Quartz crystal microbalance determination of acephate based on a molecularly imprinted polymer and sulphur-doped copper ferrites

Bahar Bankoğlu Yola 

Acephate (ACE), an effective systemic insecticide, plays a significant role in agricultural pest control. For many decades, this compound has been used to manage various insect infestations in crops, contributing to healthier yields. Hence, the detection of ACE serves as a critical indicator, signaling potential environmental degradation, public health risks, and economic challenges, thereby prompting necessary policy adjustments. The sulphur-doped copper ferrites (S@CuFe₂O₄) were initially synthesized through a hydrothermal treatment process. Subsequently, quartz crystal microbalance (QCM) chips incorporating S@CuFe₂O₄ were fabricated. This fabrication was accomplished by providing the inherent interaction between the gold surface of the QCM chip and the sulphur component present within the S@CuFe₂O₄ nanomaterial. A molecularly imprinted QCM sensor based on S@CuFe₂O₄ was developed by a UV polymerization technique. This sophisticated fabrication process involves the integration of methacryloylamidoglutamic acid (MAGA) as the monomer and *N,N'*-azobisisobutyronitrile (AIBN), which served as the crucial initiator. This innovative sensor exhibited a linear response range, spanning from 1.0×10^{-9} to 1.0×10^{-8} mol L⁻¹. Furthermore, its sensitivity was remarkable, achieving a low limit of detection (LOD) at 3.30×10^{-10} mol L⁻¹. The newly developed QCM sensor was effectively utilized for measurements in real apple juice samples, demonstrating high recovery rates. Additionally, an investigation was conducted to assess the sensor's selectivity, evaluate its repeatability and stability, and confirm its reproducibility.

1. Introduction

With the world's population expanding rapidly, there's an increasing need to obtain a sufficient food supply. This critical demand is a significant global concern, particularly regarding the application of various agrochemicals including herbicides, pesticides, and insecticides. Among these, chemical insecticides are favored in agricultural practices owing to their affordability and considerable efficacy. ACE, a harmful broad-spectrum insecticide, exerts its lethal effect by inhibiting acetylcholinesterase. This inhibition leads to the accumulation of acetylcholine and heightened cholinergic activity within the affected organism. Consequently, ACE poses a significant risk not only to pests but also to humans.^{1,2} Although ACE demonstrates dependable effectiveness against numerous insect species, direct inhalation, dermal contact, or consumption of vegetables with excessive residues can cause severe health consequences such as sciatic nerve damage, milder leukocytosis, and cancer.³ Thus, ACE analysis in foods is significant for

the well-being of both the public and the environment. The accurate and sensitive detection of insecticides is crucial, prompting researchers to investigate some analytical methodologies such as HPLC⁴ and LC-MS.⁵ Additionally, the electrochemical analytical techniques⁶ offer sensitive detection capabilities, while enzyme-based biological sensing techniques provide an alternative method for identifying biological interactions.⁷ However, these techniques have some disadvantages. For example, they often require highly skilled laboratory technicians, demand considerable time for sample preparation, and involve the use of costly instrumentation. Thus, more sensitive, accurate, selective, and reliable methods are gaining prominence in the field of food analysis.

Spinel ferrites, M²⁺M₂³⁺O₄ compounds represented by the formula MFe₂O₄ (where M can be Zn, Mn, Ni, Cu, *etc.*), have garnered significant interest due to their utility as catalysts.^{8,9} Ferrite composition and crystalline structure are crucial factors that influence their adsorption capabilities, which are intricately linked to their specific morphology. Among these, CuFe₂O₄, a spinel-type material, is highly appealing for catalytic reactions due to its narrow band gap, robust chemical stability, and impressive visible light activity. Furthermore, its low toxicity, cost-effectiveness, versatile nature, and excellent recyclability enhance its attractiveness for such applications.¹⁰ A

Department of Engineering Basic Sciences, Faculty of Engineering and Natural Sciences, Gaziantep Islam Science and Technology University, Gaziantep, 27260, Türkiye. E-mail: bahar.bankoglu@gibtu.edu.tr; Fax: +8502589800; Tel: +90-3429097500

range of techniques, including sol–gel, solid-state reaction, and coprecipitation, have been documented for synthesizing spinel ferrite microstructures. Among these, the hydrothermal method is the preferred approach due to its superior versatility, uniformity, purity, and ease of synthesis.¹¹ Despite its advantages, enhancing the effectiveness of CuFe_2O_4 is crucial due to the rapid recombination of photogenerated charge carriers. To boost its catalytic efficiencies, doping with various metals and non-metals is a favored strategy.¹² Furthermore, due to the significant difference in size and electronegativity between oxygen and sulphur, the sulphur dopants improve the optical and electrical properties of semiconductor oxides.¹³

Molecular imprinting is an advanced, three-stage polymer fabrication technique. In this process, functional monomers initially form a complex with a target molecule through either covalent or non-covalent interactions. This complex is then polymerized, and the subsequent removal of the target molecule using a suitable desorption solvent yields selective polymeric structures. These polymeric structures possess the remarkable ability to recognize the template molecule. Hence, molecularly imprinted polymers (MIPs) offer several benefits, including easy preparation, cost-effectiveness, high selectivity and sensitivity, and robust durability, making them invaluable tools in modern food safety analyses.^{14–16} MIP-based sensors offer a highly adaptable, stable, and cost-effective approach to specific molecular recognition, which is significant for advancements in diagnostics, environmental protection, and quality control.^{17–25}

This study presented a novel approach for the sensitive detection of ACE insecticide, integrating MIPs with sulphur-doped copper ferrites. Specifically, a high-sensitivity sensor was developed by combining the high selectivity properties of MIPs with the high adsorption properties of the $\text{S@CuFe}_2\text{O}_4$ nanomaterial. The research involved first synthesizing sulphur-doped copper ferrites through a hydrothermal treatment. Following this, a QCM sensor was developed using sulphur-doped copper ferrites coated with MIPs. This innovative sensor was then successfully utilized for the precise determination of ACE in apple juice samples.

2. Experimental

2.1. Chemicals and instrumentation

Malathion (MAL), triazophos (TRI), chlorpyrifos (CHL), copper(II) nitrate [$\text{Cu}(\text{NO}_3)_2$], iron(III) nitrate [$\text{Fe}(\text{NO}_3)_3$], thiourea (THI), MAGA, ethylene glycol dimethacrylate (EGDMA), 2-hydroxyethylmethacrylate (HEMA), AIBN, phosphate buffer (0.1 mol L^{-1} , PB) and sodium chloride (NaCl) were bought from Sigma-Aldrich (USA). The apparatus for analytical and structural analysis is given in the SI.

2.2. Preparation of CuFe_2O_4 and $\text{S@CuFe}_2\text{O}_4$

Copper ferrites were prepared using a hydrothermal method, initiating with the stirring of $0.20 \text{ mol per L Cu}(\text{NO}_3)_2$ and $0.40 \text{ mol per L Fe}(\text{NO}_3)_3$ solutions for 1 h. Subsequently, a 0.10 mol per L glucose solution was introduced into this

mixture and continuously stirred for 24 h at $40 \text{ }^\circ\text{C}$. The resulting solution was subjected to sonication for 1 h before being transferred to an autoclave, where it was held at $160 \text{ }^\circ\text{C}$ for 5 h. Then, the solution was allowed to cool and filtered using high-grade filter paper to isolate the product (CuFe_2O_4).

For the synthesis of $\text{S-CuFe}_2\text{O}_4$, 1.0 g of CuFe_2O_4 powder was placed into an autoclave reactor. An appropriate quantity of 1.0% THI solution was then introduced into this mixture. The resulting combination was subsequently treated in the autoclave for 4 h at $160 \text{ }^\circ\text{C}$, yielding $\text{S-CuFe}_2\text{O}_4$ nanoparticles.²⁶

2.3. QCM chip modification with $\text{S@CuFe}_2\text{O}_4$ and preparation of an ACE imprinted QCM chip based on $\text{S@CuFe}_2\text{O}_4$

QCM chips were prepared by cleaning them for 5 min in a conical flask containing 10.0 mL of an acidic piranha solution, which was formulated as a $3 : 1$ (v/v) mixture of sulfuric acid and hydrogen peroxide. Following this cleaning treatment, QCM chips were dried under a protective argon atmosphere. To enable a strong bond between the gold surface of the QCM chip and the sulfur atoms of the nanocomposite, a $\text{S@CuFe}_2\text{O}_4$ suspension (5.0 mg mL^{-1}) was then carefully applied onto the QCM chip surface. Subsequently, this modified chip ($\text{S@CuFe}_2\text{O}_4/\text{QCM}$) was preserved in an argon atmosphere to prevent degradation.

Initially, a MAGA–ACE complex solution was prepared by combining the components at a $2 : 1$ molar ratio within 5.0 mL of PB at a pH of 6.0. Subsequently, 4.0 mL of this complex solution was agitated with 2.0 mg of AIBN, 10.0 mL of HEMA, and 10.0 mL of EGDMA to form a polymerization mixture. This mixture was then applied onto the $\text{S@CuFe}_2\text{O}_4/\text{QCM}$ chip using spin coating for 10 min, ensuring the formation of a homogeneous, single-layered polymeric structure. Following this, UV polymerization was initiated directly on the QCM chip for 10 min, resulting in the production of an ACE-imprinted QCM chip ($\text{MIP/S@CuFe}_2\text{O}_4/\text{QCM}$). A mercury vapor lamp with a wavelength range of $315\text{--}400 \text{ nm}$, emitting a broad spectrum of UV light, was used as a light source and its intensity can range from 10 to 100 mW cm^{-2} . For comparative purposes, a non-imprinted QCM chip ($\text{NIP/S@CuFe}_2\text{O}_4/\text{QCM}$) was fabricated using an identical methodology omitting the ACE target molecule.

2.4. ACE removal from $\text{MIP/S@CuFe}_2\text{O}_4/\text{QCM}$ and analysis process

To effectively dissociate the electrostatic and hydrogen bonding interactions existing between the MAGA monomer and ACE analyte, a NaCl solution was utilized for the comprehensive removal of ACE. Specifically, the $\text{MIP/S@CuFe}_2\text{O}_4/\text{QCM}$ chip was submerged for 10 min in 5.0 mL of 0.1 mol per L NaCl solution to facilitate the complete elution of ACE molecules. After that, the chip was subjected to vacuum drying at $25 \text{ }^\circ\text{C}$ to ensure the elimination of the residual solvent.²⁷ Once the $\text{MIP/S@CuFe}_2\text{O}_4/\text{QCM}$ chip, with ACE removed, was integrated into the QCM cell, the system underwent an initial equilibration phase. This involved flushing 3.0 mL of PB at pH 6.0 through

the QCM cell for 10 min at a constant flow rate of 1.0 mL min^{-1} . Following this, the adsorption process was carried out using 1.0 mL aliquots of ACE solutions with concentrations varied between 1.0 and 10.0 nmol L^{-1} . Each of these ACE solutions was allowed to interact with the MIP/S@CuFe₂O₄/QCM chip for a duration of 40 min. Subsequently, the desorption phase was initiated by applying 3.0 mL of 0.1 mol per L NaCl solution over a 10-min period. This sequence was completed for a full “adsorption–desorption–regeneration” cycle for each distinct ACE concentration.²⁸

2.5. Sample preparation

To prepare the apple juice sample for analysis, an initial volume of 5.0 mL was transferred into a 25.0 mL conical flask. This sample then underwent a 10-min centrifugation step to remove any particulate residues. Following residue removal, the solution was diluted with PB at pH 6.0 to ensure the target concentration remained within the detection linear range. Finally, this diluted sample was introduced into the QCM cell for subsequent analysis.

3. Results and discussion

3.1. Structural analysis of CuFe₂O₄ and S@CuFe₂O₄

The as-prepared copper ferrite nanostructures were characterized for phase purity and crystalline nature using XRD (Fig. 1A). The analysis of the synthesized nanomaterials revealed prominent diffraction peaks at 18.11° , 29.97° , 35.63° , 36.90° , 43.36° , 53.77° , 57.20° , and 63.12° , which corresponded respectively to the Miller indices of (111), (220), (311), (222), (400), (422), (511), and (440).²⁹

XRD patterns definitively confirmed that the synthesized nanomaterials depicted a cubic spinel structure with Fe³⁺ ions occupying octahedral sites and Cu²⁺ ions occupying tetrahedral positions. Furthermore, while the presence of sulfur doping led to a notable shift of the major peaks, a decrease in the overall intensity of the diffraction peaks was observed. XRD patterns, which confirmed the cubic spinel structure of the synthesized nanomaterials with Fe³⁺ ions in octahedral sites and Cu²⁺ ions in tetrahedral positions, also clearly indicated the successful replacement of smaller oxygen ions by larger sulfur anions within the CuFe₂O₄ structure. Significantly, the absence of Fe₂O₃, FeS or CuS crystalline phases indicated the purity of the catalysts, although some additional peaks beyond 64.90° were observed, suggesting the presence of minor CuO content.^{26,30} The distinct sharpness of the observed peaks indicated that the nanomaterials in this study had a highly crystalline structure.

Fig. 1B displays the FTIR spectra for both CuFe₂O₄ and S-CuFe₂O₄ nanoparticles. A prominent peak at 533 cm^{-1} was attributed to M–O vibrational mode of the tetrahedral sites, where M denotes either copper or iron. Additionally, a peak at 441 cm^{-1} corresponded to the stretching vibrations of the octahedral planes characteristic of these spinel copper oxides. A broad band around 3490 cm^{-1} suggested O–H bending vibrations, which were associated with hydroxyl groups or water molecules on the nanomaterials' surfaces. Notably, the introduction of sulfur doping caused metal–sulfur vibrations appearing at 496 cm^{-1} , exhibiting a distinctly lower intensity compared to the Cu–O/Fe–O vibrational peaks. FTIR patterns in the range of $1025\text{--}1035 \text{ cm}^{-1}$ were attributed to C–N stretching vibrations originating from the presence of thiourea.^{26,31} In

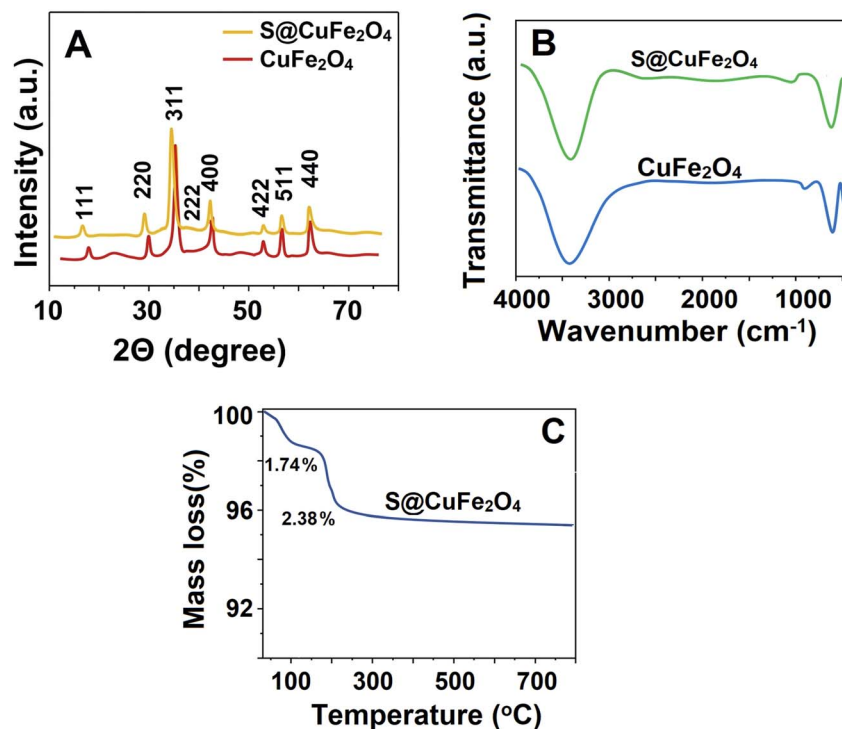

Fig. 1 (A) XRD patterns of S@CuFe₂O₄ and CuFe₂O₄, (B) FTIR spectra of S@CuFe₂O₄ and CuFe₂O₄, and (C) TGA curve of S@CuFe₂O₄.

addition, FTIR spectra of pure CuFe_2O_4 did not suggest nitrogen/carbon (N–C) vibrations.

To examine the physical property changes of the newly synthesized S– CuFe_2O_4 , thermogravimetric analysis (TGA) was conducted (Fig. 1C). These measurements were carried out in a nitrogen atmosphere, spanning a temperature range from 50 °C to 800 °C at a heating rate of 5 °C min^{-1} . The initial analysis revealed a 1.74% mass reduction occurring below 165 °C, resulting from the evaporation of both adsorbed water and solvent residues. This was a common phenomenon in nanoparticle systems due to their high surface area. The subsequent observations suggested an additional 2.38% decrease in mass as the temperature reached 220 °C, which corresponded to the thermal decomposition of metal hydroxides.³² These hydroxides were invariably formed during the synthesis of such oxide nanoparticles, particularly when employing precipitation or hydrothermal methods, and their decomposition contributed to the overall weight loss without indicating any organic contamination. After 800 °C, no additional weight loss was detected, indicating the remarkable thermal stability of the S– CuFe_2O_4 nanoparticles. In addition, this situation suggested the absence of any substantial residual carbonaceous or nitrogenous species that would typically decompose at higher temperatures. In conclusion, 4.12% mass reduction was attributed to the contamination by residual carbon/nitrogen species from incomplete THI decomposition.

SEM was employed to examine the morphological characteristics of both pristine S@ CuFe_2O_4 and CuFe_2O_4 nanostructures. The observations revealed that CuFe_2O_4 nanoparticles exhibited an agglomerated state, displaying irregular and flake-like formations. This tendency for CuFe_2O_4 nanoparticles was attributed to the agglomeration in clusters due to the attractive forces (Fig. 2A).³³ In addition, Fig. 2B reveals that sulfur doping caused a more regular flake-like morphology and a noticeable reduction in agglomeration, providing the evidence for increased nanomaterial porosity.³⁴ Consequently, the availability of active sites increased. These findings suggested that sulfur doping improved the surface area and thus contributed to an enhanced adsorption activity of CuFe_2O_4 nanoparticles. EDX results also demonstrated the

presence of copper, iron, oxygen and sulphur, confirming the successful synthesis of S@ CuFe_2O_4 (Fig. S1). Finally, an XPS experiment was performed to examine the attachment of sulphur to the gold surface of the QCM chip. The S 2p region displayed a doublet, specifically the $2p_{1/2}$ and $2p_{3/2}$ orbitals, due to the inherent spin–orbit coupling. The presence of sulphur peaks at 168.13 eV on the S@ CuFe_2O_4 /QCM chip suggested that its sulphur readily formed a bond with the gold surface of the QCM chip. Furthermore, an additional peak observed at 163.06 eV served as an indicator for the existence of a free mercapto group within the system (Fig. S2).³⁵

3.2. FTIR and AFM analysis of the ACE-imprinted film on S@ CuFe_2O_4 /QCM

Following the removal of ACE, FTIR spectroscopy was performed on the ACE-imprinted film on S@ CuFe_2O_4 /QCM, revealing characteristic absorption peaks. Specifically, the distinct bands were observed at 3618 cm^{-1} corresponding to the hydroxyl stretching vibrations of both MAGA and HEMA monomers; at 2991 cm^{-1} indicating –CH bond stretching; at 1760 cm^{-1} associated with carboxyl–carbonyl stretching; and at 1486 cm^{-1} reflecting –COO– stretching (Fig. S3A). The consistent presence of these specific spectral peaks validated the successful formation of the ACE-imprinted film on S@ CuFe_2O_4 /QCM. Furthermore, AFM images (Fig. S3B and C) presented the varying surface morphologies of a pristine QCM chip in comparison with the ACE-imprinted film on S@ CuFe_2O_4 /QCM. The quantitative analysis from AFM measurements produced an average thickness of 3.07 ± 0.14 nm for the bare QCM chip and a greater average thickness of 27.79 ± 0.09 nm for the ACE-imprinted film on S@ CuFe_2O_4 /QCM. These substantial differences in film thickness provide important evidence for the successful formation of ACE-imprinted polymeric layers on the QCM chip surface.

3.3. pH effect on the ACE-imprinted film on S@ CuFe_2O_4 /QCM and the modification effect

Due to the MAGA monomer having two pK_a values ($\text{pK}_{a1} = 2.10$ and $\text{pK}_{a2} = 4.07$), the acidic MAGA monomer depicted minimal

Fig. 2 SEM images of (A) CuFe_2O_4 and (B) S@ CuFe_2O_4 .

Fig. 3 (A) QCM sensorgrams for 5.0 nmol per L ACE at different pH values of PB and (B) QCM sensorgrams on MIP/QCM (curve a), MIP/S@CuFe₂O₄/QCM (curve b) and MIP/CuFe₂O₄/QCM (curve c) in the presence of 5.0 nmol per L ACE.

ionization under acidic pH conditions, providing limited interaction with ACE. However, as the pH increased, the carboxylic acid groups of the MAGA monomer became negatively charged. Consequently, these negative groups interacted with -NH groups of ACE.³⁶ Conversely, as the concentration of the anion form of ACE increased under alkaline conditions (*i.e.*, pH greater than 7.0), the interaction between the monomer and ACE diminished. This reduction was attributed to the electrostatic repulsion lowering their binding affinity on the QCM chip surface. As depicted in Fig. 3A, the most robust interaction between the monomer and the analyte was observed at a pH of 6.0. Therefore, this specific pH level was designated as the optimal condition for all subsequent analytical methodologies.³⁷

Fig. 3B reveals the important impact of surface modification on QCM sensor signals when exposed to 5.0 nmol per L ACE. A low QCM sensor response ($\Delta m = 2.0 \text{ ng cm}^{-2}$) was observed when using a MIP/QCM (curve a of Fig. 3B). Then, a substantial increase in the QCM sensor signal was observed on curve b of Fig. 3B when using MIP/S@CuFe₂O₄/QCM. The reasons for this large mass change caused by S@CuFe₂O₄ could be listed as follows: (i) this marked enhancement was ascribed to the

formation of highly stable self-assembled monolayers, resulting from the strong sulphur-gold covalent bonds³⁸ and sulphur doping providing increased porosity.³⁴ (ii) Sulphur doping could alter the electronic band structure of CuFe₂O₄. This change provided more favorable interactions with the specific ACE target.³⁹ (iii) Sulphur doping often introduced defects into the crystal lattice. These defects could act as enhanced adsorption sites, increasing the binding affinity and potentially the selectivity for ACE molecules. The creation of more active and specific adsorption sites due to sulphur doping could lead to a higher quantity of adsorbed ACE molecules onto the S@CuFe₂O₄ film.⁴⁰ (iv) Sulphur doping could lead to an improvement in the structural stability of the sensing material, making the QCM sensor more robust in challenging environments.⁴¹ Finally, as expected, smaller mass change values were observed when using MIP/CuFe₂O₄/QCM without sulphur doping (curve c of Fig. 3B). Thus, these advanced monolayers played a crucial role in generating more binding sites between S@CuFe₂O₄ and ACE molecules, consequently leading to a significant improvement in the sensor response and performance.

Fig. 4 (A) QCM sensorgrams with different ACE concentration on the MIP/S@CuFe₂O₄/QCM chip at pH 6.0 of PB (from 1.0 nmol L⁻¹ to 10.0 nmol per L ACE) and (B) calibration curve of ACE concentrations against QCM signals.

3.4. Sensitivity of MIP/S@CuFe₂O₄/QCM

The analytical performance of the MIP/S@CuFe₂O₄/QCM chip was characterized through QCM sensorgrams, as presented in Fig. 4A. These sensorgrams were obtained from QCM responses across a broad ACE concentration range from 1.0 to 10.0 nmol L⁻¹. From these results, a robust linear relationship was established between MIP/S@CuFe₂O₄/QCM sensor signals and the corresponding ACE concentrations (Fig. 4B). This relationship produced a precise calibration equation of y (ng cm⁻²) = 0.9940x (C_{ACE}, nmol L⁻¹) - 0.0891. This equation effectively quantified QCM sensor's analytical ability, showing its reliability for ACE detection within the specified concentration range. The MIP/S@CuFe₂O₄/QCM sensor demonstrated remarkable analytical sensitivity, achieving a limit of quantification (LOQ) of 1.0 × 10⁻⁹ mol L⁻¹ and a LOD of 3.30 × 10⁻¹⁰ mol L⁻¹, thereby confirming its robust performance (with detailed equations provided in the SI) in comparison with the other methods (Table 1). While chromatographic techniques such as LC-MS and GC-MS were employed for ACE determination,⁴²⁻⁴⁴ these methods raised important environmental concerns owing to the excessive usage of chemical agents. In contrast, this study's approach, which incorporated a hydrothermal method for the S@CuFe₂O₄ nanocomposite, significantly minimized waste generation. Therefore, the MIP/S@CuFe₂O₄/QCM system offered a rapid detection platform for critical metabolic disorders resulting from exposure to potent pesticides.

3.5. Recovery

To confirm the effectiveness of the MIP/S@CuFe₂O₄/QCM chip, the recovery assessments were conducted within apple juice samples. The results, detailed in Table 2, revealed a high recovery rate of nearly 100.00%. This high percentage suggested the sensor's high precision and its capacity to detect the ACE analyte even in the presence of complex matrix interference. Furthermore, the detection of ACE in apple juice was carried out using the application of LC-MS/MS.⁵¹ As detailed in Table 2, the data indicated a strong correlation between the measurements acquired using the MIP/S@CuFe₂O₄/QCM chip and the LC-MS/MS technique, and no important difference between the results of the two methods was found (Wilcoxon test: $T_{\text{calculated}} > T_{\text{tabulated}}$, $p > 0.05$).

To further validate the sensor's analytical capabilities, the standard addition method was employed for ACE quantification

in apple juice samples, yielding a calibration equation of y (ng cm⁻²) = 0.9972x (C_{ACE}, nmol L⁻¹) - 0.1973. The remarkable harmony between the slopes derived from this standard addition calibration and the direct calibration equation was an important indicator of the developed sensor's high specificity in the presence of complex matrix interferences.

3.6. Stability, selectivity, repeatability, and reproducibility of MIP/S@CuFe₂O₄/QCM

The stability of the novel sensor was confirmed through an 8 week evaluation of a single MIP/S@CuFe₂O₄/QCM chip. During this period, QCM sensorgrams were consistently recorded using a 5.0 nmol per L ACE solution. Remarkably, the QCM signal observed at the conclusion of the 8th week retained approximately 99.36% of the initial signal measured at the end of the first week, definitively demonstrating the high operational stability of this innovative sensing platform.

The selectivity studies in the presence of structurally similar organophosphorus pesticides such as MAL, TRI and CHL were completed using MIP/S@CuFe₂O₄/QCM towards ACE.⁴⁷ The MIP/S@CuFe₂O₄/QCM chip demonstrated superior selectivity towards the ACE analyte. This superior selectivity was verified by exposing the MIP/S@CuFe₂O₄/QCM chip to a 5.0 nmol per L concentration of ACE and the interfering substances such as MAL, TRI, and CHL (Fig. 5A). The results suggested the sensor's selectivity to bind ACE in the presence of a substantial excess of other compounds, highlighting its robustness for selective detection. Subsequently, the quantification of both selectivity (k) and relative selectivity (k') coefficients was evaluated (Table S1). These calculations showed that the MIP/S@CuFe₂O₄/QCM chip exhibited superior selectivity for the ACE analyte, proving to be 18.33 times more selective than for MAL, 27.50 times more selective than for TRI, and 55.00 times more selective than for CHL. Furthermore, Fig. 5B demonstrates the remarkable selectivity achieved through the molecular imprinting technology when compared against the non-imprinted polymer (NIP/S@CuFe₂O₄/QCM) chip. The k' values greater than 1, which ranged from 2.75 to 3.67 (as indicated in Table S1), confirmed the MIP/S@CuFe₂O₄/QCM chip's high selectivity for detecting ACE.

The repeatability of an individual MIP/S@CuFe₂O₄/QCM chip was evaluated by conducting five successive "adsorption-desorption-regeneration" cycles, each utilizing a 5.0 nmol per L ACE solution. Across all five cycles, highly consistent QCM signals of approximately 5.50 ng cm⁻², corresponding to

Table 1 The comparison of the MIP/S@CuFe₂O₄/QCM sensor with the studied methods for ACE detection

Method/material	Linear range (mol L ⁻¹)	LOD (mol L ⁻¹)	Ref.

a relative standard deviation (RSD) of 0.62%, were recorded (as illustrated in Fig. S4). This consistent performance indicated the superior repeatability of the MIP/S@CuFe₂O₄/QCM chip, highlighting its reliability for the repeated measurements.

To establish the reproducibility of the sample preparation method, 25 individual MIP/S@CuFe₂O₄/QCM chips were fabricated in the same batch *via* the procedures described in Section 2.3. The manufactured chips were stored in a sealed environment at 25 °C to protect them from temperature and pressure changes that could interfere with the crystal's natural resonance. In addition, MIP/S@CuFe₂O₄/QCM chips could be oriented horizontally. Each of these independent chips was subsequently exposed to 5.0 nmol per L ACE. The analysis of the QCM signals obtained from these 25 separate QCM chips produced a RSD of 0.89%. This low value for RSD indicated high reproducibility in the QCM sensor fabrication procedure.

3.7. Ruggedness and robustness of MIP/S@CuFe₂O₄/QCM

The ruggedness and robustness experiments of the MIP/S@CuFe₂O₄/QCM chip were evaluated with Wilcoxon test statistical analyses. To assess ruggedness, the influence of different researchers on the sensor's performance was investigated when analyzing 5.0 nmol per L ACE, and the absence of a statistically significant difference ($p > 0.05$) clearly demonstrated the sensor's excellent reliability across various operators. Similarly, the robustness of the sensor was confirmed by examining the impact of slight variations from the optimal pH (specifically at pH 5.9 and pH 6.1). The test also revealed no

significant variation ($p > 0.05$), thereby demonstrating the sensor's high tolerance to minor changes under environmental conditions.

3.8. Greenness evaluation

The environmental compatibility of the MIP/S@CuFe₂O₄/QCM chip was assessed using both the Green Analytical Procedure Index (GAPI) and Analytical GREENness (AGREE). GAPI's visual pictograms, utilizing a green, yellow, and red light system, provided a comprehensive overview of all functionalities associated with the MIP/S@CuFe₂O₄/QCM chip. Furthermore, the AGREE score, ranging from 0.0 to 1.0, yielded a result of 0.91. This robust score indicated the green nature of the methodology employed (Fig. S5 and S6) confirming the high practical applicability of the MIP/S@CuFe₂O₄/QCM chip and its associated tools.

4. Conclusion

A new QCM sensor, combining a molecularly imprinted polymer with sulfur-doped copper ferrites, was developed for the accurate detection of acephate pesticide in apple juice. This advanced sensor revealed high selectivity and sensitivity. It showed a linear detection range spanning from 1.0×10^{-9} to 1.0×10^{-8} mol L⁻¹ with a low detection limit of 3.30×10^{-10} mol L⁻¹. Furthermore, experimental data revealed high recovery rates, falling within the narrow margin of 99.77 to 100.36%. High stability, repeatability, and reproducibility of the

proposed sensor were verified. Finally, the proven efficacy of the QCM sensor based on hydrothermally synthesized sulfur-doped copper ferrites in practical applications indicated its promising potential for future identification of a wider array of pesticide residues.
