High proton conductivity of H_xWO_3 at intermediate temperatures: unlocking its application as a mixed ionic–electronic conductor

Rantaro Matsuo,  Tomoyuki Yamasaki * and Takahisa Omata *

Hydrogen tungsten bronzes (H_xWO_3), known for their mixed protonic–electronic conduction near room temperature, are extensively studied for electrochromic and gasochromic applications. However, their proton transport properties at elevated temperatures—particularly in the intermediate-temperature range (200–500 °C)—remain unexplored. This study revealed the proton transport behavior of H_xWO_3 , focusing on its potential as a proton-conducting mixed ionic–electronic conductor (MIEC) for intermediate-temperature electrochemical applications. By employing a proton-conducting phosphate glass as an electron-blocking electrode, we selectively measured the partial proton conductivity of sintered H_xWO_3 . Hydrogen incorporation into the sintered WO_3 pellet was found to occur preferentially near the surface, forming an approximately 500 μm -thick hydrogen-rich region. This region reached a composition of $x = 0.24$ and exhibited proton conductivity exceeding $10^{-1} \text{ S cm}^{-1}$ at 275 °C—well above those of the state-of-the-art perovskite proton conductors. Impedance spectroscopy revealed distinct features of proton transport, including an isotope effect. The proton diffusion coefficient was 100–1000 times greater than that of $H_{\sim 0.0001}TiO_2$, which exhibits mixed protonic–electronic conduction *via* hydrogen dissolution. The larger proton diffusion coefficient of $H_{0.24}WO_3$ suggests that large polaron formation enhances proton mobility. These findings unlock new functionality of H_xWO_3 as a MIEC in the intermediate-temperature range, paving the way for the development of next-generation hydrogen energy conversion systems.

Introduction

Tungsten trioxide (WO_3) is a well-known transition metal oxide that exhibits pronounced optical and electronic changes upon hydrogen incorporation.^{1–10} When exposed to hydrogen gas at elevated temperatures or subjected to electrochemical hydrogen injection using acidic electrolytes, WO_3 forms hydrogen tungsten bronzes (H_xWO_3). WO_3 can accommodate a large amount of hydrogen (up to $x \sim 0.5$),¹¹ corresponding to proton density (n_H) on the order of 10^{21} cm^{-3} . Upon hydrogen dissolution, hydrogen atoms are incorporated into the lattice and ionize into protons and electrons, as described by eqn (1) in Kröger–Vink notation:¹²

The electrons introduced along with protons localize on tungsten atoms, leading to the reduction of W^{6+} ions to W^{5+} . These changes result in a characteristic blue coloration and an increase in electronic conductivity. These coupled optical and

electronic changes have been widely utilized in electrochromic^{13–15} and gasochromic devices,^{16,17} hydrogen sensors,^{18–20} and resistive switching devices that operate *via* ion injection.^{21,22}

Since the optical and electronic responses in H_xWO_3 are associated with proton diffusion processes, H_xWO_3 is characterized as a proton-conducting mixed ionic–electronic conductor (MIEC), and the dynamics of proton transport have attracted significant research interest. The proton diffusion process has been studied using various techniques such as proton nuclear magnetic resonance ($^1\text{H NMR}$)^{23–27} and electrochemical measurements.^{28–30} Changes in optical absorption^{31–33} have been also utilized as experimentally accessible indicators of proton migration. These previous studies have revealed that the proton diffusion coefficient in H_xWO_3 strongly depends on crystallinity and hydrogen content. Although the reported values exhibit scatter due to the difficulty of the measurements, many studies have suggested relatively large diffusion coefficients compared with other oxides.^{34–36} While the prospect of fast proton diffusion has attracted considerable interest, the practical applications of H_xWO_3 are limited to gasochromic and electrochromic devices operating near room temperature. Only a few reports have explored other uses of its mixed conduction.^{37,38}

Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Katahira 2-1-1, Sendai 980-8577, Japan. E-mail: omoyuki.yamasaki.a1@tohoku.ac.jp; Tel: +81-22-217-5215

Owing to its intrinsic mixed protonic–electronic conductivity, H_xWO_3 is a promising candidate for electrochemical devices operating at elevated temperatures, such as protonic ceramic fuel cells and steam electrolysis systems.³⁹ In such devices, mixed protonic–electronic conductors are particularly advantageous because they allow electrochemical reactions to extend beyond narrow triple-phase boundaries (gas–electrolyte–electrode) to broader two-phase boundaries (gas–electrode).⁴⁰ This can reduce electrode polarization resistance and improve the overall efficiency, which is especially beneficial for operation in the intermediate-temperature range (200–500 °C), where sluggish electrode kinetics often limit performance. Thus, demonstrating high proton conductivity of H_xWO_3 in the intermediate-temperature range would unlock the potential use of H_xWO_3 as a MIEC, contributing to the development of next-generation energy devices such as hydrogen permeable membranes and fuel cells.

This study investigates the proton conductivity of H_xWO_3 in the intermediate-temperature range using an electron-blocking method. A proton-conducting phosphate glass with a proton transport number of unity⁴¹ is employed as an electron-blocking electrode, enabling selective detection of protonic conduction in H_xWO_3 while suppressing electronic contributions. The partial proton conductivity of sintered H_xWO_3 is above 10^{-2} S cm⁻¹ at 250 °C, which significantly exceeds that of well-known perovskite-type proton conducting oxides. We discuss the large proton diffusion coefficient underlying the high proton conductivity in terms of the activation energy and the magnitude of the pre-exponential factor.

Experimental

Sample preparation

The sintered WO_3 samples were prepared by spark plasma sintering (SPS; SPS-511S, Fuji Electronic Industrial Co., Ltd, Japan). The raw yellowish green WO_3 powder (99.9%, Kojundo Chemical Laboratory Co., Ltd, Japan) was ground using a mortar and pestle made of stabilized ZrO_2 , put into a carbon mold with a diameter of 20 mm, and then sintered at 800 °C under 50 MPa for 10 min in vacuum. All sintered pellets were polished to a uniform thickness of 2.3 mm. The as-sintered sample had a black appearance, owing to oxygen deficiency caused by annealing under an atmosphere with low oxygen chemical potential. After subsequent annealing in pure oxygen at 600 °C for 40 h, the sinters turned back yellowish green, indicating that oxygen vacancies were filled with oxygen. The apparent density of the sinters, determined by the Archimedes method, was approximately 99% of the theoretical density. To promote hydrogen incorporation into the sintered WO_3 samples, a 100 nm-thick Pd film^{6,42} was deposited on both faces by magnetron sputtering (JFC-1600, JEOL, Japan), followed by annealing in a hydrogen atmosphere at 300 °C for up to 144 h. After hydrogen annealing, the surface of the sinter turned dark blue, indicating the formation of W^{5+} due to hydrogen incorporation, *i.e.*, the formation of H_xWO_3 . A cross-sectional scanning electron microscope image (FE-SEM; JSM-7800F, JEOL,

Japan) of H_xWO_3 confirmed fine grains and no visible open pores (see Fig. S1), consistent with the high apparent density.

Evaluation of hydrogen incorporation into sintered WO_3

The crystalline phase in the sintered H_xWO_3 was identified by X-ray diffraction (XRD; SmartLab, Rigaku, Japan) using Cu-K α radiation. Prior to measurement, the sintered pellet was mechanically polished to obtain a flat surface for accurate diffraction analysis. To evaluate the depth profile of hydrogen, a two-dimensional hydrogen concentration map was acquired by using time-of-flight secondary ion mass spectrometry (TOF-SIMS; TOF-SIMS5, ION-TOF GmbH, Germany) over a 500 μ m-wide region from the outer surface of the cross-sectional face of the H_xWO_3 pellet. The amount of hydrogen dissolved in the sintered H_xWO_3 was quantified by thermal desorption spectrometry (TDS) using a quadrupole mass spectrometer (QMASS; M-200QA, ANELVA, Japan). A small piece of the sintered sample (approximately 0.1 g), either oxygen- or hydrogen-annealed, was placed in a SiO_2 -glass crucible, which was then set in a closed-end alumina tube. The tube was placed in a furnace and connected to an analyzing chamber equipped with a QMASS. After the experimental apparatus, comprising the sample and analyzing chambers, was evacuated by using a turbomolecular pump (TMU-261, Pfeiffer Vacuum, Germany) down to $<1 \times 10^{-7}$ Pa at room temperature, the furnace was heated up to 1000 °C at a rate of 2.5 °C min⁻¹. H_2O ($m/z = 18$) and H_2 ($m/z = 2$) gases released from the samples were detected by the QMASS and quantified using $La(OH)_3$ and TiH_2 as standard samples. Details of the TDS apparatus and experimental procedure have been described elsewhere.⁴³ If hydrogen dissolution proceeds according to eqn (1), the amount of hydrogen in the sintered H_xWO_3 could in principle also be evaluated from measurements of the electron carrier density. However, since reliable determination of the electron carrier density in H_xWO_3 is challenging due to its polaronic behavior,^{44–46} we did not attempt such an analysis in this study.

Partial proton conductivity measurements

The partial proton conductivity was measured by the electron-blocking method using the proton-conducting phosphate glass ($36HO_{1/2}-4NbO_{5/2}-2BaO-4LaO_{3/2}-4GeO_2-1BO_{3/2}-49PO_{5/2}$ glass) with a thickness of 20–30 μ m and a proton transport number of unity⁴¹ as the electron-blocking electrode. The junction between the sintered H_xWO_3 and the glass was fabricated through hot-pressing, as previously reported.^{47,48} To reduce interfacial resistance across the junction between the sintered H_xWO_3 and the glass, a 100 nm-thick Pd buffer layer deposited by rf-magnetron sputtering (1" sputter cathode, Kenix, Japan) was inserted in the junction. Next, 100 nm-thick Pd reversible electrodes for protons and electrons were deposited on both ends of the cell by rf-magnetron sputtering. The conductivity was measured by using both DC and AC-impedance methods (VersaSTAT-3F, Princeton Applied Research, USA) at 200–275 °C under dry H_2 or deuterium (D_2) atmospheres without any additional drying treatment. The applied voltage for the DC measurement was 100 mV. For AC-

impedance measurements, the frequency range varied from 100 mHz to 1 MHz with an amplitude of 10 mV (rms).

Results & discussion

Hydrogen incorporation into sintered WO₃

Fig. 1(a) presents the XRD patterns obtained from the surface and core regions of the WO₃ pellet annealed in H₂ for 144 h at 300 °C. The inset shows a cross-sectional image of the pellet, with the measured regions corresponding to the XRD data. The cross-section reveals a sharp transition from the dark blue surface to a pale blue core. The diffraction peaks from the surface and core are indexed to the tetragonal and monoclinic phases of WO₃, respectively.^{49,50} The blue coloration deepens as the hydrogen content increases,⁴ and its crystal structure varies accordingly—monoclinic for $x \leq 0.1$, orthorhombic for $0.1 \leq x \leq 0.15$, and tetragonal for $0.15 \leq x \leq 0.5$.^{1,51} These results suggest that the outer surface of the pellet is hydrogen-rich, while the inner core is hydrogen-poor.

Fig. 1(b) displays the hydrogen depth profile of the sinter annealed in H₂ for 144 h at 300 °C, obtained by lateral averaging a two-dimensional hydrogen distribution map measured by using TOF-SIMS. The hydrogen signal is less detectable at the edge of the pellet, but a hydrogen-rich region is clearly observed near the surface. The concentration gradually begins to decrease around a depth of 500 μm, corresponding to the color boundary, and approaches the background level toward the core. Further details on the TOF-SIMS measurement are provided in Fig. S2.

The hydrogen-rich surface and hydrogen-poor core regions were separated through mechanical grinding, and the hydrogen content in each region was determined by TDS. The hydrogen content was determined to be $x = 0.24$ in the hydrogen-rich surface and $x = 0.0048$ in the hydrogen-poor core (Fig. S3).

Fig. S4 shows the time evolution of the color-change front observed in the sintered pellets during hydrogen annealing. The front advanced slowly into the pellet with time, indicating that the inward progression of hydrogenation of WO₃ is markedly sluggish. Even after 144 h at 300 °C, the hydrogen-rich region extended only to a depth of ~500 μm from the surface. This slow advance suggests that the overall hydrogen flux is governed by the low proton diffusivity in the WO₃ pellet. However, the SIMS depth profiles reveal that there is no hydrogen concentration gradient within the hydrogen-rich region. According to Fick's law,

$$J = -D(c) \frac{dc(x)}{dx} \quad (2)$$

where J is the proton flux, $D(c)$ is the proton diffusion coefficient as a function of the local proton concentration c , and $dc(x)/dx$ represents the hydrogen concentration gradient along the depth coordinate x . A flat profile therefore implies a relatively large diffusion coefficient in this region. Similar behavior has also been reported for the gasochromic properties of H_xWO₃ thin films.³³ In that study, the diffusion coefficient was found to be larger in the hydrogen-rich tetragonal phase and smaller in the hydrogen-poor monoclinic phase. Thus, the slow diffusion in the hydrogen-poor region can be identified as the rate-limiting process governing the overall hydrogen diffusion in the present samples.

Proton conductivity of H_xWO₃ in hydrogen atmosphere

Fig. 2(a) shows a schematic illustration of the electron-blocking cell, together with a top-view photograph of the sample. The phosphate glass was tightly laminated onto the surface of the sintered H_xWO₃, which exhibited high apparent density so that mechanical gas leakage through the pellet can be neglected.

Fig. 1 (a) XRD patterns of the surface (red) and core regions (blue) of the H_xWO₃ pellet. The inset shows a cross-sectional optical microscope image of the pellet, revealing a sharp color transition from the dark blue surface to the pale blue core. (b) Depth profile of hydrogen-related ions (H⁻ and OH⁻) obtained by TOF-SIMS near the phase boundary in the cross section of H_xWO₃.

Fig. 2 (a) Schematic image of the electron-blocking cell along with a top-view photograph. (b) Time evolution of the DC current (under a 100 mV applied bias) during the sequential switching of the atmosphere from H_2 to D_2 and back to H_2 at 250 °C.

This configuration provides a well-defined interface that allows reliable characterization of proton conduction under electron-blocking conditions (Fig. S5). Nevertheless, the cell inevitably includes multiple interfaces, and electronic currents arising from hydrogen evolution reactions at these interfaces may flow. We discussed their contributions to the electrical measurements, as shown in SI Section S5.1.

Fig. 2(b) shows the current–time profile measured under the application of a constant DC voltage of 100 mV as the atmosphere was switched between H_2 and D_2 . The increase and decrease in current upon switching between H_2 and D_2 clearly demonstrate an isotope effect, suggesting that protons contribute to the current and that electronic conduction is effectively suppressed by the phosphate glass.

Fig. 3(a) shows the decay of the transient current immediately after the application of a DC voltage of 100 mV, indicating that the electron-blocking cell contains not only a resistive component associated with proton transport, but also a capacitive component. To examine the details of this behavior, the frequency-dependent responses of the cell were measured by AC impedance spectroscopy. Fig. 3(b) shows the overall Nyquist plot of the electron-blocking cell, revealing the following distinct components: a high-frequency intercept resistance (R_1), mid-frequency arcs, and a low-frequency inclined straight-line response. Among these, the straight line observed in the low-frequency region has a slope close to 1, indicative of Warburg impedance (R_w).⁵² As shown in the enlarged view in Fig. 3(c), two distinct arcs are observed in the mid-frequency region. These

are denoted as R_2 and R_3 and are visually highlighted in red and blue, respectively, for clarity.

The equivalent circuit of the asymmetric electron-blocking cell can be described by a complex transmission line model that represents mass and charge transport, as shown in Fig. S7.⁵³ The model includes elements related to charge transport at interfacial regions, leading to a complex impedance response. However, this complex impedance response makes it difficult to readily identify the resistive component associated with proton transport in H_xWO_3 . Although the transmission line model provides a physically meaningful representation of the system, previous studies have shown that fitting with a series of Randles circuits yields nearly equivalent results.^{48,54} Therefore, while the transmission line model is more appropriate for physical interpretation, we herein discuss the fitting results based on the simplified equivalent circuit shown in the upper part of Fig. 3(c).

As a first step, the contribution from proton transport in the glass electrode can be readily separated, as its relaxation is the fastest and appears as a distinct high-frequency resistance. As shown in Fig. S8, the temperature dependence of R_1 agrees well with the reported value of the proton-conducting glass,⁴¹ allowing it to be assigned to proton transport within the glass. The remaining impedance components were identified through the subsequent measurements.

Fig. 4(a) presents the Nyquist plots of the electron-blocking cell measured under H_2 and D_2 atmospheres. Switching the atmosphere from H_2 to D_2 increased not only R_1 , reflecting the isotope effect in the glass electrode, but also R_2 and R_3 . This

(c) Enlarged view of the mid-frequency region in (b) along with the simplified equivalent circuit (top) used for fitting and the fitting result (green line).

Fig. 4 (a) Nyquist plots of the impedance spectra measured under H_2 (top) and D_2 (bottom) atmospheres at 250 °C. (b, left) Fitted resistance values of R_1 , R_2 , and R_3 under H_2 and D_2 . (b, right) Corresponding resistance ratios ($R(D_2)/R(H_2)$) representing isotope effects for each component. (c) Nyquist plots of impedance spectra measured under H_2 at 250 °C for samples with different thicknesses (2.3 mm and 1.8 mm, polished). (d, left) Fitted resistance values of R_1 , R_2 , and R_3 for 2.3 mm- and 1.8 mm-thick samples. (d, right) Corresponding resistance ratios ($R(1.8 \text{ mm})/R(2.3 \text{ mm})$) for each component.

phenomenon provides evidence that these arcs are associated with proton-related processes such as proton transport in H_xWO_3 or interfacial charge transfer. The corresponding resistance values are plotted in Fig. 4(b).

To further elucidate the assignment of the R_2 and R_3 components, we performed impedance measurements on

H_xWO_3 pellets of different thicknesses. The pellet with an initial thickness of 2.3 mm was mechanically polished by 500 μm from the side opposite to the glass layer to reduce its thickness to 1.8 mm. The corresponding Nyquist plots are shown in Fig. 4(c), and the changes in the R_1 , R_2 , and R_3 components are summarized in Fig. 4(d). As noted in Fig. S4, the thickness of the

hydrogen-rich region is approximately 500 μm . Therefore, removing an area of approximately 500 μm from one side of the pellet effectively reduces the thickness of the hydrogen-rich region by about half, while leaving the hydrogen-poor core nearly unchanged. This reduction primarily affected the R_2 component, which suggests that R_2 corresponds to the proton transport resistance within the hydrogen-rich region.

In contrast, the low-frequency element R_w exhibited only minor changes upon isotope substitution or variation in pellet thickness. R_w is therefore interpreted as proton diffusion in the hydrogen-poor monoclinic region, where proton transport is limited by the inherently low diffusion coefficient and the scarcity of carrier protons.

Finally, the R_3 component exhibited a clear isotope effect but only minor dependence on pellet thickness. This behavior indicates that R_3 is clearly associated with proton-related resistance, and its large capacitance further supports an interfacial origin (Fig. S9). As discussed in SI Section S5.1, the contributions of the Pd/glass and Pd/ H_xWO_3 interfaces can be regarded as negligible. We therefore attribute R_3 mainly to proton transport across the boundary between the hydrogen-rich and hydrogen-poor regions.

Fig. 5(a) displays the Arrhenius plot of the proton conductivity (σ_H) of H_xWO_3 measured in a hydrogen atmosphere. The conductivity was calculated for the hydrogen-rich $\text{H}_{0.24}\text{WO}_3$ region (thickness: 1 mm) from the R_2 component. The corresponding electronic conductivity (σ_e), determined by the DC four-probe method (Fig. S10(a)), is also plotted. Although the proton transport number in the measured temperature range is relatively low ($<1 \times 10^{-3}$), σ_H reaches $1 \times 10^{-1} \text{ S cm}^{-1}$ at 275 $^\circ\text{C}$. This value significantly exceeds that of perovskite-type proton-conducting electrolytes in the intermediate-temperature range,^{55–57} indicating that H_xWO_3 holds promise as an electrode material when combined with such electrolytes.

Fig. 5(b) presents the temperature dependence of the proton diffusion coefficient (D_H) in $\text{H}_{0.24}\text{WO}_3$ calculated from proton conductivity and proton carrier density using the Nernst–Einstein relation:

$$D_H = \frac{k_B T \sigma_H}{e^2 n_H} \quad (3)$$

where k_B is the Boltzmann constant, and T is the absolute temperature, e is the elementary charge. The value of D_H extrapolated to lower temperatures agrees well with that reported in an earlier work,³⁰ indicating that the excellent proton transport properties are retained over a wide temperature range.

Herein, we compare the proton diffusion behavior of H_xWO_3 with that of rutile-type H_xTiO_2 , which also incorporates protons *via* hydrogen dissolution (eqn (1)).^{58,59} Like WO_3 , TiO_2 undergoes a transition from a d^0 to a d^1 electronic configuration

upon hydrogen incorporation, leading to the formation of Ti^{3+} species. However, the amount of hydrogen incorporated into TiO_2 is significantly smaller than that in WO_3 , typically resulting in proton densities on the order of 10^{18} to 10^{19} cm^{-3} corresponding to a hydrogen composition of $x \sim 0.0001$.³⁶ In both H_xWO_3 and H_xTiO_2 , equal amounts of protons and electrons are introduced by hydrogen dissolution, leading to coupled proton–electron transport, referred to as ambipolar diffusion.⁶⁰ Notably, the D_H of $\text{H}_{0.24}\text{WO}_3$ is 100–1000 times greater than that of $\text{H}_{\sim 0.0001}\text{TiO}_2$ along its one-dimensional *c*-axis diffusion pathways.^{36,61} In H_xTiO_2 , the electrons tend to localize at Ti sites, forming small polarons (Ti_i^{\cdot}) with low mobility.^{62,63} The negative charge of these polarons electrostatically attracts protons and acts as proton traps, thereby limiting the proton mobility. In contrast, in H_xWO_3 , the electrons introduced *via* hydrogen dissolution are likely to form polarons with a relatively larger polaron radius, as suggested by the small activation energies (E_a) for electronic conduction (Fig. S10(b)).^{44,45,64} These highly mobile and delocalized electrons do not produce strong localized electrostatic fields that immobilize protons, accounting for the larger D_H of $\text{H}_{0.24}\text{WO}_3$ than that of $\text{H}_{\sim 0.0001}\text{TiO}_2$.

Interestingly, $\text{H}_{0.24}\text{WO}_3$ exhibits E_a for proton diffusion that is comparable to or even higher than that of $\text{H}_{\sim 0.0001}\text{TiO}_2$ along the *c*-axis, despite the significantly higher diffusion coefficient. The temperature dependence of diffusion coefficient can be determined using the Arrhenius equation:

$$D_H = D_0 \exp\left(-\frac{E_a}{k_B T}\right) \quad (4)$$

where D_0 is the pre-exponential factor. The large D_H in $\text{H}_{0.24}\text{WO}_3$ associated with the formation of a large polaron can be attributed to a larger D_0 compared to that of $\text{H}_{\sim 0.0001}\text{TiO}_2$, as shown in Table 1. From the random-walk theory, D_0 is described as follows:

$$D_0 = \frac{a^2}{6} \nu_0 \exp\left(\frac{\Delta S_a}{k_B}\right) \quad (5)$$

where a is the jump distance, ν_0 is the attempt frequency (*i.e.*, the number of attempted jumps per unit time), and ΔS_a is the activation entropy. Thus, the pre-exponential factor of the diffusion coefficient can be described by fundamental parameters that characterize the elementary diffusion process. For proton conducting oxides, a can be taken as the distance between the neighboring oxide ions where proton transfer occurs, and ν_0 can be related to be the frequencies of M–O vibrational modes, such as O–M–O bending or M–O stretching modes.^{64,65} The increase in the pre-exponential factor may arise from a greater number of accessible diffusion pathways for protons in $\text{H}_{0.24}\text{WO}_3$, and it may also reflect a higher statistical multiplicity of microstates associated with the absorption of multiple phonons required to overcome the migration barrier.⁶⁵ Although our interpretation of the large pre-exponential factor for proton diffusion in H_xWO_3 remains speculative, we anticipate that further understanding of this behavior will contribute to the development of advanced proton-conducting materials.

Conclusions

This study reported on the proton conductivity of hydrogen tungsten bronze (H_xWO_3) in the intermediate-temperature range using an electron-blocking method with a phosphate glass electrolyte. The sample exhibited a spatially inhomogeneous hydrogen distribution, consisting of a hydrogen-rich surface region ($x = 0.24$) and a hydrogen-poor core ($x = 0.0048$). The limited penetration depth of hydrogen ($\sim 500 \mu\text{m}$) even after prolonged annealing suggests that the low diffusion coefficient in the hydrogen-poor region restricts further hydrogen incorporation. The impedance component corresponding to proton conduction in $H_{0.24}WO_3$ was separated from the overall impedance based on comparative measurements obtained using isotope substitution and pellets with different thicknesses. The resulting proton conductivity of $H_{0.24}WO_3$ reached $10^{-1} \text{ S cm}^{-1}$ at $275 \text{ }^\circ\text{C}$ under a H_2 atmosphere. This value significantly exceeds that of perovskite-type proton-conducting electrolytes in the intermediate-temperature range, which suggests that H_xWO_3 is a promising electrode material for use in combination with these electrolytes. A comparison with rutile-type $H_{\sim 0.0001}TiO_2$ revealed that $H_{0.24}WO_3$ possesses proton diffusion coefficients that are 100–1000 times larger, indicating the formation of large polarons of electrons. The delocalized electrons do not electrostatically trap protons at specific positions, thereby allowing efficient proton migration. Furthermore, $H_{0.24}WO_3$ exhibits a larger D_0 than that of $H_{\sim 0.0001}TiO_2$. This phenomenon likely reflects the presence of a wide variety of accessible proton migration pathways or reduced vibrational constraints in the activated state in $H_{0.24}WO_3$, contributing to its high proton diffusivity despite a comparable or higher E_a . These results highlight the critical role of entropic contributions in the proton diffusion process of H_xWO_3 , offering a new perspective for designing proton-conducting materials with high proton conductivity.
