole interface is characterized by TFM.

various conditions, allowing for predictions of interface behavior based on physical and biochemical principles. Discrete models represent individual cells or boundaries as finite elements, while continuum models treat tissue interfaces as continuous entities, influenced by the underlying field properties.

**4.2.1 Discrete models.** Discrete models, such as the deformable polygon (DP) model<sup>30</sup> and the vertex model,<sup>29</sup> are crucial for simulating interface dynamics. Unlike continuum models, discrete models emphasize the role of individual cell properties in shaping interface behavior, enabling the exploration of how factors such as adhesion strength, shape constraints, and other cell characteristics affect interface stability and evolution. The DP model, a lattice-based approach, simulates cell shape and interactions by assigning energy to each cell based on adhesion, area, and other factors. In the DP model, cells are represented as deformable polygons composed of  $N_v$  vertices<sup>177,178</sup> (Fig. 12(a)). The total shape energy of the system  $U_{\text{shape}}$  can be expressed as:<sup>66,179</sup>

$$U_{\text{shape}} = \sum_{m=1}^N \sum_{i=1}^{N_v} \frac{N_v k_c}{2} (l_{m,i} - l_0)^2 + \sum_{m=1}^N \frac{k_a}{2} (a_m - a_0)^2 + \sum_{m=1}^N \sum_{i=1}^{N_v} \frac{k_b}{2} (\cos \theta_{(i-1,i+1)} - 1)^2 \quad (14)$$

where  $l_{m,i} = |\mathbf{r}_{m,i} - \mathbf{r}_{m,i+1}|$  is the length of the  $i$  section of the cell numbered  $m$ .  $l_0 = p_0/N_v$  is the equilibrium length of the cell side length, and  $p_0$  is the cell perimeter.  $k_c$  is the modulus resisting length changes.  $a_m$  and  $a_0$  are the current and reference areas of the cell, respectively.  $k_a$  is the areal modulus.  $k_b$  is the bending modulus of the cell boundary.  $\theta_{(i-1,i+1)}$  stands for the angle between adjacent edges. The motion of the vertexes is governed

by the overdamped Langevin equation:

$$\mu \frac{d\mathbf{r}_{m,i}}{dt} = -\nabla_{m,i}(U_{\text{shape}}) + \mathbf{F}_{m,i}^{\text{int}} + \mathbf{F}_{m,i}^{\text{trac}} \quad (15)$$

where  $\mu$  is the damping coefficient,  $\nabla_{m,i}$  is the gradient operator, and  $F_{m,i}^{\text{int}}$  and  $F_{m,i}^{\text{trac}}$  denote the force created by the cell-cell interaction and the traction, respectively. Intercellular forces and traction require a flexible choice of models depending on the problem being studied.<sup>180–183</sup> Using the DP model, the evolution of double-tissue interfaces between soft and hard tissues<sup>30</sup> (Fig. 12(c)) and matrix stiffness-regulated holes formation have been investigated<sup>66</sup> (Fig. 12(d)).

The vertex model, another widely used discrete modeling approach for simulating tissue interfaces, represents cells as polygons, with each vertex serving as a connection point between neighboring cells. This model allows for the control of cell shape and tissue structure, providing insights into the mechanics of interface dynamics<sup>184,185</sup> (Fig. 12(b)). The mechanical energy of vertex model can be described as<sup>186–188</sup>

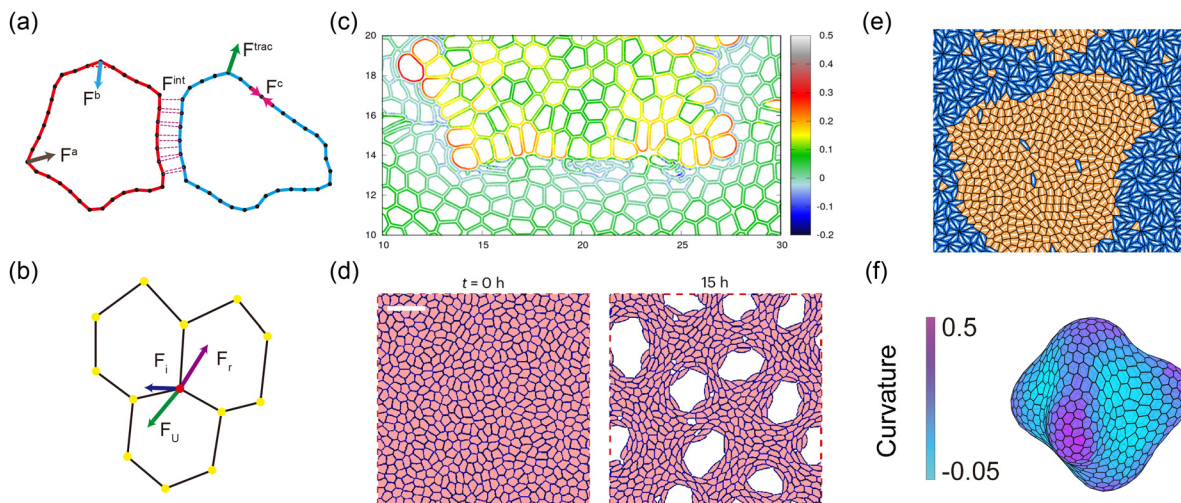

$$U = \sum_n \frac{1}{2} \Gamma_n L_n^2 + \sum_n \frac{1}{2} K_a (A_n - A_0)^2 + \sum_{i,j} \Lambda l_{ij} \quad (16)$$

where  $L_n$  and  $A_n$  are the perimeter and area of the cell, respectively.  $\Gamma_n$  is the perimeter coefficient,  $K_a$  is the areal modulus and  $\Lambda$  is the interfacial tension coefficient.  $A_0$  is the preferred area and  $l_{ij}$  is the edge length between vertices  $i$  and  $j$ . The motion of the vertex is governed by

$$\eta \frac{d\mathbf{r}_i}{dt} = -\frac{\partial U}{\partial \mathbf{r}_i} + \mathbf{F}_i \quad (17)$$

where  $\mathbf{r}_i$  is the coordinate of the vertex  $i$ ,  $\eta$  is the friction coefficient, and  $\mathbf{F}_i$  represents other non-potential force.

Recently, biochemical signaling pathways have been incorporated into discrete models to better understand tissue

**Fig. 12** Examples of discrete models in the study of interface morphodynamics. (a) Sketch of DP model. (b) Sketch of vertex model. (f) Morphological evolution of 3D multicellular spherical shells.

dynamics.<sup>189–191</sup> Typically, a reaction–diffusion equation is introduced to describe the spatiotemporal evolution of biochemical factors within the system,<sup>192</sup> as shown in the equation below:

$$\partial_t \mathbf{c} = D \nabla^2 \mathbf{c} + \mathbf{R}(\mathbf{c}) \quad (18)$$

where  $\mathbf{c}(\mathbf{x}, t)$  represents the concentration of biochemical factors, which can be simplified to a scalar for a single factor.  $D$  is the diagonal matrix of the diffusion coefficient, and  $\mathbf{R}$  denotes the biochemical reaction. These equations are further integrated into the energy formulation to correlate biochemical concentrations with various system properties.

The vertex model has proven effective in elucidating mechanisms underlying interface evolution in processes such as cell sorting<sup>29</sup> (Fig. 12(e)), epithelial folding,<sup>193</sup> and wound healing.<sup>16</sup> Additionally, recent advancements have led to the development of 3D discrete models, offering a robust method to study the evolution of 3D interfaces *in vivo*<sup>28,194–196</sup> (Fig. 12(f)).

The key distinction between the DP model and the vertex model lies in their treatment of intercellular adhesion. In the DP model, intercellular adhesion is simplified as the interaction between the vertices of neighboring cells, with forces including both tangential and normal components along the boundary.<sup>66,197</sup> In contrast, the vertex model simplifies intercellular adhesion as boundary tension, as adjacent cells share a common boundary, and the tension is directed along the boundary.<sup>125,186</sup>

**4.2.2 Continuum models.** Continuum models treat tissue interfaces as smooth entities influenced by force or concentration fields, making them ideal for studying large-scale tissue deformation or complex flow dynamics. In the context of multicellular interfaces, active liquid crystal theory has been developed to simulate interface behavior. In this approach, a scalar parameter,  $\varphi$ , is introduced to characterize both the bulk and the interface.<sup>198</sup> For single-tissue interface simulations,  $\varphi = 1$  represents the phase region, while  $\varphi = 0$  represents the interface.<sup>86</sup> For double-tissue interface simulations,  $\varphi = \pm 1$  represents the two phase regions, with  $\varphi = 0$  denoting the interface<sup>199</sup> (Fig. 13(a)). The free energy of the system is written as<sup>32,200</sup>

$$F = \int_s \left[ \frac{1}{2} A_\varphi (\varphi^2 - 1)^2 + \frac{1}{2} k_\varphi (\nabla \varphi)^2 \right] ds \quad (19)$$

where  $A_\varphi$  and  $k_\varphi$  are the model parameters that maintain phase ordering and surface tension. The evolution of  $\varphi$  obeys<sup>32,198,200</sup>

$$\partial_t \varphi + \nabla \cdot (\mathbf{v} \varphi) = M \Delta \mu \quad (20)$$

where  $\mathbf{v}$  is the velocity field,  $M$  is the mobility coefficient and  $\mu = \delta F / \delta \varphi$  is the effective chemical potential. The unit vector  $\mathbf{n} = (\cos \theta, \sin \theta)$  is introduced to describe the local orientation, where  $\theta$  indicates the local direction.<sup>86</sup> For monolayer systems,  $\mathbf{n} = -\mathbf{n}$  is generally satisfied. To describe the orientation of the

Fig. 13 Application of continuum model in interface morphodynamics. (a) Formation and evolution of double-tissue interface. (b) 3D interface morphological diagram as a function of achiral and chiral activity. Reprinted from ref. 204 with permission. Copyright 2024, American Physical Society.

system, a second-order tensor

$$\mathbf{Q} = \frac{dq(\mathbf{nn} - \mathbf{I})}{d(d-1)} \quad (21)$$

is introduced, where  $d$  denotes the dimensions of the system,  $q$  represents the order parameter of the system, and  $\mathbf{I}$  is the identity matrix.<sup>96</sup> The order parameter  $\mathbf{Q}$  satisfies the following evolution equation<sup>96,201</sup>

$$\partial_t \mathbf{Q} + \mathbf{v} \cdot \nabla \mathbf{Q} - \mathbf{S} = \Gamma \mathbf{H} \quad (22)$$

where  $\mathbf{S}$  represents the coupling field of orientation and velocity,  $\Gamma$  represents the relaxation rate, and  $\mathbf{H}$  represents the molecular field, indicating the energy minimization of the system. The velocity field is governed by

$$\rho(\partial_t + \mathbf{v} \cdot \nabla) \mathbf{v} = -\nabla p + \eta \Delta \mathbf{v} + \nabla \cdot (\boldsymbol{\sigma}_p + \boldsymbol{\sigma}_{\text{act}}) + \mathbf{f}_{\text{cap}} - \beta \mathbf{v} \quad (23)$$

$$\nabla \cdot \mathbf{v} = 0 \quad (24)$$

where  $\rho$  is the density,  $p$  is the pressure,  $\eta$  is the viscosity coefficient and  $\beta$  is the damping coefficient. The active stress is expressed as

$$\boldsymbol{\sigma}_{\text{act}} = -\zeta \mathbf{Q} \quad (25)$$

where  $\zeta$  denotes the activity coefficient.<sup>202</sup> Typically, these equations are solved using the hybrid lattice Boltzmann method.<sup>203</sup>

The above introduction is based on single- $\phi$  model. While this model can simulate the morphological evolution of double-tissue interfaces, it cannot capture interphase interactions. This limitation is addressed by the double- $\phi$  model, which introduces two scalar fields,  $\phi_1$  and  $\phi_2$ . Here,  $\Delta\phi = \phi_1 - \phi_2 = \pm 1$  represents the two phase regions, while  $\Delta\phi = 0$  denotes the interface.<sup>25</sup> Interphase interactions are incorporated through a free energy formulation. Additionally, the development of 3D active liquid crystal theory provides a theoretical framework to model the expansion and twisting of interfaces during 3D tissue morphogenesis.<sup>205</sup> As shown in Fig. 13(b), Li *et al.*<sup>204</sup> used a 3D model to investigate the regulation of chiral and achiral active stresses on the 3D morphologies of organoids. In summary, active liquid crystal theory offers a means of understanding interface evolution as an active matter system with liquid crystal properties, making it particularly useful for tissues with elongated cells.<sup>32</sup>

In addition to discrete and continuous models, recent efforts have focused on developing hybrid models that integrate both approaches. For instance, to investigate cellular orientation and active stress, the orientation field from active liquid crystal theory was incorporated into the vertex model, leading to the development of the active nematic vertex model.<sup>206,207</sup> This hybrid model processes continuous parameters, such as orientation fields, by referencing the positions of individual cell vertices, making it an extension of the vertex model. Similar approaches have advanced other active matter studies. Mou *et al.*<sup>208</sup> developed a hybrid model to simulate bacterial movement in a 3D passive liquid crystal. In this framework, bacterial motion is governed by a self-propelled active particle model, while the systems flow and orientation fields are described using active liquid crystal theory. This approach offers inspiration for modeling single-tissue interface evolution, where discrete models could represent cellular assemblies, while the surrounding environment is captured through a continuum framework.

## 5 Applications and biological implications of interface morphodynamics

Understanding the morphodynamics of tissue interfaces holds transformative potential across diverse biological contexts, including developmental biology, regenerative medicine, and cancer research. By gaining insights into interface behavior, we can decipher how cellular and tissue architecture adapt, repair, and malfunction, offering valuable knowledge applicable to various health and disease-related fields.

### 5.1 Morphogenesis

Morphogenesis, the intricate process by which tissues and organs acquire their complex structures and shapes, is

inherently and profoundly dependent on the dynamic interactions and behaviors of tissue interfaces.<sup>209</sup> During the process of organogenesis, tissue interfaces undergo a series of complex and highly regulated phenomena, including folding, bending, and branching. A clear example of this can be seen during the formation of the neural tube, where the folding of the epithelial sheet marks a critical step in central nervous system development.<sup>50</sup> Similarly, the branching of mammary glands involves a similar series of processes that rely on the proper functioning and evolution of tissue interfaces to establish the distinct cellular architectures necessary for breast tissue formation.<sup>210</sup>

Compartmentalization is also deeply intertwined with the process of interface formation and evolution. As tissues develop and grow, cells are required to self-organize into distinct compartments or functional domains that allow for the specialization of tissues, as exemplified by the boundary formation between different sections of the *Drosophila* wing.<sup>211</sup> A key mechanism driving the creation of these compartmentalized interfaces is cell sorting.<sup>129</sup> As cells sort into their respective domains, interfaces between these cell groups are established, contributing to the overall structure of the developing tissue.

At the later stage of morphogenesis, the evolution of these interfaces gradually stabilizes, ensuring that tissue architecture remains intact as the organism matures. The continued maintenance and flexibility of these interfaces are paramount for preserving the integrity of the tissue compartments. Such as the heart, where the precise arrangement of cardiac cells in different atria and ventricles is necessary for proper cardiac function.<sup>212</sup> Similarly, the blood–brain barrier, an interface that controls the movement of substances between the blood and the brain, relies on the dynamic regulation of tissue interfaces.<sup>213</sup> The formation of skin as an organized tissue structure also highlights the importance of interface stability, where epidermal and dermal layers must remain segregated while allowing for communication across the boundary to ensure proper skin function and repair.<sup>214</sup> Thus, the role of tissue interfaces in morphogenesis is foundational not only for the proper development of individual organs but also for the functional integrity of the entire organism.

### 5.2 Tissue repair

Tissue repair refers to the biological process by which an organism replaces damaged or destroyed tissue with newly generated tissue, a crucial mechanism for maintaining the organism's integrity and functionality following injury.<sup>215</sup> One of the most common forms of tissue repair is wound healing, during which tissue interfaces undergo adaptive changes in response to the injury.<sup>16</sup> During this process, tissue interfaces evolve through active morphological changes, allowing cells to migrate, proliferate, and differentiate as needed to close the wound and repair the damaged tissue.<sup>58,216</sup> The evolution and morphological dynamics of tissue interfaces in wound healing are tightly regulated by a complex interplay of factors such as cortical tension, cellular adhesion, and growth factors.

However, deficiencies or imbalances in tissue repair processes can lead to significant pathological outcomes. For example, excessive tissue repair can result in the formation of epidermal keloids, characterized by the overproduction of extracellular matrix and the formation of fibrous scars.<sup>217</sup> In the heart, excessive tissue repair can lead to myocardial fibrosis, a condition where the normal cardiac tissue is replaced by fibrous tissue, impairing heart function and leading to complications such as heart failure.<sup>218</sup> Thrombosis is another condition that can arise due to improper tissue repair, where dysfunctional tissue interfaces in blood vessels contribute to the formation of clots and the disruption of blood flow.<sup>219</sup> In each of these conditions, misregulated tissue interface evolution plays a key role in the pathological remodeling process. Therefore, understanding the mechanisms that govern tissue interface morphodynamics is essential for developing therapeutic strategies aimed at minimizing the destructive consequences of abnormal interface remodeling and promoting optimal tissue repair.

### 5.3 Cancer progression and metastasis

Cancer remains one of the most significant threats to human health today.<sup>220</sup> The progression of cancer is intricately linked to the continuous evolution of the interface between malignant and adjacent healthy tissues.<sup>221</sup> During the early stages of cancer, this interface evolves relatively slowly, maintaining a distinct and regular boundary between cancerous and normal tissues.<sup>52</sup> However, as the disease progresses into intermediate and advanced stages, cancer cells begin to exhibit a range of alterations. These include the increased expression of MMPs, which, in conjunction with the EMT, facilitate the acquisition of a more mesenchymal phenotype.<sup>222</sup> As a result, the cancer cells undergo significant changes in adhesion properties, enabling them to degrade the ECM and enhance cellular motility. These modifications allow them to breach the original interfaces, invade surrounding tissues and metastasize to distant sites.<sup>122,158</sup> During this period, the interface between cancer tissue and normal tissue exhibits active morphology and dynamics, exhibiting significant morphological changes as the tumor continues to invade and spread.

Tumor heterogeneity also complicates interface evolution. On the one hand, the mechanical properties of tumors exhibit spatial heterogeneity, with higher hydrostatic pressure and stiffness in the core than in peripheral regions. The elevated internal pressure can lead to the collapse of blood vessels and lymphatic vessels in tumors, distorting or eliminating their interfaces and impairing vascular function, which hinders drug delivery while promoting cancer invasion.<sup>223–225</sup> On the other hand, heterogeneity also exists at the cellular level. Within tumors, cancer cells display genetic, phenotypic, and functional diversity, stabilizing interfaces through interactions among multiple cell types. Beyond intrinsic heterogeneity, stromal cells, particularly cancer-associated fibroblasts (CAFs), actively modulate tumor interfaces.<sup>226</sup> CAFs secrete a large number of inflammation-related molecules, such as TGF- $\beta$ , IL-6 and CXCL12, which not only stimulate the rapid proliferation and

invasion of cancer cells, but also change the structure around the tumor, thus promoting the continuous evolution of the tumor interface.<sup>227</sup> Overall, tumor interface dynamics involve multi-stage, multi-factor, and multi-cell interactions. Understanding these processes is crucial for predicting tumor progression and developing targeted therapies.

## 6 Challenges and future directions

Despite significant progress in the study of tissue interface morphodynamics in recent years, several critical issues remain that warrant further investigation. Firstly, the evolution of tissue interfaces is driven by mechanical, chemical, and biological factors. Current theories focus on molecular and cell biology, focusing on the analysis of molecular or biochemical signaling pathways, and lack systematic exploration of mechanical factors and their coupling with biochemical factors. There is a pressing need to develop unified models that integrate mechanochemical coupling and feedback mechanisms, particularly for capturing emergent behaviors in complex biological systems.

Moreover, tissue morphodynamics involves changes across molecular, cellular, and tissue scales, which require diverse observational and analytical techniques. However, current experimental approaches face limitations in capturing accurate data of complex dynamics interfaces. While 2D experiments allow for precise control of biochemical and mechanical conditions, they often lack physiological relevance, whereas 3D experiments face challenges such as imaging resolution and tracking of dynamic evolution. Theoretical models, including discrete models and continuum methods, have limitations in considering cross-scale interactions. Hybrid modeling approaches that integrate discrete and continuum frameworks offer a promising direction, and factors such as tissue heterogeneity and non-equilibrium dynamics should also be taken into account.

Furthermore, the vigorous development of artificial intelligence (AI) provides a solution for the quantification of key information in the process of complex interface evolution. By constructing AI models, it is expected to extract mechanical, chemical, topological and other features in the process of interface evolution, guide the development of theoretical models, and finally realize the prediction of interface evolution.

Finally, translating *in vitro* findings into clinically relevant insights remains a major challenge. Future efforts should focus on developing physiologically relevant models that better recapitulate *in vivo* conditions and leveraging computational approaches to predict interface behaviors in disease contexts. Bridging the gap between fundamental research and biomedical applications will be crucial for advancing the diagnosis and treatment of interface-related pathologies.

## 7 Conclusion

The morphodynamics of tissue interfaces is fundamental to understanding complex biological processes, ranging from

development and tissue repair to disease progression. This review aims to offer a comprehensive exploration of tissue interface morphodynamics, focusing on interface classification, regulatory mechanisms, and the methodologies used to study interface evolution. These aspects have significant practical implications, from elucidating mechanisms of tumor progression and metastasis to developing innovative strategies in regenerative medicine and tissue engineering. By advancing our understanding of tissue interface morphodynamics, we could uncover new pathways for studying and manipulating biological systems, ultimately leading to breakthroughs in biomedical science and therapy.
