# CO<sub>2</sub>-based biodegradable plastics and their precursor production using photo-biocatalytic processes

 Yu Kita,<sup>a</sup> Mika Takeuchi<sup>b</sup> and Yutaka Amao \*<sup>abc</sup>

Biodegradable plastics are materials that can be decomposed by the action of microbes into water, CO<sub>2</sub>, and biomass. They are attractive materials to solve the issue of serious environmental pollution due to plastic disposal. Some biodegradable plastics are produced entirely from petroleum-based precursors. The production of new biodegradable plastics and their precursors from CO<sub>2</sub> and persistent organic or bio-based compounds using visible-light driven redox with biocatalytic processes is one of the effective resolutions for the environmental issues of plastic pollution and global warming. In this review article, recent research on the visible-light driven production of CO<sub>2</sub>-based biodegradable plastics and their precursors using a system of light-driven redox and biocatalytic processes is introduced. As a first example, an overview of research into the production of biodegradable plastics, poly(hydroxybutyrate) (PHB) and their precursors such as acetate, shikimic acid, acetoin and so on from CO<sub>2</sub> using a semiconductor photocatalyst-based photoredox system with a microbial cell as a biocatalytic process is provided. As a second example, an overview is provided of studies on the production of biodegradable plastic precursors, 3-hydroxybutyrate, L-malate and fumarate from CO<sub>2</sub> and small organic molecules using an organic dye-based photoredox system with an electron donor, an electron mediator and enzyme-based biocatalytic processes.

## Introduction

Plastic is a versatile, lightweight, and relatively inexpensive material that has been an indispensable part of modern life.<sup>1</sup> Most plastics are made from fossil resources, primarily petroleum, and their entire manufacturing process lead to increasing

**Yu Kita**

Miss Yu Kita received her BSc and MSc from Osaka City University in 2020 and 2022, respectively, under the supervision of Professor Yutaka Amao. She has been working at Nippon Shokubai Co., Ltd since April 2023. Her research interest lies in the development of a solar-driven carbon dioxide-based synthesis system for biodegradable plastic precursors, such as 3-hydroxybutyrate, using a photo-/bio-hybrid catalyst system.

**Mika Takeuchi**

Miss Mika Takeuchi received her BSc from Osaka City University in 2021 and her MSc from Osaka Metropolitan University in 2023 under the supervision of Professor Yutaka Amao. She has been working at Daicel Corporation since April 2024. Her research interest in graduate school was the development of a solar-driven system for biodegradable plastic precursor production such as fumarate from carbon dioxide and biobased material using a photo-/bio-hybrid catalyst.

greenhouse gas emissions.<sup>2</sup> Plastics pose environmental pollution concerns throughout their life cycle, from production to use and ultimately disposal.<sup>3,4</sup> However, plastics have a wide range of functions and are useful materials that support modern society, so it is necessary to establish methods for their production, use, and disposal without causing environmental pollution.<sup>5</sup> Accordingly, biodegradable plastics are attracting attention as a material to replace conventional plastics.<sup>6–12</sup> Biodegradable plastics and their derivative materials are broken down by microbes into water and CO<sub>2</sub> within a period of time.<sup>13–17</sup> Among the various biodegradable plastics, aliphatic polyester-based biodegradable plastics include poly(lactic acid) (PLA),<sup>18–21</sup> poly(hydroxyalkanoate) (PHA),<sup>22–31</sup> poly(glycolic acid) (PGA),<sup>32–35</sup> poly(caprolactone) (PCL),<sup>36–40</sup> poly(butylene succinate) (PBS),<sup>41–44</sup> poly(carbonate)<sup>45–49</sup> and so on, as shown in Fig. 1.

The precursors of these biodegradable plastics are synthesised from various molecules, such as biological and petroleum-derived molecules. Therefore, it is required to establish precursor synthesis methods from renewable raw materials such as CO<sub>2</sub> and biomass-derived molecules in the future. In natural photosynthesis, visible light energy is used as the driving force to produce glucose, starch, and oxygen using CO<sub>2</sub> and water as raw materials.<sup>50–55</sup> Thus, natural photosynthetic processes can serve as models for the CO<sub>2</sub>-based synthesis of polymers and their precursors. Natural photosynthesis consists of light-dependent reactions and dark reactions. The main components involved in the light-dependent reactions are the photosystem, the complexes

Fig. 1 Chemical structures of typical biodegradable plastics.

that capture light energy, chlorophyll, the main light-absorbing pigments, the electron transport chain that transports electrons and contributes to the production of adenosine triphosphate (ATP) and the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH), ATP synthase and ferredoxin NADP<sup>+</sup> reductase. In summary, a light-dependent reaction is a process that converts absorbed visible-light energy into ATP and NADPH.

The dark reactions, collectively known as the Calvin cycle,<sup>56,57</sup> do not directly require visible-light energy but utilize the ATP and NADPH produced during the light-dependent reactions to fix CO<sub>2</sub> into organic compounds, such as ribulose-1,5-bisphosphate, and convert them into glucose through enzymatic processes. Biodegradable plastics and their precursors are synthesized starting from compounds synthesized from CO<sub>2</sub> produced in the Calvin cycle using microalgae. It has been reported that D-lactate, a precursor for poly(lactic acid), was produced using malic enzyme (ME)-overexpressing strains of cyanobacterium *Synechocystis* sp. PCC6803, as shown in Fig. 2.<sup>58</sup>

A metabolic map of the TCA cycle in *Synechocystis* sp. PCC 6803 is shown in Fig. 3.<sup>59</sup> As shown in Fig. 3, not only D-lactate but also various biodegradable plastic precursors, such as succinate, 3-hydroxybutyrate, and 3-hydroxypropionate, can be produced from CO<sub>2</sub> under visible-light irradiation using *Synechocystis* sp. PCC 6803. Additionally, poly(hydroxybutyrate) (PHB) is produced from CO<sub>2</sub> using *Synechocystis* sp. PCC 6803. The metabolic map in Fig. 3 shows that the production of acetyl Co-A from CO<sub>2</sub> leads to the production of various biodegradable plastic precursors. It will also be possible to produce biodegradable plastic precursors, such as fumarate and malate.

In this way, by linking the TCA cycle and glycolysis with the photosynthetic process, it is possible to synthesize biodegradable plastics and their precursors from CO<sub>2</sub> driven by light energy.

To develop a visible-light driven process for the production of CO<sub>2</sub>-based biodegradable plastics and their precursors, based on the mechanisms of natural photosynthesis and microalgae, a method of linking light-driven redox (light-dependent reaction) with reactions mediated by biocatalytic

Yutaka Amao

Professor Yutaka Amao received his doctorate in Engineering in 1997 from the Tokyo Institute of Technology, Japan. He worked as a Researcher at the Kanagawa Academy of Science and Technology from 1997 to 1998, as a researcher at the National Aerospace Laboratory from 1998 to 2001, and as an Associate Professor in the Department of Applied Chemistry of Oita University from 2001 to 2013. He also worked as a

PRESTO Researcher at the Japan Science and Technology Agency from 2011 to 2016. From 2013 to 2020, he was a Full Professor at the Advanced Research Institute for Natural Science and Technology, Osaka City University. In 2020, he was appointed as a Full Professor at the Research Centre for Artificial Photosynthesis, Osaka City University (now Osaka Metropolitan University after its merger with Osaka Prefecture University in 2022). He was appointed as a Fellow of the Royal Society of Chemistry in 2018. His current research interests include the development of photocatalysts, molecular catalysts, biocatalysts, and strategies for the carbon dioxide conversion to organic molecules using hybrid catalysis systems.

Fig. 4 CO<sub>2</sub>-based biodegradable plastics and their precursor production using systems comprising visible-light-driven redox reactions and biocatalytic processes.

plastics and their precursors can be produced by fixing CO<sub>2</sub> to organic molecules using visible-light energy as a driving force.

In this review article, recent research on the visible-light-driven production of CO<sub>2</sub>-based biodegradable plastics and their precursors with a system comprising light-driven redox and biocatalytic processes is introduced. First, research on the production of biodegradable plastics and their precursors using semiconductor photocatalysts as photoredox and microorganisms as biocatalytic processes is introduced. Second, research on the production of biodegradable plastic precursors using organic dye-based photoredox and enzyme-based biocatalytic processes is introduced.

### Strategy for the visible-light-driven production of CO<sub>2</sub>-based biodegradable plastics and their precursors with a photocatalyst and microbial cell hybrid system

Semiconductor-based photocatalysts are highly efficient at capturing and converting solar energy compared to the light-harvesting function of natural photosynthesis. Meanwhile, natural CO<sub>2</sub> fixation, primarily by plants and microorganisms, is the basis of life and biological processes. By directly contacting semiconductor-based photocatalysts with microbial cells expressing a CO<sub>2</sub> fixation pathway, as shown in Fig. 5(a), light-driven biodegradable plastics and their precursors can be produced. Additionally, a system for biodegradable plastics and their precursor production from CO<sub>2</sub> using microbial cells and extract containing enzymes as the biocatalyst in a visible light-driven redox system, consisting of an electron donor (ED), a visible light sensitizer (PS), and an electron mediator (EM), has been proposed, as shown in Fig. 5(b).

In the system shown in Fig. 5(a) and (b), a visible light-responsive photocatalyst capable of decomposing water into oxygen and hydrogen is used.<sup>60–65</sup> However, the CO<sub>2</sub> fixation pathway within microbial cells for the production of biodegradable plastics and their precursors is shown in Fig. 6. As shown in Fig. 6, natural CO<sub>2</sub> fixation pathways are classified into the following six categories: Calvin Benson Bassham (CBB) cycle,<sup>66</sup> 3-hydroxypropionate pathway,<sup>67</sup> reductive acetyl-CoA (Wood-Ljungdahl (WL) pathway) pathway,<sup>68</sup> reductive TCA cycle,<sup>69</sup> dicarboxylate/4-hydroxybutyrate cycle,<sup>70</sup> and 3-hydroxypropionate/4-hydroxybutyrate cycle.<sup>71</sup> In particular, the reductive acetyl-CoA

processes such as microbial or enzymes (dark reaction) has been envisaged, as shown in Fig. 4.

Using semiconductor photocatalysts and organic dyes in a light-driven redox system, light-harvesting and sensitizing functions can be enhanced compared to natural photosynthesis, such as that in microalgae. Biocatalytic processes use microorganisms directly or through cascades of enzymes to produce biodegradable plastics and their precursors from CO<sub>2</sub>. By linking these two processes, it is expected that biodegradable

Fig. 5 Visible-light-driven production of biodegradable plastics and their precursors based on CO<sub>2</sub> fixation using a photocatalyst and microbial cell hybrid system (a) and a hybrid system of photoredox consisting of an electron donor (ED), a visible light sensitizer (PS), and an electron mediator (EM) and the microbial cells or biocatalysts (b).

pathway, known as the Wood-Ljungdahl (WL) pathway, is expressed in *Moorella thermoacetica* (*M. thermoacetica*) and is used to produce acetate from CO<sub>2</sub><sup>72–75</sup> combined with a photocatalyst.

### Visible-light-driven acetate production from CO<sub>2</sub> with a photocatalyst and microbial cell hybrid system

First, a production system for acetate, a precursor of biodegradable plastics, from CO<sub>2</sub> using a combination of photocatalysts is introduced.

Visible-light-driven acetate production from CO<sub>2</sub> using the hybridisation of CdS nanoparticles and *M. thermoacetica* has been accomplished. Fig. 7(A) shows a schematic representation

Fig. 7 Image of the visible-light-driven acetate production from CO<sub>2</sub> using a hybrid system comprising CdS nanoparticles and *M. thermoacetica* (A). Mechanism of visible-light-driven acetate production from CO<sub>2</sub> using CdS nanoparticles and *M. thermoacetica* in the presence of Cys (B). Reproduced with permission from ref. 76. Copyright 2016, the American Association for the Advancement of Science.

Fig. 6 Six natural CO<sub>2</sub> fixation pathways: (a) Calvin Benson Bassham (CBB) cycle. (b) 3-hydroxypropionate pathway. (c) Wood-Ljungdahl (WL) pathway. (d) Reductive TCA cycle. (e) Dicarboxylate/4-hydroxybutyrate cycle. (f) Hydroxypropionate/4-hydroxybutyrate cycle.

of acetate production from CO<sub>2</sub> using a hybrid system comprising CdS nanoparticles and *M. thermoacetica* (ATCC 39073) under visible-light irradiation.<sup>76</sup>

In this system, acetate can be produced from CO<sub>2</sub> using the photosensitizing function of CdS and the WL pathway in *M. thermoacetica*. In this system, CdS is constantly regenerated by incorporating cysteine (Cys) into the reaction. Visible-light-driven acetate production by *M. thermoacetica* and CdS is a two-step, one-pot synthesis, as shown in Fig. 7(B). First, CdS precipitation by *M. thermoacetica* is induced by adding Cd<sup>2+</sup> and cysteine as sulfur sources.<sup>77</sup> *M. thermoacetica* performs acetate production using electrons generated from irradiated CdS nanoparticles, as shown in Fig. 7(B).

The Cys quenches h<sup>+</sup> of CdS, producing the oxidized disulfide form of cystine (CySS). Overall, this process is shown in Fig. 8.

Fig. 9 shows the time dependence of acetate production using a hybrid system of CdS–*M. thermoacetica* in the presence of Cys. The irradiation source is an in-house fabricated circular LED array composed of 405 ± 5 nm violet LEDs with a measured photon flux of 5.5 × 10<sup>18</sup> cm<sup>-2</sup> s<sup>-1</sup>. As shown in Fig. 9, ca. 1.3 mM of acetate production is observed using a hybrid system of CdS–*M. thermoacetica* under visible-light irradiation. However, no acetate production is observed using *M. thermoacetica* under only visible-light irradiation. Moreover, no acetate production is observed using a hybrid system of CdS-sterilised *M. thermoacetica* under visible-light irradiation.

Fig. 8 Overall process for the visible-light-driven acetate production from CO<sub>2</sub> using the hybrid system of CdS–*M. thermoacetica* in the presence of Cys.

Fig. 9 Time dependence of acetate production from CO<sub>2</sub> using the hybrid system of CdS–*M. thermoacetica* in the presence of Cys under visible-light irradiation and dark conditions. Reproduced with permission from ref. 76. Copyright 2016, the American Association for the Advancement of Science.

Additionally, a decrease in the acetate concentration is observed under dark conditions. A maximum yield of ca. 90% acetate based on the initial Cys concentration is accomplished using a hybrid system of CdS–*M. thermoacetica* under visible-light irradiation. After 12 h of irradiation, 1.43 mM of acetate is produced.

Visible-light-driven acetate production using CO<sub>2</sub> as a raw material has also been reported using a hybrid system comprising gold nanoparticles (AuNPs) and *M. thermoacetica*.<sup>78</sup> Using this system, acetate production is estimated to be 6.01 mmol g<sup>-1</sup> per week.

A tandem inorganic–biological hybrid system consisting of a TiO<sub>2</sub> nanoparticle loaded with a manganese(II) phthalocyanine (MnPc) cocatalyst, CdS and *M. thermoacetica* capable of oxygenic photosynthesis of acetate from CO<sub>2</sub> has been reported.<sup>79</sup> Fig. 10(A) shows a schematic representation of acetate production from CO<sub>2</sub> using a hybridisation system comprising CdS nanoparticles and *M. thermoacetica* under visible-light irradiation.

A feature of this system is that the photooxidation catalyst TiO<sub>2</sub> is loaded with the cocatalyst MnPc to regenerate the CySS/Cys redox shuttle, thereby coupling water oxidation with CySS reduction. Fig. 10(B) shows the time dependence of acetate production using the tandem system of TiO<sub>2</sub> nanoparticles loaded with MnPc, CdS and *M. thermoacetica* in the presence of Cys. The irradiation source is a filtered 75 W Xenon lamp (AM1.5G, 5% Sun).

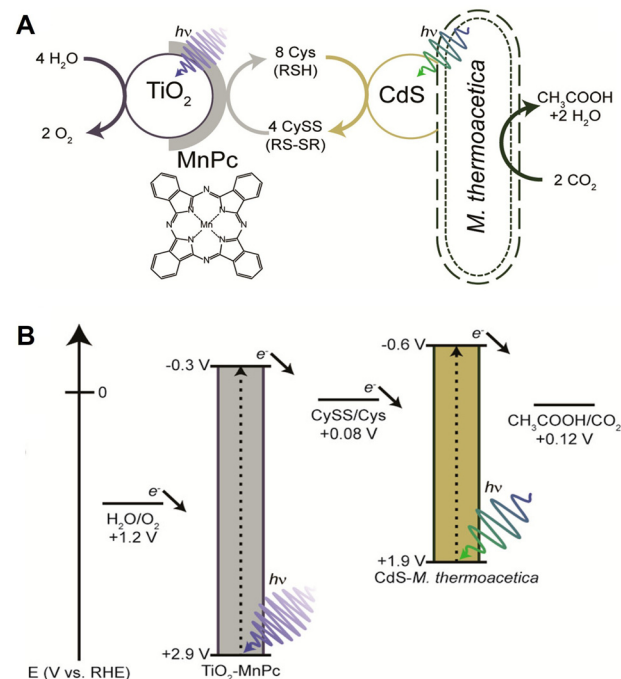

Fig. 10 Visible-light-driven acetate production from CO<sub>2</sub> using a hybrid system comprising TiO<sub>2</sub> nanoparticles loaded with MnPc, CdS nanoparticles and *M. thermoacetica* (A). Energy level diagram depicting the relative alignment of the energies of TiO<sub>2</sub> and CdS with the relevant redox processes (B). Reproduced with permission from ref. 79. Copyright 2016, American Chemical Society.

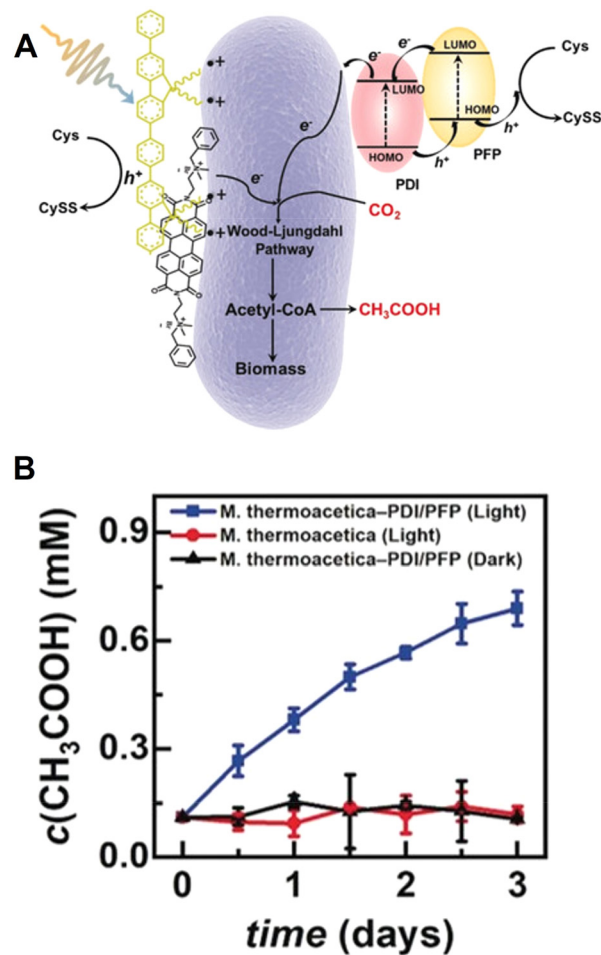

As shown in Fig. 11, comparing CdS-*M. thermoacetica* and MnPc-loaded TiO<sub>2</sub> to the control, the combined tandem system shows increased acetate production. Both CdS-*M. thermoacetica* alone and the MnPc-loaded TiO<sub>2</sub>-*M. thermoacetica* control shows reduced acetate production below the stoichiometric limit imposed by Cys. Without MnPc, the TiO<sub>2</sub>-only tandem system performed poorly. A comparison of the cumulative electron equivalents of acetate (8e<sup>-</sup>) and O<sub>2</sub> (4e<sup>-</sup>) measured over 3.5 days shows a strong correlation between the reduced product, acetate and the oxidized product, O<sub>2</sub>. Using this system, 1.2 mM of acetate is produced after 1 day.

Visible-light-driven acetate production from CO<sub>2</sub> has been reported in which perylene diimide derivatives (PDI) and poly(fluorene-co-phenylene) (PFP) are applied to the *M. thermoacetica* surface as photosensitizers to form a p-n heterojunction (PFP/PDI) layer, as shown in Fig. 12(A).<sup>80</sup>

The accumulated acetate yield of PDI/PFP/*M. thermoacetica* (ca. 0.63 mM) is significantly higher than that of PDI/*M. thermoacetica* (ca. 0.25 mM) or PFP/*M. thermoacetica* (ca. 0.4 mM)

**Fig. 11** Time dependence of acetate production from CO<sub>2</sub> with a tandem system comprising TiO<sub>2</sub> nanoparticles loaded with MnPc, CdS and *M. thermoacetica* in the presence of Cys under visible-light irradiation (■) (A). □: Tandem system comprising TiO<sub>2</sub> nanoparticles, CdS and *M. thermoacetica*, ▲: hybrid system comprising CdS and *M. thermoacetica*, ●: hybrid system of TiO<sub>2</sub> nanoparticles loaded with MnPc and *M. thermoacetica*. under irradiation using a Xenon fiber optic lamp with filters larger than 420 nm. Fig. 12(B) shows the time dependence of the acetate produced using PDI/PFP/*M. thermoacetica* in an alternating light-dark cycle of 12 h each.

After 3 days of incubation with irradiation, the accumulation amount of the acetate is estimated to be 0.63 mM. The quantum yield of 1.6% is calculated based on the initial Cys concentration. Here, the quantum yield is calculated using eqn (1) ( $n$ : number of electrons,  $C$ : total acetate concentration,  $V$ : total suspension volume,  $\phi$  (cm<sup>-2</sup> s<sup>-1</sup>): photo flux,  $A$ : area of illumination,  $t$ : reaction time, and  $N_A$ : Avogadro's number). Acetate is produced by the 8-electron reduction of CO<sub>2</sub>; therefore, the  $n$  value is 8.

$$\text{Quantum yield (\%)} = \frac{nCVN_A}{\phi tA} \times 100 \quad (1)$$

where  $n$ : number of electrons,  $C$ : total acetate concentration,  $V$ : total suspension volume,  $\phi$  (cm<sup>-2</sup> s<sup>-1</sup>): photo flux,  $A$ : area of

illumination ( $5 \text{ cm}^2$ ),  $t$ : reaction time, and  $N_A$ : Avogadro's number.

*Sporomusa ovata* (*S. ovata*) is a type of bacterium characterized by banana-shaped cells. *S. ovata* cells are strictly anaerobic, Gram-negative, spore-forming, straight or slightly curved rods that are motile by lateral flagella.<sup>81</sup> There has been much research on the electrosynthesis of energy-containing carbon chains using *S. ovata*.<sup>82,83</sup> *S. ovata* is a candidate biological catalyst that converts sunlight, water, and  $\text{CO}_2$  into oxygen and liquid fuel or variable chemicals.

Visible-light-driven acetate production from  $\text{CO}_2$  using the hybridisation of CdS nanoparticles and *S. ovata* (CdS-*S. ovata*) has also been accomplished. Fig. 13 (A) shows a schematic representation of acetate production from  $\text{CO}_2$  using CdS-*S. ovata* under visible-light irradiation.<sup>84</sup>

In this system, photoelectrons are generated by CdS under light irradiation and transferred to *S. ovata* to achieve acetate

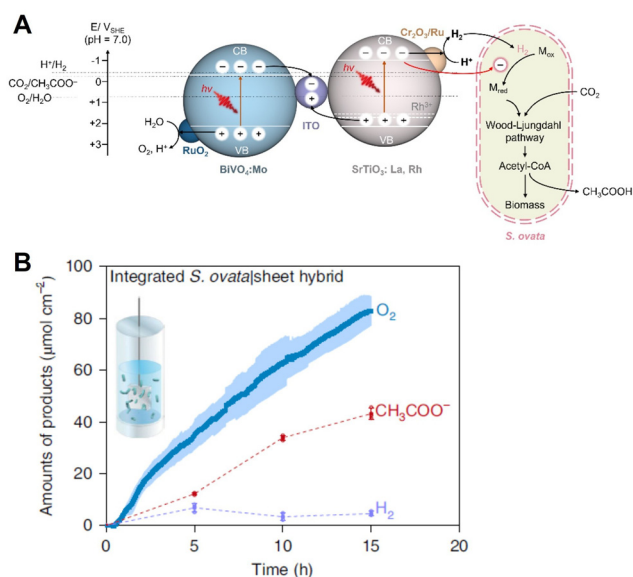

**Fig. 13** Schematic of the visible-light-driven acetate production from  $\text{CO}_2$  using CdS-*S. ovata* (A). Acetate production using CdS-*S. ovata* after 1 day of light irradiation in the presence of Cys. Bio-CdS (No Cys + Light): in the absence of Cys, Bio (light): only *S. ovata*, Bio(Dead)-CdS (Light): sterilized *S. ovata* and CdS hybrid system, Bio-CdS ( $\text{N}_2$  + Light): without  $\text{CO}_2$  gas, CdS (Light): only CdS. production using  $\text{CO}_2$  as a raw material *via* the WL pathway. In this system, it is found that formate is produced as an intermediate and then is rapidly converted to the final product, acetate. Fig. 13(B) shows the visible-light-driven acetate production using CdS-*S. ovata* after 1 day of light irradiation and the controls in the presence of Cys. The intensity of light ( $400 \pm 5 \text{ nm}$ ) is estimated to be  $0.20 \text{ mW cm}^{-2}$ . Each experiment is pressurized with 2.0 atm, 80%  $\text{N}_2$  and 20%  $\text{CO}_2$ . In this figure, Bio-CdS means CdS-*S. ovata*. As shown in Fig. 13(B), a high concentration of acetate is observed using CdS-*S. ovata* during visible-light irradiation in contrast to the other systems. Using CdS-*S. ovata*, the quantum yield reaches  $16.8\% \pm 9\%$ , and the active time of the system can last for 5 days. The quantum yield is also estimated using eqn (1).

Visible-light-driven acetate production from  $\text{CO}_2$  by the hybridization of a Z-scheme semiconductor photocatalytic system with *S. ovata* has been reported, as shown in Fig. 14(A).<sup>85</sup> In this system, the Z-scheme consists of particulate semiconductors La and Rh co-doped  $\text{SrTiO}_3$  ( $\text{SrTiO}_3$ : La, Rh) and Mo-doped  $\text{BiVO}_4$  ( $\text{BiVO}_4$ : Mo). In this system, photocatalytic particles are immobilised onto a sheet.

Using the hybridization of a Z-scheme semiconductor photocatalytic system consisting of  $\text{SrTiO}_3$ : La, Rh and  $\text{BiVO}_4$ : Mo with *S. ovata*, *ca.* 40 and  $80 \mu\text{mol cm}^{-2}$  of acetate and oxygen production are observed after 15 h with 1 sun ( $\text{AM } 1.5\text{G}$ ,  $100 \text{ mW cm}^{-2}$ ) irradiation, as shown in Fig. 14(B). A gas mixture of 80%  $\text{N}_2$  and 20%  $\text{CO}_2$  is used in this system. The solar energy to acetate efficiency is estimated to be  $0.70\% \pm 0.04\%$ , and the apparent quantum yield is calculated to be

**Fig. 14** Schematic of the visible light-driven acetate production from  $\text{CO}_2$  by the hybridization of a Z-scheme semiconductor photocatalytic system consisting of  $\text{SrTiO}_3$ : La, Rh and  $\text{BiVO}_4$ : Mo with *S. ovata* (A). Time course of photosynthetic acetate,  $\text{O}_2$  and  $\text{H}_2$  production over *S. ovata*| $\text{Cr}_2\text{O}_3$ /Ru- $\text{SrTiO}_3$ :La,Rh|ITO| $\text{RuO}_2$ - $\text{BiVO}_4$ :Mo hybrids (B). 21.3% at  $420 \pm 15$  nm. The quantum yield is also estimated using eqn (1) in this experiment.

Visible-light-driven acetate production from  $\text{CO}_2$  using a system that hybridises a semiconducting polymer with *S. ovata* is also studied.<sup>86</sup> The polymer semiconductor poly(3-hexylthiophene) (P3HT; chemical structure is shown in Fig. 15), widely used in the organic photovoltaic field,<sup>87,88</sup> is applied in this system.

Fig. 16 shows the schematic representation of visible-light-driven acetate production from  $\text{CO}_2$  using a system of P3HT immobilised onto an indium tin oxide (ITO) coated glass substrate and *S. ovata* in the presence of Cys and an electron mediator (M).

Fig. 17 shows a schematic diagram of the exciton generation, separation, and transport processes in P3HT, [6,6]-phenyl- $\text{C}_{61}$ -butyric acid methyl ester (P3HT:PCBM) heterojunction (bulk heterojunction (BHJ)), and a film with an ITO/ZnO/P3HT:PCBM/ $\text{MoO}_3$  multilayer structure.

Here, visible-light-driven acetate production from  $\text{CO}_2$  is investigated using a hybrid system comprising each P3HT-immobilised device and *S. ovata*. Cys and potassium ferricyanide are added as a hole-trapping agent and an electron mediator, respectively. The LED white light is used as an irradiation source with adjustable light intensity. A gas mixture

Fig. 15 Chemical structure of P3HT.

Fig. 16 Schematic of the visible light-driven acetate production from  $\text{CO}_2$  using a system of P3HT immobilised ITO substrate with *S. ovata* in the presence of Cys and M. Reproduced with permission from ref. 86. Copyright 2024, the American Association for the Advancement of Science.

Fig. 17 Schematic of the exciton separation and recombination of polymer semiconductor films with P3HT, P3HT:PCBM bulk-heterojunction (BHJ), and multilayer film structures. of 80%  $\text{N}_2$  and 20%  $\text{CO}_2$  is used as a carbon source in this system. Fig. 18 shows the total amount of acetate production from  $\text{CO}_2$  using a hybrid system comprising each P3HT-immobilised device and *S. ovata*.

It is found that acetate production is improved using the hybrid system comprising ITO/ZnO/P3HT:PCBM/ $\text{MoO}_3$  multilayer and *S. ovata* compared to other devices, as shown in Fig. 18. The quantum yield of the hybrid system comprising ITO/ZnO/P3HT:PCBM/ $\text{MoO}_3$  multilayer and *S. ovata* reaches about 10%, which is obviously higher than 0.5% of the control system without a polymer semiconductor device. Additionally, in this experiment, the quantum yield is estimated using eqn (1).

Visible-light-driven acetate production from  $\text{CO}_2$  using a system hybridising InP/ZnSe/ZnS quantum dots (QDs) with *S. ovata* in the presence of Cys and potassium ferricyanide is studied.<sup>89</sup> InP with a bandgap of 1.35 eV and a Bohr radius of approximately 10 nm can effectively absorb visible light.<sup>90</sup> Fig. 19(A) shows the schematic representation of visible-light-

driven acetate production from  $\text{CO}_2$  using a hybridising system of InP/ZnSe/ZnS QDs and *S. ovata*.

By growing a multilayer shell of ZnSe and ZnS on InP QDs synthesized using the hot injection method, the surface of the QDs can be passivated, and the stability of the InP QDs can be improved.<sup>91,92</sup> Furthermore, the low biotoxicity of InP QDs makes them potentially promising biological hybrid materials.<sup>93</sup>

In this system, Cys and potassium ferricyanide are also added as a hole-trapping agent and an electron mediator, respectively. The Xenon lamp with an AM 1.5 G filter is used as the irradiation source with adjusted light intensity. A gas mixture of 80%  $\text{N}_2$  and 20%  $\text{CO}_2$  is used as the carbon source in this system. Fig. 20(B) shows the total amount of acetate production from  $\text{CO}_2$  using a hybridising system comprising InP/ZnSe/ZnS QDs and *S. ovata*. It is found that acetate production is improved using the hybridising system comprising InP/ZnSe/ZnS QDs and *S. ovata* in the presence of ferricyanide compared to other conditions, as shown in Fig. 20(B). The quantum yield of the hybridising system comprising InP/ZnSe/ZnS QDs and *S. ovata* in the presence of ferricyanide reaches about 7.0% estimated using eqn (1).

Visible-light-driven acetate production from  $\text{CO}_2$  using a photoelectrochemical cell consisting of silicon nanowire integrated *S. ovata* as a photocathode has been reported, as shown in Fig. 20.<sup>94</sup>

Fig. 20 Schematic of a photoelectrochemical cell consisting of silicon nanowire-integrated *S. ovata*: (a) Proposed approach for solar-powered  $\text{CO}_2$  fixation includes four general steps: (1) harvesting solar energy, (2) generating reducing equivalents, (3) reducing  $\text{CO}_2$  to biosynthetic intermediates, and (4) producing value-added chemicals. Through the integration of materials science and biology, such an approach combines the advantages of solid-state devices with living organisms. (b) As a proof of concept, under mild conditions, sunlight can provide the energy to directly treat exhaust gas and generate acetate as the biosynthetic intermediate, which can be upgraded into liquid fuels, biopolymers, and pharmaceutical precursors. FPP: farnesyl pyrophosphate. Reproduced with permission from ref. 94. Copyright 2015, American Chemical Society.

Using a photoelectrochemical cell consisting of silicon nanowire integrated with *S. ovata*, visible-light acetate production is accomplished. Moreover, variable organic molecules are produced using a hybridisation system comprising engineered *E. coli* with this photoelectrochemical cell. In addition, it has been found that acetate production is improved using methanol-adapted *S. ovata* in this system.<sup>95</sup>

### Visible-light-driven production of other plastic precursors from $\text{CO}_2$ using a photocatalyst and microbial cell hybrid system

Other plastic precursors that can be produced from  $\text{CO}_2$  driven by visible light using a photocatalyst and microbial cell hybrid system are introduced.

Shikimic acid is a precursor for lignin production and can be a raw material for bioplastics.<sup>96</sup>

Visible-light-driven shikimic acid production using a system of polyphenol-functionalised indium phosphide (InP) with common heterotrophs, *Saccharomyces cerevisiae* (*S. cerevisiae*), has been reported, as shown in Fig. 21.<sup>97</sup> In this system, yeast strain *S. cerevisiae*  $\Delta\text{zwf1}$  is selected. *S. cerevisiae*  $\Delta\text{zwf1}$  is genetically engineered to overexpress four genes to enhance carbon flux through the shikimic acid pathway.<sup>98</sup>

Fig. 22 shows the specific shikimic acid production with the system using InP-*S. cerevisiae*  $\Delta\text{zwf1}$  under visible-light

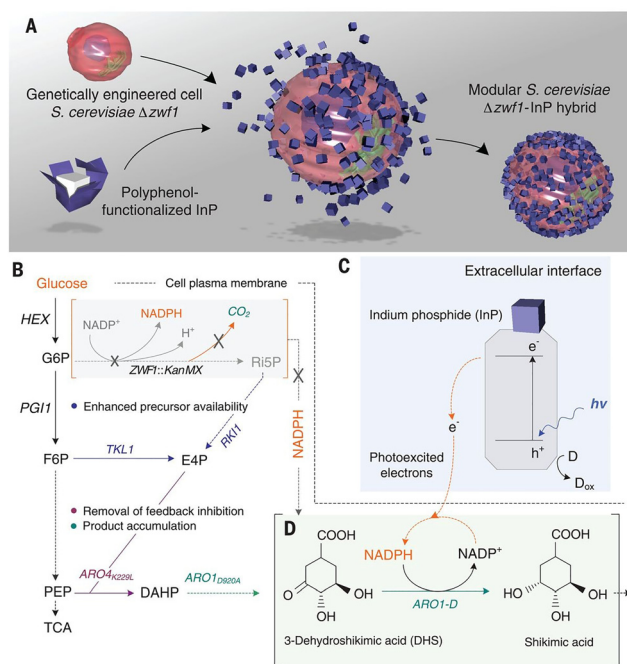

Fig. 21 Schematic of the preparation of InP-*S. cerevisiae*  $\Delta zwf1$  (A). Metabolic engineering diagram for the overproduction of shikimic acid. *S. cerevisiae*  $\Delta zwf1$  has the oxidative pentose phosphate pathway disrupted (ZWF1), leading to low cytosolic NADPH pools, which directly affect the shikimic acid pathway and reduce carbon loss in the production of  $\text{CO}_2$  (B). Schematic of the cellular NADPH regeneration and shikimic acid biosynthesis assisted by photogenerated electrons from InP nanoparticles (C and D). G6P, glucose-6-phosphate; F6P, fructose-6-phosphate; Ri5P, ribulose-5-phosphate; E4P, erythrose-4-phosphate; PEP, phosphoenolpyruvate; DAHP, 3-deoxy-d-arabinoheptulosonate-7-phosphate; HEX, hexokinase; ZWF1, glucose-6-phosphate 1-dehydrogenase; PGI1, phosphoglucose isomerase; RKI1, ribose-5-phosphate ketol-isomerase; TKL1, transketolase; ARO4<sub>K229L</sub>, feedback-insensitive DAHP synthase; ARO1<sub>D920A</sub>, mutant pentafunctional aromatic enzyme; TCA, tricarboxylic acid cycle;  $h$ , Planck's constant;  $\nu$ , frequency;  $h^+$ , electron hole;  $e^-$ , electron;  $D$ , putative electron donors in the cell culture medium;  $D_{ox}$ , oxidized electron donor species. irradiation ( $5.6 \text{ mW cm}^{-2}$ ). The specific shikimic acid production with *S. cerevisiae*  $\Delta zwf1$  or wild-type *S. cerevisiae* under the conditions of dark incubation is shown in Fig. 22. As shown in Fig. 22, the specific shikimic acid production increases using InP-*S. cerevisiae*  $\Delta zwf1$  under visible-light irradiation compared with that of the system using *S. cerevisiae*  $\Delta zwf1$  or wild-type *S. cerevisiae* under dark conditions.

3-Hydroxybutanone (acetoin) and 2,3-butanediol are two important four-carbon platform compounds with pharmaceutical and chemical synthesis applications.<sup>99–102</sup> (S,S)-Butane-2,3-diol is produced from acetoin in the presence of NADH with (S,S)-butanediol dehydrogenase (BDH; EC EC 1.1.1.76), as shown in Fig. 23.

Visible-light-driven acetoin production from  $\text{CO}_2$  with a hybrid system comprising eosin Y and *Ralstonia eutropha* (*R. eutropha*) has been reported.<sup>106</sup> *R. eutropha* has attracted significant research attention due to its excellent  $\text{CO}_2$  fixation

Fig. 22 Total shikimic acid production with InP-*S. cerevisiae*  $\Delta zwf1$  under visible-light irradiation ( $5.6 \text{ mW cm}^{-2}$ ), with *S. cerevisiae*  $\Delta zwf1$  or wild-type *S. cerevisiae* under the condition of dark incubation. Fig. 23 BDH-catalysed (S,S)-butane-2,3-diol production from acetoin in the presence of NADH.

capacity and potential for expanding production diversity.<sup>107</sup> Fig. 24 shows the schematic representation of a hybrid system comprising eosin Y and *R. eutropha* for visible-light acetoin production from  $\text{CO}_2$ . In this system, eosin Y specifically binds to the membrane-bound hydrogenase (MBH) of *R. eutropha* and achieves targeted electron transfer to the hydrogenase-mediated electron transport and transformation pathway of

Fig. 24 Visible-light-driven acetoin production from  $\text{CO}_2$  using a hybrid system comprising eosin Y and *R. eutropha*. Reproduced with permission from ref. 106. Copyright 2025, The Authors. Published by Elsevier Ltd. Creative Commons CC-BY license.

*R. eutropha* (pathway I). To enhance ATP synthesis, an oxygen-independent proton pump (*Gloeobacter rhodopsin*) is introduced into *R. eutropha* (pathway II). To promote carbon metabolic flux towards acetoin production, the by-product biosynthetic pathway is blocked (pathway III). The genetically engineered *R. eutropha* strain named REH01 is used in this system.

Fig. 25(A) shows the time dependence of acetoin production using a hybrid system comprising eosin Y and REH01 during visible-light irradiation using LED lamps ( $\lambda = 520$  nm) with a certain light intensity (2, 5, or 10 mW cm<sup>-2</sup>). Throughout the reaction, a gas mixture of CO<sub>2</sub>/O<sub>2</sub> (molar ratio: 99/1) is continuously sparged into the reaction system. In this figure, biohybrid means a hybrid system comprising eosin Y and REH01.

As shown in Fig. 25(A), ca. 0.8 mM of acetoin production is observed after 24 h of irradiation. However, little acetoin

production has been observed under other conditions. Furthermore, metabolic engineering strategies have been employed to enhance the acetoin-producing capability of REH01. REH01 strains lacking the GR and/or *ldh* and *ackA2* genes have been prepared. Fig. 25(B) shows the time dependence of acetoin production with a hybrid system comprising eosin Y and genetically modified REH01 during visible-light irradiation. As shown in Fig. 25(B), the engineered eosin Y-GR expressing REH01 without the *ldh* and *ackA2* biohybrid system achieves an acetoin yield of 1.41 ± 0.06 mM, which is 2.07 times larger than that of H<sub>2</sub>-supplied autotrophic fermentation. Therefore, carbon flux can be directed towards acetoin production by inhibiting the L-lactate and acetate biosynthetic pathways.

### Visible-light-driven polyhydroxybutyrate (PHB) production from CO<sub>2</sub> using a photocatalyst and microbial cell hybrid system

Among biodegradable plastics based on aliphatic polyesters, plastics derived from poly-3-hydroxybutyrate (PHB) are attractive because they are compostable, made from renewable feedstocks, and biodegradable.<sup>108–115</sup> The PHB can be produced from CO<sub>2</sub> driven by visible light using a photocatalyst and a microbial cell hybrid system. A hydrogen-oxidizing bacterium, *Ralstonia eutropha*, is used as a microbial cell for PHB production.<sup>116</sup>

The PHB production using an electrochemical system comprising cobalt-phosphorus (Co-P) alloy cathode and cobalt phosphate (CoP<sub>i</sub>) anode with *Ralstonia eutropha* is reported for the first time.<sup>117</sup>

Visible-light-driven PHB production with a system comprising photocatalyst graphitic carbon nitride (g-C<sub>3</sub>N<sub>4</sub>) and *Ralstonia eutropha* H16 in the presence of triethanol amine (TEOA) is reported, as shown in Fig. 26(A).<sup>118</sup> As shown in Fig. 26(A), PHB is produced in *Ralstonia eutropha* H16 by utilizing the TCA cycle, Calvin-Benson-Bassham (CBB) cycle, NADH regeneration, and hydrogen.

Fig. 26(B) shows the total amount of PHB production using g-C<sub>3</sub>N<sub>4</sub> and *Ralstonia eutropha* H16 in the presence of TEOA after 96 h of irradiation using an LED light set at 4200 lux. This figure also shows the amount of PHB produced in the absence of TEOA or g-C<sub>3</sub>N<sub>4</sub>. After 96 h irradiation, PHB production is improved 1.4 times to 6.73 ± 0.45 g l<sup>-1</sup> with the system using g-C<sub>3</sub>N<sub>4</sub> and *Ralstonia eutropha* H16 in the presence of TEOA. However, decreasing PHB production is observed using only *Ralstonia eutropha* H16 or without g-C<sub>3</sub>N<sub>4</sub>.

The development of a water-splitting enzymatic photocatalyst made of g-C<sub>3</sub>N<sub>4</sub> coupled with H<sub>2</sub>O<sub>2</sub>-degrading catalase and its utilisation for a hybrid system with *Ralstonia eutropha* for visible-light-driven PHB production, as shown in Fig. 27(A).<sup>119</sup> Using catalase, it is possible to decompose hydrogen peroxide produced due to the two-electron oxidation of water into oxygen<sup>120</sup> by g-C<sub>3</sub>N<sub>4</sub>.<sup>121</sup>

Fig. 27(B) shows the total amount of PHB production using catalase-modified g-C<sub>3</sub>N<sub>4</sub> and *Ralstonia eutropha* H16 after 48 h of irradiation using a 500 W Xe lamp with an AM1.5G filter.

Fig. 25 Time-dependent acetoin production from CO<sub>2</sub> using a hybrid system comprising eosin Y and REH01 during visible-light irradiation. Red: dark condition, Blue: only REH01, Green: only eosin Y (A). Time dependence of acetoin production from CO<sub>2</sub> using a hybrid system comprising eosin Y and REH01 during visible-light irradiation. Green: eosin Y and GR expressing REH01 without *ldh* and *ackA2*. Blue: eosin Y and REH01 without *ldh* and *ackA2*. Red: eosin Y and GR expressing REH01. Black: eosin Y and REH01 (B). Fig. 26 Schematic of the visible-light-driven PHB production from CO<sub>2</sub> or fructose using a system comprising g-C<sub>3</sub>N<sub>4</sub> and *Ralstonia eutropha* H16 in the presence of TEOA (A). Total PHB production using the system comprising g-C<sub>3</sub>N<sub>4</sub> and *Ralstonia eutropha* H16 in the presence of TEOA after 96 h of irradiation with an LED light set at 4200 lux (B). Reproduced with permission from ref. 118. Copyright 2019, The Royal Society of Chemistry.

This figure also shows the amount of PHB produced using the system only *Ralstonia eutropha* H16, without g-C<sub>3</sub>N<sub>4</sub>, without catalase and under dark conditions.

The hybrid system built using the water-splitting g-C<sub>3</sub>N<sub>4</sub>-catalase photocatalyst doubles the production of the PHB by *Ralstonia eutropha* H16 from CO<sub>2</sub> and increases it by 1.84-fold from fructose. After 48 h of irradiation, ca.41 mg of PHB production is observed using catalase-modified g-C<sub>3</sub>N<sub>4</sub> and *Ralstonia eutropha* H16 without any sacrificial electron donor reagent, such as TEOA.

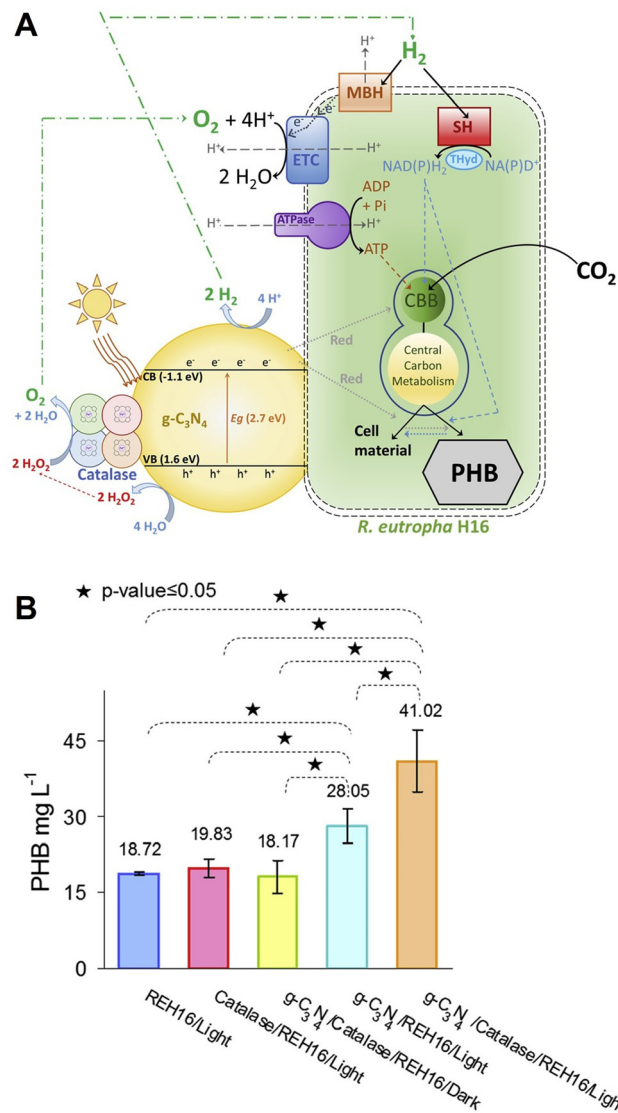

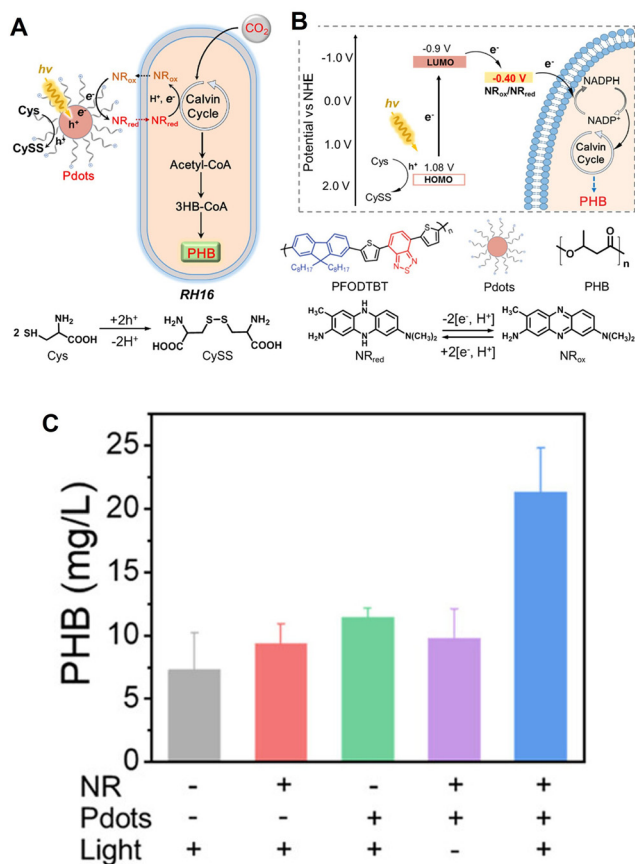

Fig. 27 Schematic of the visible-light-driven PHB production from CO<sub>2</sub> using a system comprising catalase-modified g-C<sub>3</sub>N<sub>4</sub> and *Ralstonia eutropha* H16 (A). Total PHB production using the system comprising catalase-modified g-C<sub>3</sub>N<sub>4</sub> and *Ralstonia eutropha* H16 after 48 h of irradiation using a 500 W Xe lamp with an AM1.5G filter (B). Visible-light-driven PHB production from CO<sub>2</sub> using a system of conjugated polymer dots (Pdots) consisting of poly[*N*-9'-heptadecanyl-2,7-carbazole-*alt*-5,5-(4',7'-di-2-thienyl-2',1',3'-benzothiadiazole)] (PFODTBT) and triblock copolymer ABA, poly(*N,N*-dimethylamino ethyl methacrylate)-*B*-poly(9,9-*N*-diethyl-2,7-fluorene)-*B*-poly(*N,N*-dimethylamino ethyl methacrylate) and PS-PEG-COOH (copolymer polystyrene grafted with carboxy-terminated polyethylene oxide) (PFODTBT Pdots)<sup>122</sup> and *Ralstonia eutropha* H16 (RH16/NR/Pdots) has been reported, as shown in Fig. 28(A) and (B).<sup>123</sup> In this system, Cys and neutral red (NR) are used as an electron donor and an electron mediator, as the example of Fig. 5(b). A Xenon fiber optic lamp with filters is employed using an AM 1.5G filter. The optimal

**Fig. 28** Schematic of the visible-light-driven PHB production from CO<sub>2</sub> with RH16/NR/Pdots (A). Metabolic pathway of PHB production from CO<sub>2</sub> in RH16. 3HB-CoA: 3-hydroxybutyryl-CoA; PHB: polyhydroxybutyrate; h<sup>+</sup>: electron hole; e<sup>-</sup>: electron; Cys: cysteine; CySS: cystine; NR<sub>ox</sub>: the oxidized state of NR; NR<sub>red</sub>: the reduced state of NR (B). Schematic of Pdots promoting PHB production with RH16. Total PHB production using a system of RH16/NR/Pdots in the presence of Cys after 48 h of irradiation. optical power density is determined to be 2.5 mW cm<sup>-2</sup>. A gas mixture of 80% N<sub>2</sub> and 20% CO<sub>2</sub> is used as a carbon source in this system. Under light irradiation, the PHB production of RH16 is estimated to be only 7.3 ± 2.91 mg L<sup>-1</sup> due to accumulation in the initial stage of autotrophic, as shown in Fig. 28(C).

The PHB productions of RH16/Pdots, RH16/NR, and RH16/NR/Pdots (under dark conditions) are estimated to be 9.3 ± 1.56, 11.4 ± 0.76, and 9.8 ± 2.35 mg L<sup>-1</sup>, respectively.

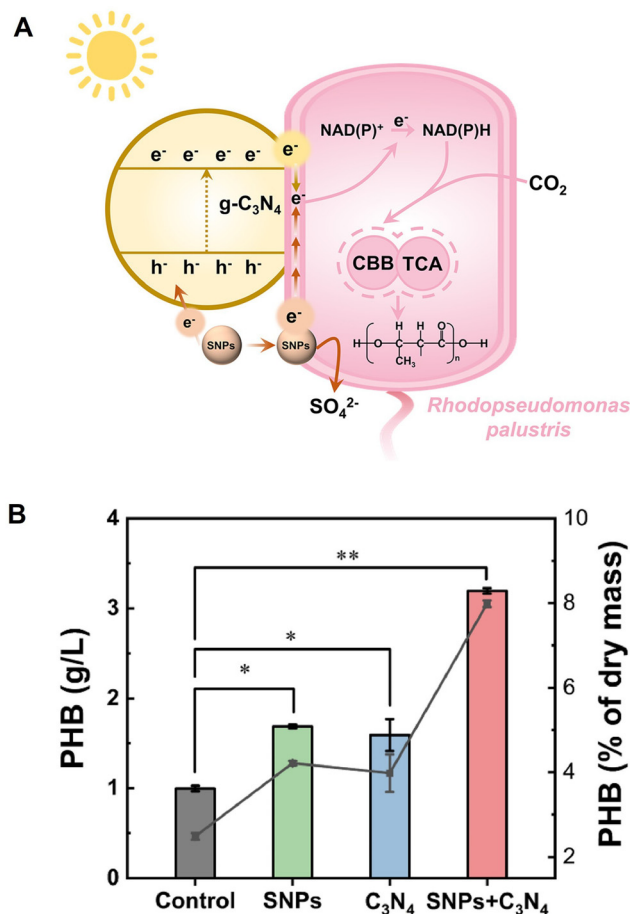

As shown in Fig. 28(C), the production of PHB from the biohybrid system is slightly higher than that of RH16, suggesting that the addition of Pdots and NR is responsible for the increased amount of PHB in the solution. Under visible-light irradiation, the cumulative PHB production of RH16/NR/Pdots (21.3 ± 3.78 mg L<sup>-1</sup>) increases significantly, which is an increase of 192% compared with only RH16. This is mainly because the visible-light-induced electrons of Pdots could be effectively transferred to the inside of RH16 by NR.

Visible-light-driven PHB production using a system comprising photocatalyst g-C<sub>3</sub>N<sub>4</sub> and *Rhodospseudomonas palustris* (*R. palustris*)<sup>124</sup> in the presence of sulfur nanoparticles (SNPs) (g-C<sub>3</sub>N<sub>4</sub>-SNPs-*R. palustris*) is reported, as shown in Fig. 29(A).<sup>125</sup> In this system, SNPs act as dual electron donors, as shown in Fig. 29(A).

Fig. 29(B) shows the total PHB production using a system of g-C<sub>3</sub>N<sub>4</sub>-SNPs-*R. palustris* under irradiation with simulated daylight (~7000 lux) after 8 days. A gas mixture of 80% N<sub>2</sub> and 20% CO<sub>2</sub> is used as a carbon source in this system. Fig. 29(B) shows the PHB concentrations and percentage of cell dry weight occupied by PHB on day 8 (grey line).

The optimized g-C<sub>3</sub>N<sub>4</sub>-SNPs-*R. palustris* achieves a remarkable PHB production titer of 3.19 ± 0.03 g L<sup>-1</sup> with 11.79% ± 0.93% quantum efficiency using solely CO<sub>2</sub> and SNPs.

A homogeneously autotrophic K/O co-doped g-C<sub>3</sub>N<sub>4</sub> (K/O-CN) and *R. eutropha* biohybrid system is reported for visible-light-driven PHB production from CO<sub>2</sub>, as shown in Fig. 30(A).<sup>126</sup> This system introduces nano-sized, scattered rod-like K/O co-doped g-C<sub>3</sub>N<sub>4</sub> (K/O-CN) as a replacement for bulk g-C<sub>3</sub>N<sub>4</sub>,

**Fig. 29** Schematic of visible-light-driven PHB production from CO<sub>2</sub> using a system of g-C<sub>3</sub>N<sub>4</sub>-SNPs-*R. palustris* (A). Total PHB production from CO<sub>2</sub> using a system of g-C<sub>3</sub>N<sub>4</sub>-SNPs-*R. palustris* after 8 days of irradiation (B). Reproduced with permission from ref. 125. Fig. 31 Schematic of the visible-light-driven PHB production from CO<sub>2</sub> using a system of CNNS-*R. eutropha* (A). Time-dependent PHB production from CO<sub>2</sub> using the hybrid system of CNNS-*R. eutropha* under visible-light irradiation (B). Reproduced with permission from ref. 128. Copyright 2025, American Chemical Society.

therefore increasing the interface contact and mass transfer at the abiotic-biotic interface *R. eutropha*.

Fig. 30(B) shows the time dependence of PHB production using a system of K/O-CN-*R. eutropha* under visible-light irradiation with light at an intensity of 4000 lux (0.75 mW cm<sup>-2</sup>). A gas mixture (N<sub>2</sub>:H<sub>2</sub>:CO<sub>2</sub>:O<sub>2</sub> = 76:10:10:4) is used as a carbon source in this system. As shown in Fig. 30(B), the K/O-CN-*R. eutropha* biohybrid achieves a PHB yield of 49.35 ± 0.85 mg L<sup>-1</sup> day<sup>-1</sup>, surpassing non-metal-based biohybrids by adding co-factors and reaching a quantum efficiency of 5.88% ± 0.16%, which exceeds most metal-based biohybrid systems. Using K/O-CN-*R. eutropha*, the PHB production is improved compared to the dark condition or the system excluding K/O-CN.

A nanosheet composed of g-C<sub>3</sub>N<sub>4</sub> is one of the promising visible light-responsive photocatalysts.<sup>127</sup> The g-C<sub>3</sub>N<sub>4</sub> nanosheet (CNNS)-*R. eutropha* is reported for visible-light-driven PHB production from CO<sub>2</sub>, as shown in Fig. 31(A).<sup>128</sup>

Fig. 31(B) shows the time dependence of PHB production using the CNNS-*R. eutropha* system under continuous irradiation at an intensity of 4000 lx. A gas mixture (N<sub>2</sub>:H<sub>2</sub>:CO<sub>2</sub>:O<sub>2</sub> = 76:10:10:4) is used as a carbon source in this system. Comparative experiments are conducted under both light and dark

conditions, as shown in Fig. 31(B). The CNNS-*R. eutropha* system exhibits the highest PHB yield of 37.25 ± 0.9 mg L<sup>-1</sup> day<sup>-1</sup> under irradiation with 0.5 g L<sup>-1</sup> CNNS, demonstrating a 41.47% increase compared to the only *R. eutropha* under dark conditions (26.33 mg L<sup>-1</sup> day<sup>-1</sup>). Thus, the PHB production yield also surpasses the yields observed under both light and dark conditions without CNNS. Under dark conditions, the PHB yield is similar to whether CNNS is added. This result indicates that CNNS does not exert toxic effects on *R. eutropha* and that the enhancement in PHB production within this system is light-dependent.

We focus on the photocatalyst in a hybrid system comprising photocatalysts and microbial cells, as introduced in this section. The photocatalysts used in hybrid systems are visible-light-responsive semiconductors, and most of them have a proven track record in hydrogen production based on the photolysis of water. In hybrid systems, efficient electron and proton transfer from the photocatalyst to the microbial cell governs the CO<sub>2</sub> conversion rate. Therefore, developing catalysts that bring semiconductor photocatalysts into contact with the surface of microbial cells is crucial to achieving efficient CO<sub>2</sub> conversion.

Next, the separation of products based on CO<sub>2</sub> conversion using hybrid systems is discussed. Currently, the products from

the hybrid systems described in this section are separated only by high-performance liquid chromatography (HPLC). In addition, since microbial cells are used, suppressing by-products is another challenge for scaling up this system.

### Visible-light-driven 3-hydroxybutyrate production from CO<sub>2</sub> and acetone with the photocatalytic dye and cell extract, including a multi-enzyme hybrid system

Another visible-light-driven production of biodegradable polymer precursor from CO<sub>2</sub> method is to use a cell extract containing crude enzymes, as shown in Fig. 32, instead of the microbial cell shown in Fig. 5(b).

This section describes the production of 3-hydroxybutyrate, a precursor of PHB, and a promising biodegradable plastic. The research example on visible-light-driven 3-hydroxybutyrate production with acetone carboxylase (AC; EC 6.4.1.6) and 3-hydroxybutyrate dehydrogenase (HBDH; EC 1.1.1.30) added as a catalyst in Fig. 32 is introduced. Fig. 33 shows the AC-catalysed acetoacetate production from acetone and bicarbonate in the presence of ATP (a) and HBDH-catalysed 3-hydroxybutyrate production based on the acetoacetate reduction in the presence of NADH (b). Using a dual-enzyme

Fig. 32 Visible-light-driven production of biodegradable plastic precursors based on CO<sub>2</sub> fixation using a hybrid system of photoredox consisting of ED, PS, and EM and a cell-extract containing crude enzymes.

Fig. 33 AC-catalysed acetoacetate production from acetone and bicarbonate in the presence of ATP (a). HBDH-catalysed 3-hydroxybutyrate production based on the reduction of acetoacetate in the presence of NADH (b).

Fig. 34 Chemical structures of ZnTPPS<sup>4-</sup> (a) and [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup> (b).

consisting of AC and HBDH, 3-hydroxybutyrate can be produced from acetone and bicarbonate *via* acetoacetate as an intermediate.<sup>129,130</sup>

Visible-light-driven 3-hydroxybutyrate production from bicarbonate or CO<sub>2</sub> and acetone with a system comprising TEOA, zinc tetraphenylporphyrin tetrasulfonate (ZnTPPS<sup>4-</sup>; chemical structure is shown in Fig. 34(a)), rhodium coordination complex ([RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup>; Cp\* = pentamethylcyclopentadienyl, bpy = 2,2'-bipyridyl; chemical structure is shown in Fig. 34(b)), NAD<sup>+</sup>, ATP, AC and HBDH is reported.<sup>131,132</sup>

AC<sup>133,134</sup> and HBDH<sup>130</sup> are expressed from photosynthetic bacteria *Rhodobacter capsulatus* SB1003 (*Rb. capsulatus* SB1003) cultured in acetone-bicarbonate medium. The cell extract containing AC and HBDH is obtained from *Rb. capsulatus* SB1003. First, visible-light-driven 3-hydroxybutyrate production from acetone and bicarbonate instead of CO<sub>2</sub> gas using a system comprising TEOA, ZnTPPS<sup>4-</sup>, [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup>, NAD<sup>+</sup>, ATP, and cell extract containing AC and HBDH is introduced.<sup>131</sup> After 5 h of irradiation using a 250 W halogen lamp ( $\lambda > 390$  nm), 379  $\mu$ M of 3-hydroxybutyrate is produced in the sample solution of acetone (0.5 mM), TEOA (0.2 M), ZnTPPS<sup>4-</sup> (50  $\mu$ M), [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup> (5.0  $\mu$ M), NAD<sup>+</sup> (2.0 mM), sodium bicarbonate (50 mM), sodium ATP (2.0 mM), magnesium chloride (5.0 mM) and cell extract (AC 0.051 U, HBDH 0.47 U) in 5.0 mL of 500 mM HEPES-NaOH buffer (pH 7.0). Using this system, the conversion yield of acetone to 3-hydroxybutyrate is approximately 76%.

Visible-light-driven 3-hydroxybutyrate production from acetone and directly captured CO<sub>2</sub> from a mixture of N<sub>2</sub> and CO<sub>2</sub> gases using the system comprising TEOA, ZnTPPS<sup>4-</sup>, [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup>, NAD<sup>+</sup>, ATP and enzyme extract containing AC and HBDH is introduced.<sup>132</sup> Fig. 35 shows the time dependence of acetoacetate (a) and 3-hydroxybutyrate (b) concentration in the sample solution of acetone (0.5 mM), TEOA (0.2 M), ZnTPPS<sup>4-</sup> (50  $\mu$ M), [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup> (5.0  $\mu$ M), NAD<sup>+</sup> (2.0 mM), sodium ATP (2.0 mM), magnesium chloride (5.0 mM) and cell extract (AC 0.062 U, HBDH 0.7 U) in 5.0 mL of 500 mM HEPES-NaOH buffer (pH 7.0) under conditions with varying ratios of CO<sub>2</sub> and N<sub>2</sub> in the gas phase with irradiation using a 250 W Halogen lamp ( $\lambda > 390$  nm).

The results using this system are summarized in Table 1. The data in Table 1 are calculated from the figures published in ref. 132.

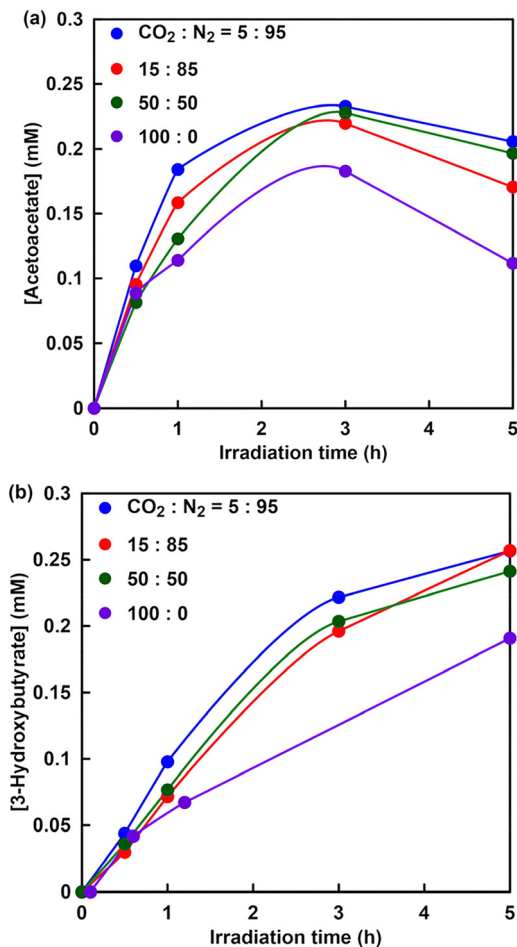

Fig. 35 Time-dependent concentration of acetoacetate (a) and 3-hydroxybutyrate (b) in the sample solution of acetone, TEOA, ZnTPPS<sup>4-</sup>, [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup>, NAD<sup>+</sup>, ATP, magnesium chloride and cell extract (AC, HBDH) in a HEPES-NaOH buffer (pH 7.0) under varying ratios of CO<sub>2</sub> and N<sub>2</sub> in the gas phase and irradiation. Reproduced with permission from ref. 132. Copyright 2023, The Royal Society of Chemistry.

As shown in Table 1, no significant difference in 3-hydroxybutyrate production is observed in the mixed gas with the ratio of CO<sub>2</sub> to N<sub>2</sub> not exceeding 0.5. In contrast, 3-hydroxybutyrate production decreases under conditions with 100% CO<sub>2</sub> gas compared to other conditions. This is because the reaction

Table 1 Concentration of 3-hydroxybutyrate produced and conversion yield of acetone to 3-hydroxybutyrate in the solution containing acetone, TEOA, ZnTPPS<sup>4-</sup>, [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup>, NAD<sup>+</sup>, ATP, magnesium chloride and cell extract containing AC and HBDH using a mixture gas with various ratios of CO<sub>2</sub> and N<sub>2</sub> ([CO<sub>2</sub>]/[N<sub>2</sub>]) after 5 h of visible light irradiation

system is isochoric and CO<sub>2</sub> in the gas phase dissolves into the sample solution, leading to a decrease in pressure, as shown in Table 1. Under the condition of 100% CO<sub>2</sub>, especially, it is predicted that the catalytic activity of cell extract involving AC and HBDH is inhibited based on the decrease in pressure in the reaction system during irradiation. Therefore, gaseous CO<sub>2</sub> can be directly used as a raw material without using bicarbonate because of the gas-phase low concentration gaseous CO<sub>2</sub> trapping function of the HEPES-NaOH buffer solution used in the reaction. In addition, the captured gaseous CO<sub>2</sub> is converted to bicarbonate in the HEPES-NaOH buffer and acts as a carboxylating agent for acetone with an enzyme extract, including AC. This suggests that several to 20% of the gaseous CO<sub>2</sub> contained in gases emitted from thermal power stations, steel mills and chemical plants<sup>142</sup> could be used as feedstock in this system.

Finally, waste acetone and low-concentration CO<sub>2</sub> are used as raw materials in the visible-light-driven 3-hydroxybutyrate production with the system comprising TEOA, ZnTPPS<sup>4-</sup>, [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup>, NAD<sup>+</sup>, ATP and cell extract, including AC and HBDH.<sup>132</sup> Acetone is an abundant and useful chemical in the laboratory because it serves as a non-halogenated organic solvent that is miscible with water.<sup>143</sup> Acetone is relatively cheap, reasonably harmless and is often the solvent of choice in chemical laboratories for cleaning glassware contaminated with organic deposits. Although acetone is useful as a solvent, it also requires an efficient method for recycling after use. Because black permanent marker ink contains various organic solvents, such as *m*-xylene, iso-butanol, resin and oil soluble dyestuff, it can be used as a model for insoluble stains. The commercial black permanent marker ink used in this experiment contains 58% *m*-xylene, 14% iso-butanol, 16% resin and 12% oil soluble dyestuff. Here, black permanent marker ink dissolved in acetone is used as a waste solvent model. After adding the waste acetone to the HEPES-NaOH buffer, the supernatant is separated from the precipitate, and the supernatant, including acetone, *m*-xylene and iso-butanol, is used for the visible-light-driven 3-hydroxybutyrate production. The reaction mixture consists of supernatant, including acetone (0.5 mM), sodium ATP (2.0 mM), magnesium chloride (5.0 mM), TEOA (0.2 M), ZnTPPS<sup>4-</sup> (50 μM), [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup> (5.0 μM), NAD<sup>+</sup> (2.0 mM) and cell extract (AC: 0.062 U and HBDH: 0.7 U), with a mixed gas of a CO<sub>2</sub> to N<sub>2</sub> ratio of 0.15 in 5 mL of 500 mM HEPES-NaOH buffer. Fig. 36 shows the time dependence of acetoacetate and 3-hydroxybutyrate concentrations in the sample solution during irradiation using a 250 W halogen lamp (λ > 390 nm).

After 5 h of irradiation, 0.28 mM of 3-hydroxybutyrate is produced. No significant difference is observed between pure and waste acetone in the visible-light-driven 3-hydroxybutyrate synthesis using low concentrations of gaseous CO<sub>2</sub>.

### Strategy for the visible-light-driven production of CO<sub>2</sub>-based biodegradable plastic precursors using a photocatalytic dye and multi-enzyme hybrid system

The method of directly using microbial cells as a biocatalyst has the advantages of being simple and high in product yield, but it

Fig. 36 Time-dependent concentration of acetoacetate or 3-hydroxybutyrate in the solution of the supernatant containing acetone, ATP, magnesium chloride, TEOA, ZnTPPS<sup>4-</sup>, [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup>, NAD<sup>+</sup> and the cell extract (AC and HBDH:) in a HEPES–NaOH buffer in the presence of a gas mixture of a CO<sub>2</sub> to N<sub>2</sub> ratio of 0.15 in the gas phase under irradiation. Reproduced with permission from ref. 132. Copyright 2023, The Royal Society of Chemistry.

also has the drawback of difficulty in controlling the selectivity of the target product. Therefore, it has been proposed to produce biodegradable plastic precursors by incorporating an enzyme (ENZ) with the function of CO<sub>2</sub> fixation into a photoredox system consisting of an electron donor (ED), a visible light sensitizer (PS), and an electron mediator (EM), as shown in Fig. 37.<sup>135–137</sup>

By incorporating hydrogenase (H<sub>2</sub>ase; EC 1.12.2.1; cytochrome-*c*<sub>3</sub> hydrogenase,<sup>138–144</sup> EC 1.12.7.2; ferredoxin hydrogenase<sup>145–150</sup>) and formate dehydrogenase<sup>151–155</sup> (FDH; EC 1.17.1.9; NAD<sup>+</sup>-dependent, EC 1.17.1.10; NADP<sup>+</sup>-dependent, and EC 1.17.98.4; selenium-containing formate dehydrogenase H) into a photoredox system consisting of ED, PS, and EM, visible-light-driven hydrogen production and formate production based on CO<sub>2</sub> reduction are achieved.

The first example of applying this system to the fixation of CO<sub>2</sub> to a substrate is shown in Fig. 38.<sup>156</sup>

In this system, [Ru(bpy)<sub>3</sub>]<sup>2+</sup> (chemical structure is shown in Fig. 39) is used as the PS.

Fig. 37 Visible-light-driven production of biodegradable plastic precursors based on CO<sub>2</sub> fixation to a substrate using a system comprising an electron donor (ED), a visible-light sensitizer (PS), an electron mediator (EM) and an enzyme (ENZ).

Fig. 38 Visible-light-driven CO<sub>2</sub> fixation using a photoredox system comprising 2-mercaptoethanol (RSH), tris(2,2'-bipyridyl)ruthenium(II) ([Ru(bpy)<sub>3</sub>]<sup>2+</sup>) and methyl viologen (MV<sup>2+</sup>)-linked enzymes. FNR: ferredoxin-NADP<sup>+</sup> reductase, ICDH: isocitrate dehydrogenase, FUM: fumarase, ASP: L-aspartase.

As shown in Fig. 38, FDH (EC 1.12.2.1), ICDH (EC 1.1.1.42), and ME (EC 1.1.1.40) can be used as CO<sub>2</sub> conversion enzymes in the photoredox system. When FDH is used as the enzyme in a photoredox system, the MV<sup>+</sup> can be used directly as a coenzyme instead of NAD(P)H. However, when ICDH or ME is used as an enzyme in a photoredox system, it is necessary to incorporate NADPH regeneration. As depicted in Fig. 38, biodegradable plastic precursors malate, fumarate, and aspartate are produced from CO<sub>2</sub> as a raw material using a photoredox system incorporating enzymes. Polymers derived from malate or aspartate precursors are biodegradable, as shown in Fig. 40.

Fumarate can also be used as a precursor to biodegradable plastic PBS. For the first time, a system incorporating ME, FUM (EC 4.2.1.2), and ASP (EC 4.3.1.1) as catalysts in a photoredox system comprising RSH, [Ru(bpy)<sub>3</sub>]<sup>2+</sup>, MV<sup>2+</sup>, FNR (EC 1.18.1.2) and NADP<sup>+</sup> is successfully used to produce fumarate and aspartate from CO<sub>2</sub> and pyruvate under visible-light irradiation. Fig. 41 shows the time dependence of fumarate (a) and aspartate (b) production with a system comprising RSH (16 mM), [Ru(bpy)<sub>3</sub>]<sup>2+</sup> (23 μM), MV<sup>2+</sup> (0.16 mM), NADP<sup>+</sup> (0.32 mM), pyruvic acid (40 mM), sodium bicarbonate (0.16 M), ammonium ion

Fig. 40 Chemical structures of poly(malic acid)<sup>157–159</sup> and poly(aspartic acid)<sup>160,161</sup>.

Fig. 41 Time-dependent concentration of aspartate (a) and fumarate (b) in a system comprising RSH,  $[\text{Ru}(\text{bpy})_3]^{2+}$ ,  $\text{MV}^{2+}$ ,  $\text{NADP}^+$ , pyruvic acid, sodium bicarbonate, ammonium ion, manganese chloride, FNR, ME, FUM and ASP in Tris-buffer solution during visible-light irradiation. Reproduced with permission from ref. 156. Copyright 1988, The Royal Society of Chemistry.

(80 mM), manganese chloride (80  $\mu\text{M}$ ), FNR (0.5 U), ME (0.5 U), FUM (156 U) and ASP (3.0 U) in 4.0 mL of 0.16 M Tris-buffer solution (pH 7.9) during visible-light irradiation (1000 W halogen quartz lamp with 400 nm cut-off filter).

As shown in Fig. 41, fumarate and aspartate production increase during visible-light irradiation. After 5 h of irradiation, *ca.* 1.3 and 2.0 mM of fumarate and aspartate are produced. In the absence of ASP, no aspartate is produced and malate and fumarate are produced during visible-light irradiation. Additionally, visible-light-driven malate production with the system comprising RSH (19 mM),  $[\text{Ru}(\text{bpy})_3]^{2+}$  (21  $\mu\text{M}$ ),  $\text{MV}^{2+}$  (0.19 mM),  $\text{NADP}^+$  (0.18 mM), pyruvic acid (47 mM), sodium bicarbonate (0.20 M), manganese chloride (95  $\mu\text{M}$ ), FNR (0.2 U) and ME (1.33 U) in 4.2 mL of 0.20 M Tris-buffer solution (pH 7.9) under a gaseous atmosphere of  $\text{CO}_2$  during visible-light irradiation (1000 W halogen quartz lamp with 400 nm cut-off filter). After 2 h of irradiation, 3.0 mM of malate production is observed.<sup>156</sup>

Thus, in order to produce biodegradable plastic precursors, such as malate, fumarate, and aspartate, it is essential to develop a visible-light-driven  $\text{NAD(P)H}$  regeneration system consisting of ED, PS, EM, and a catalyst that can be linked to an enzyme-based biocatalytic process. Visible-light-driven  $\text{NAD(P)H}$  regeneration, consisting of ED, PS, EM, and a catalyst, has been extensively studied in two main systems (Fig. 42).<sup>135–137</sup> The first is a visible-light-driven NADPH regeneration system using FNR as a catalyst (Fig. 42(a)). The other is a visible-light-driven  $\text{NAD(P)H}$  regeneration system using  $[\text{RhCp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$  as a catalyst (Fig. 42(b)). In the system shown in Fig. 42(a), visible-light-driven NADPH regeneration systems using  $[\text{Ru}(\text{bpy})_3]^{2+}$ ,<sup>156</sup> 5-deazariboflavin,<sup>162</sup> riboflavin,<sup>162</sup> proflavin,<sup>161,162</sup> oligothio-phenes derivatives,<sup>164</sup> CdS,<sup>165</sup> CdSe quantum dots<sup>166</sup> and polyethylene glycol-modified chlorophyll-*a* (PEG-Chl-*a*)<sup>167</sup> as PSs are

Fig. 42 Visible-light-driven  $\text{NAD(P)H}$  regeneration using a system comprising ED, PS, EM and FNR (a) and ED, PS, and  $[\text{RhCp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$  (b).

reported. In addition to 4,4'-bipyridinium salts, such as  $\text{MV}^{2+}$ , 2,2'-bipyridinium salts and ferredoxin are used as EMs in this system.<sup>163</sup> As shown in the system of Fig. 42(b), however, visible-light-driven  $\text{NAD(P)H}$  regeneration systems using carbon-doped  $\text{TiO}_2$ ,<sup>168</sup> phosphate-doped  $\text{TiO}_2$ ,<sup>169</sup> eosin-Y,<sup>170</sup> porphyrin derivatives<sup>171,172</sup> and proflavin<sup>173</sup> as PSs are reported. Research examples on visible light-driven  $\text{NAD(P)H}$  regeneration systems are summarized and reported in several reviews.<sup>135–137,174,175</sup>

The strategy for visible-light-driven  $\text{CO}_2$ -based biodegradable plastic precursor production using a photocatalytic dye and multi-enzyme hybrid system involves the integrated coupling of an  $\text{NAD(P)H}$  regeneration system and an enzyme-based biocatalytic process.

### Visible-light-driven malate production using a photocatalytic dye and enzyme hybrid system

As mentioned above, visible-light-driven malate production from  $\text{CO}_2$  and pyruvate using a system comprising RSH,  $[\text{Ru}(\text{bpy})_3]^{2+}$ ,  $\text{MV}^{2+}$ ,  $\text{NADP}^+$ , FNR and ME has been developed for the first time. Some studies have been reported on the production of malate using visible light-driven NADPH regeneration catalysed by FNR in the presence of ME.

Visible-light-driven malate production from  $\text{CO}_2$  and pyruvic acid (2.0 mM) using the system comprising RSH (27 mM), CdS or  $\text{TiO}_2$  microcrystals fixed in the interlayer spacings of sodium montmorillonite ( $\text{TiO}_2/\text{clay}$ ) (1.25 mM) as a PS,  $\text{MV}^{2+}$  (1.0 mM),  $\text{NADP}^+$  (0.1 mM), FNR (0.2 U) and ME (1.0 U) in  $\text{CO}_2$ -saturated Tris-buffer (10 mL) has been reported.<sup>175</sup> For the system using CdS or  $\text{TiO}_2/\text{clay}$ , *ca.* 1.0 or 0.3 mM of malate is produced after 5 h of irradiation using a 500 W high-pressure Hg arc lamp, respectively.

Visible-light-driven malate production using chlorophyll derivative, zinc chlorin e6 ( $\text{ZnCe6}$ ; chemical structure is shown in Fig. 43) as PS in the system shown in Fig. 52(a) has also been reported.<sup>176</sup>

After 3 h of irradiation using a 250 W tungsten lamp ( $\lambda > 365$  nm), 0.65 mM of malate production is observed using the system comprising NADH (3.0 mM),  $\text{ZnCe6}$  (50  $\mu\text{M}$ ),  $\text{MV}^{2+}$  (1.0 mM), FNR (4.0 U), pyruvic acid (10 mM), sodium

Fig. 43 Chemical structure of zinc chlorin e6 (ZnCe6).

Fig. 44 Chemical structure of PEG-Chl-a.

bicarbonate (10 mM),  $\text{NADP}^+$  (10 mM) and ME (4.5 U) in 50 mM of Bis-Tris buffer (3.0 mL; pH 8.0).

It has been reported that NADPH can be regenerated even in the absence of  $\text{MV}^{2+}$  using PEG-Chl-a (the chemical structure is shown in Fig. 44) as PS, as depicted in Fig. 42(a).<sup>167</sup>

Using PEG-Chl-a (15  $\mu\text{M}$ ) as a PS, malate production in the system comprising sodium ascorbate (6.0 mM), sodium bicarbonate (180 mM), magnesium chloride (15 mM), sodium pyruvate (0.8 mM),  $\text{NADP}^+$  (3.2 mM), FNR (2.5 U) and ME (5.0 U) in 50 mM of phosphate buffer (10 mL; pH 7.4) during irradiation using a 60 W incandescent lamp from a distance of 10 cm (light intensity,  $200 \text{ J m}^{-2} \text{ s}^{-1}$ ) is observed, and 0.15 mM of malate is produced after 4 h irradiation.

In addition, the optical activity of the malate produced in the reaction system introduced in this section, D- or L-, has not been identified.

Next, a research example on visible-light-driven malate production with ME added as a catalyst, as depicted in Fig. 42(b), is introduced. Visible-light-driven L-malate production from sodium bicarbonate and pyruvate using the system comprising triethanol amine (TEOA) as ED, water-soluble zinc porphyrin, ZnTPPS<sup>4-</sup> as PS,  $[\text{RhCp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$ ,  $\text{NAD}^+$ , and ME is introduced.<sup>177</sup>

After 5 h of irradiation using a 250 W Halogen lamp ( $\lambda > 390 \text{ nm}$ ), 0.16 mM of L-malate production is observed using the system comprising sodium pyruvate (5.0 mM), TEOA (0.2 M), ZnTPPS<sup>4-</sup> (10  $\mu\text{M}$ ),  $[\text{RhCp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$  (10  $\mu\text{M}$ ),  $\text{NAD}^+$  (0.5 mM), sodium bicarbonate (100 mM), magnesium chloride (5.0 mM) and ME (0.7 U) in  $\text{CO}_2$ -saturated 500 mM HEPES-NaOH buffer (5.0 mL; pH 7.3). However, 40  $\mu\text{M}$  of L-malate production is

observed under Ar-saturated 500 mM HEPES-NaOH buffer (pH 7.3). This result suggests that the equilibrium between gaseous  $\text{CO}_2$  in the gas phase and bicarbonate ions in the sample solution is important for ME-catalysed L-malate production. In particular, this sealed isochoric system has the problem of a decrease in pressure within the system because gaseous  $\text{CO}_2$  in the gas phase of the reaction vessel is captured by the weak basic buffer solution. Therefore, visible-light-driven L-malate production has also been reported using an isobaric reaction system attached to a balloon filled with 1 L of  $\text{CO}_2$  gas.<sup>178</sup> After 5 h of irradiation using a 250 W Halogen lamp ( $\lambda > 390 \text{ nm}$ ), ca. 0.16 mM of L-malate production is observed using the system comprising sodium pyruvate (5.0 mM), TEOA (0.2 M), ZnTPPS<sup>4-</sup> (10  $\mu\text{M}$ ),  $[\text{RhCp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$  (10  $\mu\text{M}$ ),  $\text{NAD}^+$  (0.5 mM), magnesium chloride (5.0 mM) and ME (0.7 U) in 500 mM HEPES-NaOH buffer (5.0 mL; pH 7.3). A balloon filled with 1 L of  $\text{CO}_2$  gas is attached to the reaction vessel, and the pressure inside the reaction system is maintained at 1.0 atm. Furthermore, no sodium bicarbonate is added to the reaction sample. The increase in L-malate over the irradiation time indicates that bicarbonate is continuously captured from  $\text{CO}_2$  gas and fixed to pyruvate by ME together with NADH regenerated by visible light irradiation. Using this isobaric system, L-malate can be produced directly using gaseous  $\text{CO}_2$  as a raw material.

In addition, visible-light-driven L-malate production using a water-soluble cationic zinc porphyrin, zinc tetrakis(4-N,N-trimethylaminophenyl)porphyrin (ZnTMAP<sup>4+</sup>; chemical structure is shown in Fig. 45), as a PS has also been reported.<sup>179</sup>

After 5 h of irradiation using a 250 W Halogen lamp ( $\lambda > 390 \text{ nm}$ ), ca. 0.25 mM of L-malate production is observed with the system comprising sodium pyruvate (5.0 mM), TEOA (0.2 M), ZnTMAP<sup>4+</sup> (50  $\mu\text{M}$ ),  $[\text{RhCp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$  (10  $\mu\text{M}$ ),  $\text{NAD}^+$  (0.5 mM), magnesium chloride (5.0 mM) and ME (0.7 U) in 500 mM HEPES-NaOH buffer (5.0 mL; pH 7.3). A balloon filled with 1 L of  $\text{CO}_2$  gas is attached to the reaction vessel, and the pressure inside the reaction system is maintained at 1.0 atm. Using ZnTMAP<sup>4+</sup> as a photosensitizer, approximately 1.5 times more L-malate is produced than in the system with ZnTPPS<sup>4-</sup>. As a stable  $\text{NAD}^+$  reduction, NADH

Fig. 45 Chemical structure of ZnTMAP<sup>4+</sup>.

in a system comprising TEOA and  $[\text{Cp}^*\text{Rh}(\text{bpy})(\text{H}_2\text{O})]^{2+}$  with  $\text{ZnTMAP}^{4+}$  as a PS compared to a system using  $\text{ZnTPPS}^{4-}$ ; thus, the efficiency of visible-light-driven L-malate production is improved using  $\text{ZnTMAP}^{4+}$ .

As described above, L-malate production from  $\text{CO}_2$  and pyruvate using ME as a photoredox catalyst is achieved. However, in the production of L-malate using ME as a catalyst, L-lactate is produced through the reduction of pyruvate under a low concentration of  $\text{CO}_2$  or bicarbonate. Therefore, a system mimicking the mitochondrial pyruvate malate shuttle,<sup>180,181</sup> consisting of pyruvate carboxylase (PC; EC 6.4.1.1) and malate dehydrogenase (MDH; EC 1.1.1.37) in the presence of ATP and NADH, is proposed to produce L-malate using low-concentration  $\text{CO}_2$  as a feedstock.

Fig. 46 shows the PC-catalysed oxaloacetate production from pyruvate and bicarbonate in the presence of ATP (a) and MDH-catalysed L-malate production based on oxaloacetate reduction in the presence of NADH (b). Using a dual-enzyme consisting of PC and MDH, L-malate can be produced from pyruvate and bicarbonate *via* oxaloacetate as an intermediate. In addition, using PC as a catalyst, no reduction process of pyruvate is involved to suppress L-lactate production and enable the use of low-concentration  $\text{CO}_2$  as a raw material.<sup>182,183</sup>

Visible-light-driven L-malate production from pyruvate and  $\text{CO}_2$  using a system comprising TEOA,  $\text{ZnTMAP}^{4+}$ ,  $[\text{RhCp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$ ,  $\text{NAD}^+$ , ATP, acetyl-CoA, PC and MDH has been reported.<sup>184</sup> Fig. 47 shows the time dependence of L-malate production using a system comprising sodium pyruvate (5.0 mM), acetyl-CoA (1.0 mM), magnesium chloride (5.0 mM), sodium ATP (5.0 mM), TEOA (0.2 M),  $\text{ZnTMAP}^{4+}$  (50  $\mu\text{M}$ ),  $\text{NAD}^+$  (5.0 mM),  $[\text{Rh Cp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$  (0.1 mM), PC (1.0 U) and MDH

Fig. 46 PC-catalysed oxaloacetate production from pyruvate and bicarbonate in the presence of ATP (a). MDH-catalysed L-malate production based on the reduction of oxaloacetate in the presence of NADH (b).

Fig. 47 Time-dependent concentration of L-malate in a system comprising sodium pyruvate, acetyl-CoA, magnesium chloride, sodium ATP, TEOA,  $\text{ZnTMAP}^{4+}$ ,  $\text{NAD}^+$ ,  $[\text{Rh Cp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$ , PC and MDH in an HEPES–NaOH buffer solution (pH 7.8) under visible-light irradiation. The gas phase of the reaction vessel was introduced with 15.0 (red) or 100%  $\text{CO}_2$  (blue) gas. Reproduced with permission from ref. 184. Copyright 2025, the American Chemical Society.

(20 U) in 5.0 mL of 500 mM HEPES–NaOH buffer solution (pH 7.8) under visible-light irradiation using a 250 W halogen lamp ( $\lambda > 390$  nm). A balloon filled with 1 L of a gas mixture of  $\text{N}_2$  and  $\text{CO}_2$  is attached to the reaction vessel, and the pressure inside the reaction system is maintained at 1.0 atm. As shown in Fig. 47, more L-malate production is observed under 15.0%  $\text{CO}_2$  conditions compared with under 100%  $\text{CO}_2$  conditions. The change in the pH of the sample solution during the reaction is measured, and the pH decreases from 7.8 to 7.0 under 100%  $\text{CO}_2$  conditions. However, no change is observed in the pH of the sample solution during reaction under 15.0%  $\text{CO}_2$  conditions. It has been reported that the rate of visible-light-driven NADH regeneration decreases as the pH of the sample solution decreases. Therefore, the low L-malate production under 100%  $\text{CO}_2$  conditions is due to a decrease in NADH regeneration induced by a drop in pH during irradiation. By complementing the catalytic function of ME with PC and MDH, visible-light-driven L-malate production using low-concentration  $\text{CO}_2$  as a direct feedstock is accomplished.

Finally, an overview of the visible-light-driven L-malate production from  $\text{CO}_2$  and pyruvate using a photocatalytic dye and enzyme hybrid system, as reviewed in this section, is summarized in Table 2.

#### Visible-light-driven fumarate production from $\text{CO}_2$ and pyruvate with the photocatalytic dye and enzyme hybrid system

Malate is a precursor to PMLA but can be converted by dehydration to fumarate, a precursor to a more versatile biodegradable plastic. In other words, by incorporating FUM in addition to ME, fumarate can be produced from  $\text{CO}_2$ .

**Table 2** Summary of the visible-light-driven malate production from carbonate species and pyruvate using a photocatalytic dye and enzyme hybrid system

System	Malate production (mM)	Ref.
RSH (19 mM), [Ru(bpy) <sub>3</sub> ] <sup>2+</sup> (21 μM), MV <sup>2+</sup> (0.19 mM), NADP <sup>+</sup> (0.18 mM), pyruvic acid (47 mM), sodium bicarbonate (0.20 M), manganese chloride (95 μM), FNR (0.2 U) and ME (1.33 U)	1.5	156

sodium pyruvate (5.0 mM), acetyl-CoA (1.0 mM), magnesium chloride (5.0 mM), sodium ATP (5.0 mM), TEOA (0.2 M), ZnTMAP <sup>4+</sup> (50 μM), NAD <sup>+</sup> (5.0 mM), [RhCp*(bpy)(H <sub>2</sub> O)] <sup>2+</sup> (0.1 mM), PC (1.0 U) and MDH (20 U)	0.23 (15% CO <sub>2</sub> ) 0.15 (100% CO <sub>2</sub> )	184

The production of fumarate from CO<sub>2</sub> as a raw material by hybridising a visible-light-driven NADH regeneration system consisting of a photocatalytic dye and a catalyst with a dual enzyme consisting of ME and FUM is introduced in this section.

As mentioned above, visible-light-driven fumarate production from CO<sub>2</sub> and pyruvate is achieved using a system comprising RSH, [Ru(bpy)<sub>3</sub>]<sup>2+</sup>, MV<sup>2+</sup>, NADP<sup>+</sup>, FNR, ME and FUM. No other studies have been reported on the production of fumarate using visible-light-driven NADPH regeneration catalysed by FNR in the presence of ME and FUM.

First, visible-light-driven fumarate production from pyruvate and bicarbonate instead of CO<sub>2</sub> gas using a system comprising TEOA, ZnTPPS<sup>4-</sup>, [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup>, NAD<sup>+</sup>, ME and FUM is introduced.<sup>172</sup> The sample solution consists of TEOA (0.2 M), ZnTPPS<sup>4-</sup> (10 μM), [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup> (10 μM), NAD<sup>+</sup> (0.5 mM), sodium pyruvate (5.0 mM), sodium bicarbonate (100 mM), magnesium chloride (5.0 mM), ME (0.7 U) and FUM (0.5 U) in 5.0 mL of CO<sub>2</sub>-saturated 500 mM HEPES-NaOH buffer (5.0 mL; pH 7.8). The sample solution is irradiated with visible light using a 250 W halogen lamp ( $\lambda > 390$  nm). Using this system, the concentrations of L-malate and fumarate are estimated to be 194 and 48 μM, respectively, after 5 h of irradiation. Although the production of L-malate tends to reach a constant concentration, the fumarate concentration linearly increases during irradiation. Visible-light-driven fumarate production has also been reported using an isobaric reaction system attached to a balloon filled with 1 L of CO<sub>2</sub> gas.<sup>178</sup> After 5 h of irradiation using a 250 W halogen lamp ( $\lambda > 390$  nm), *ca.* 190 and 49 μM of L-malate and fumarate production are observed using a system comprising sodium pyruvate (5.0 mM), TEOA (0.2 M), ZnTPPS<sup>4-</sup> (10 μM), [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup> (10 μM), NAD<sup>+</sup> (0.5 mM), magnesium

chloride (5.0 mM), ME (0.7 U) and FUM (0.5 U) in 500 mM HEPES-NaOH buffer (5.0 mL; pH 7.8). A balloon filled with 1 L of CO<sub>2</sub> gas is attached to the reaction vessel, and the pressure inside the reaction system is maintained at 1.0 atm. Furthermore, no sodium bicarbonate is added to the reaction sample. No significant difference in fumarate production is observed under 100% CO<sub>2</sub> conditions in the gas phase and the presence of bicarbonate conditions. However, it has been reported that as the CO<sub>2</sub> ratio in the mixed gas in the balloon decreases, the production of L-malate and fumarate also decreases.

Using a system comprising TEOA, ZnTPPS<sup>4-</sup>, [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup>, NAD<sup>+</sup>, ME and FUM, the concentration of fumarate produced remains significantly lower than that of L-malate, whether CO<sub>2</sub> gas or bicarbonate is used as the feedstock. For example, it has been reported that the addition of phosphate improves the catalytic activity of FUM for the production of fumarate based on the dehydration of L-malate.<sup>185</sup> In other words, anionic or cationic substances may control the catalytic activity of FUM. Thus, the effect of water-soluble zinc porphyrin on the FUM-catalysed dehydration of L-malate to produce fumarate has been investigated. The effects of water-soluble zinc porphyrins, ZnTPPS<sup>4-</sup> and ZnTMAP<sup>4+</sup>, as well as zinc tetra(4-carboxyphenyl)porphyrin (ZnTCPP<sup>4-</sup>) and zinc tetrakis(4-methylpyridyl)porphyrin (ZnTMPyP<sup>4+</sup>) on the enzyme activity of FUM for fumarate production have been investigated. Fig. 48 shows the chemical structures of ZnTCPP<sup>4-</sup> and ZnTMPyP<sup>4+</sup>.

As shown in Fig. 49, the addition of cationic zinc porphyrins, ZnTMPyP<sup>4+</sup> or ZnTMAP<sup>4+</sup>, did not alter fumarate production from L-malate by FUM compared to the control experiment. By adding anionic zinc porphyrins, ZnTCPP<sup>4-</sup> or ZnTPPS<sup>4-</sup>, in contrast, fumarate production from L-malate with FUM is

Fig. 48 Chemical structures of ZnTCPP<sup>4-</sup> (a) and ZnTMPyP<sup>4+</sup> (b).

Fig. 49 Time-dependent fumarate production from L-malate with FUM in the presence of zinc porphyrin during incubation. Reproduced with permission from ref. 186. Copyright 2023, The Royal Society of Chemistry.

suppressed. In particular, fumarate production with FUM is strongly inhibited in the presence of ZnTPPS<sup>4-</sup>.

It is suggested that the sulfo-group bonded to zinc porphyrin has a stronger effect on the catalytic activity of FUM than that of the carboxy-group.<sup>186</sup>

Here, we focus on the structural interactions between FUM and water-soluble zinc porphyrins. As presented in this section, FUM is an enzyme derived from porcine heart. The three-dimensional structures of porcine heart-derived and related FUMs have been reported.<sup>187–189</sup> It has been reported that porcine heart-derived FUM is composed of four subunits. FUM has four active sites (site A) with high affinity for substrates, as well as an additional binding site (site B) with low affinity for substrates.<sup>189</sup> Fig. 50 is a schematic diagram showing the active high-affinity substrate binding sites (A) and low-affinity binding sites (B) in the FUM.

For example, tetracarboxylic acid, benzene-1,2,4,5-tetracarboxylate and sulfate have been reported as strong inhibitors for FUM.<sup>189</sup> In particular, it is found that one molecule of benzene-1,2,4,5-tetracarboxylic acid can bind to both sites A and B simultaneously, and that four carboxyl groups of

Fig. 50 Schematic showing the active high-affinity substrate binding sites (A) and low-affinity binding sites (B) in FUM. Reproduced with permission from ref. 189. Copyright 1998 ASBMB. Currently published by Elsevier Inc.; originally published by the American Society for Biochemistry and Molecular Biology. Creative Commons CC-BY-NC license.

benzene-1,2,4,5-tetracarboxylic acid per FUM molecule bind with high affinity, acting as bridges between the two subunits. These results suggest that the four benzenesulfonate groups of ZnTPPS<sup>4-</sup> also bind with high affinity to the substrate-binding sites (sites A and B) of FUM, inhibiting the dehydration of L-malate and reducing the production of fumarate.

Therefore, a visible-light-driven fumarate production system has been reported that uses ZnTMAP<sup>4+</sup> as PS instead of ZnTPPS<sup>4-</sup>, which does not affect FUM enzyme activity.<sup>179</sup> Visible-light-driven fumarate production has also been reported using an isobaric reaction system attached to a balloon filled with 1 L of CO<sub>2</sub> gas.<sup>179,190</sup> After 5 h of irradiation using a 250 W halogen lamp ( $\lambda > 390$  nm), ca. 97  $\mu\text{M}$  of fumarate production is observed using a system comprising sodium pyruvate (5.0 mM), TEOA (0.2 M), ZnTMAP<sup>4+</sup> (50  $\mu\text{M}$ ), [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup> (10  $\mu\text{M}$ ), NAD<sup>+</sup> (0.5 mM), magnesium chloride (5.0 mM), ME (0.7 U) and FUM (0.5 U) in 500 mM HEPES–NaOH buffer (5.0 mL; pH 7.8). A balloon filled with 1 L of CO<sub>2</sub> gas is attached to the reaction vessel, and the pressure inside the reaction system is maintained at 1.0 atm. Fig. 51 shows the fumarate concentration using ZnTMAP<sup>4+</sup> or ZnTPPS<sup>4-</sup> after 5 h of irradiation.

The efficiency of visible-light-driven fumarate production from pyruvate and gaseous CO<sub>2</sub> using ZnTMAP<sup>4+</sup> as the PS in a system combining NAD<sup>+</sup> reduction with [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup> and a dual-biocatalyst consisting of ME and FUM in the presence of TEOA is improved by approximately 2.0 times that produced in the system using ZnTPPS<sup>4-</sup>, a conventional PS.

As a relevant study of this system, fumarate production from pyruvate and bicarbonate using a core-shell type of benzodiazole oligomer-BaSO<sub>4</sub>-immobilised [RhCp\*(bpy)(H<sub>2</sub>O)]<sup>2+</sup> (BaPP@BDO-Rh) instead of water-soluble zinc porphyrin as a visible-light sensitising material with dual-biocatalyst consisting of ME and FUM has been reported, as shown in Fig. 52(A).<sup>191</sup> In this study, ME and FUM are expressed in *E. coli* strain DE3

Fig. 51 Concentration of fumarate production in a system comprising sodium pyruvate, magnesium chloride, TEOA,  $[\text{RhCp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$ ,  $\text{NAD}^+$ , ME, FUM and  $\text{CO}_2$  gas in the presence of  $\text{ZnTMAP}^{4+}$  (red) or  $\text{ZnTPPS}^{4-}$  (blue) after 5 h of irradiation. using the pET28a vector; then, the enzymes are purified for use in this reaction. The ME and FUM are designated MaeB and FumC, respectively. The sample solution consists of TEOA (1.0 M),  $1 \text{ g L}^{-1}$  BaPP@BDO-Rh,  $\text{NAD}^+$  (1.0 mM), sodium pyruvate (5.0 mM), sodium bicarbonate (100 mM), magnesium chloride (5.0 mM), MaeB (1.0 U) and FumC (1.0 U) in 3.0 mL of 100mM phosphate buffer. The sample solution is irradiated using a 100 W xenon lamp at room temperature as a visible light source. Using this system, the concentrations of L-malate and fumarate are estimated to be 114 and 63  $\mu\text{M}$ , respectively, after 1 h of irradiation, as shown in Fig. 52(B).

In this study, ME and FUM are expressed in *E. coli* strain DE3 using the pET28a vector; then, the enzymes are purified for use in this reaction. The ME and FUM are designated MaeB and FumC, respectively. The sample solution consists of TEOA (1.0 M),  $1 \text{ g L}^{-1}$  BaPP@BDO-Rh,  $\text{NAD}^+$  (1.0 mM), sodium pyruvate (5.0 mM), sodium bicarbonate (100 mM), magnesium chloride (5.0 mM), MaeB (1.0 U) and FumC (1.0 U) in 3.0 mL of 100 mM phosphate buffer. The sample solution is irradiated using a 100 W xenon lamp at room temperature as a visible light source. Using this system, the concentrations of L-malate and fumarate are estimated to be 114 and 63  $\mu\text{M}$ , respectively, after 1 h of irradiation, as shown in Fig. 52(B).

However, no L-malate and fumarate production are observed under dark conditions. It is believed that malate production under irradiation and dark conditions in this reference is reversed. Moreover, 79  $\mu\text{M}$  of fumarate is produced using this system after 3 h of irradiation. The production of L-malate and fumarate tends to reach a constant concentration during irradiation in this system.

Visible-light-driven fumarate production from pyruvate and  $\text{CO}_2$  using a system comprising TEOA,  $\text{ZnTMAP}^{4+}$ ,  $[\text{RhCp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$ ,  $\text{NAD}^+$ , ATP, acetyl-CoA, PC, MDH and FUM has been reported.<sup>184</sup> L-Malate and fumarate production are observed

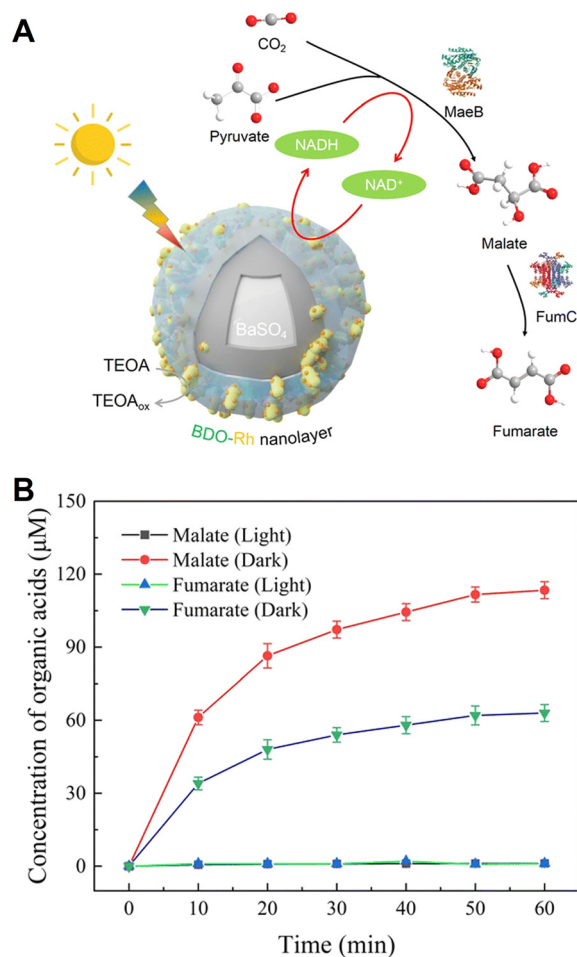

Fig. 52 Schematic of the visible-light-driven fumarate production from pyruvate and  $\text{CO}_2$  using a system comprising TEOA, BaPP@BDO-Rh,  $\text{NAD}^+$ , MaeB and FumC (A). Time-dependent malate and fumarate production from pyruvate and  $\text{CO}_2$  using the system comprising TEOA, BaPP@BDO-Rh,  $\text{NAD}^+$ , MaeB and FumC (B). using a system comprising sodium pyruvate (5.0 mM), acetyl-CoA (1.0 mM), magnesium chloride (5.0 mM), sodium ATP (5.0 mM), TEOA (0.2 M),  $\text{ZnTMAP}^{4+}$  (50  $\mu\text{M}$ ),  $\text{NAD}^+$  (5.0 mM),  $[\text{RhCp}^*(\text{bpy})(\text{H}_2\text{O})]^{2+}$  (0.1 mM), PC (1.0 U), MDH (20 U) and FUM (0.5 U) in 5.0 mL of 500 mM HEPES-NaOH buffer solution (pH 7.8) under visible-light irradiation with a 250 W halogen lamp ( $\lambda > 390 \text{ nm}$ ). A balloon filled with 1 L of a gas mixture of  $\text{N}_2$  and  $\text{CO}_2$  is attached to the reaction vessel, and the pressure inside the reaction system is maintained at 1.0 atm. Under conditions using a gas mixture containing 15%  $\text{CO}_2$ , ca. 213 and 57.6  $\mu\text{M}$  of L-malate and fumarate are produced after 5 h of irradiation, respectively. Furthermore, no significant difference is observed between L-malate and fumarate production under mixed gas conditions containing 50%  $\text{CO}_2$ .

However, it has also been shown that L-malate and fumarate production is reduced by approximately half under mixed gas conditions containing 100%  $\text{CO}_2$  or 2%  $\text{CO}_2$ . By complementing the catalytic function of ME with PC and MDH and using it

**Table 3** Summary of the visible-light-driven fumarate production from carbonate species and pyruvate using a photocatalytic dye and enzyme hybrid system

together with FUM, visible-light-driven fumarate production can be achieved using low-concentration CO<sub>2</sub> (approximately 15%) as a direct feedstock.

Finally, an overview of the visible-light-driven fumarate production from CO<sub>2</sub> and pyruvate using a photocatalytic dye and enzyme hybrid system, as reviewed in this section, is summarized in Table 3.

## Major challenges and future trends

Here, the problems and prospects for future demonstrations of the systems introduced in this study will be discussed. First, we discuss the challenges to the practical application of visible-light-driven plastic precursor production from CO<sub>2</sub> using a photocatalyst and microbial cell hybrid system. The reaction scale of visible-light-driven plastic precursor production from CO<sub>2</sub> using a photocatalyst and microbial cell hybrid system will be discussed. As described in the paper, the reaction scale of the hybrid system is approximately 1.0 L at the maximum laboratory level. Scaling up this system for material production involves several significant challenges, including maintaining product quality stability, ensuring process efficiency, and, in some cases, complying with regulatory requirements.

In addition, although Xe and halogen lamps are currently used as visible light sources, it will be necessary to directly utilize solar-light in the future, and the design of the reaction vessel for this purpose will be an important factor. Visible-light-driven plastic precursor production from CO<sub>2</sub> using a photocatalyst and microbial cell hybrid system is still under development, and future developments in chemical engineering will likely pave the way for its practical application through the design of the reaction apparatus. However, a hybrid system has the advantage of efficiently promoting CO<sub>2</sub> conversion within microbial cells through induced electrons from solar energy efficiently absorbed using semiconductor photocatalysts and

organic dyes. This suggests the potential for more efficient utilization of solar energy compared to CO<sub>2</sub> conversion by photosynthetic microorganisms such as microalgae. In other words, it would be possible to apply a CO<sub>2</sub> conversion apparatus that utilizes the photosynthetic function of microalgae and other organisms, which is already in practical use, to a hybrid system.

Visible-light-driven plastic precursor production from CO<sub>2</sub> using a photocatalyst and microbial cell hybrid system is attracting attention as an innovative technology that can achieve both the resolution of global challenges and economic growth, but currently, high costs are a major challenge. In particular, this system relies on the growth of microorganisms, resulting in low productivity and increased equipment and purification costs. To overcome these challenges, it is necessary to work on improving large-scale culture technology, advanced separation and purification technology, and the development of bioreactors. Furthermore, the production of high-value-added biodegradable plastics and their precursors from CO<sub>2</sub> will further enhance the value of this system.

Next, we focus on the direct use of CO<sub>2</sub> gas in hybrid systems. In the visible-light-driven plastic precursor production from CO<sub>2</sub> using a photocatalyst and microbial cell hybrid system, a mixed gas with an approximate N<sub>2</sub> to CO<sub>2</sub> ratio of 80:20 is used as the raw material. This is a mixed gas composition optimized for substance production in microbial cells. In some cases, adding hydrogen to a gas mixture can improve the efficiency of producing the desired substance. In particular, in the case of visible-light-driven plastic precursor production from CO<sub>2</sub> using a photocatalyst and microbial cell hybrid system, the use of mixed gases, such as exhaust gases emitted from coal-fired power plants, has not yet been considered.

In a visible-light-driven biodegradable plastic precursor production system using photocatalytic dyes and multi-enzymes, however, it is possible to change the composition of the CO<sub>2</sub> gas used as a raw material. In other words, this system has the

potential to use CO<sub>2</sub> diluted with N<sub>2</sub>, *etc.*, emitted from coal-fired power plants, as a raw material. It has been reported that exhaust gases contain approximately 0.02–0.3% NO<sub>x</sub> and SO<sub>2</sub>.<sup>192</sup> Here, a significant advantage of the visible-light-driven biodegradable plastic precursor production system using photocatalytic dyes and multi-enzymes is that it allows for the capture of CO<sub>2</sub> gas in the reaction solution using a weakly basic buffer. In addition, because a buffer solution is used, even if NO<sub>x</sub> or SO<sub>2</sub> is captured, the pH of the reaction solution does not change, and it is expected that this does not significantly affect the total process.

Finally, we discuss the hybrid systems introduced in this study from the perspective of life cycle analysis (LCA). There are currently no reported cases of LCA estimation for photocatalysts, biocatalysts, or microbial cell hybrid systems. Therefore, this approach depending on reports on life cycle assessments (LCAs) for hydrogen production based on water splitting using semiconductor photocatalysts is discussed.<sup>193</sup> According to this report, in the production of 1 kg of hydrogen using semiconductor photocatalysts, greenhouse gases are mainly released during the preparation of the photocatalyst (95.87%). However, we discuss LCA for biocatalytic CO<sub>2</sub> conversion based on bioelectrochemical methods using microbial cells.<sup>194</sup> LCA evaluations of this system indicate that its carbon footprint is comparable to that of fermentation or plant-based manufacturing methods. In other words, it goes without saying that a hybrid system comprising semiconductor photocatalysts and microbial cells also has the potential to contribute to CO<sub>2</sub> reduction. These conclusions suggest that at this stage, there are many hurdles to overcome before hybrid systems can achieve significant CO<sub>2</sub> reduction. However, the fact that value-added substances can be produced from CO<sub>2</sub> and biomass-derived compounds using light energy as a driving force suggests that it would be better to shift the focus from CO<sub>2</sub> reduction to its effective use as a raw material.

## Conclusion and outlook

In this review article, focusing on biodegradable plastics and their precursor production from gaseous CO<sub>2</sub> using systems comprising visible-light-driven redox reactions with biocatalytic processes, the following types are outlined.

(1) The visible-light-driven production of biodegradable plastic precursors such as acetate, shikimic acid and acetoin from CO<sub>2</sub> using a hybrid system comprising the inorganic- or organic-based semiconductor photocatalyst and a microbial cell.

(2) The visible-light-driven production of biodegradable plastic PHB from CO<sub>2</sub> using a hybrid system comprising inorganic- or organic-based semiconductor photocatalysts and a microbial cell.

(3) The visible-light-driven production of biodegradable plastic precursor 3-hydroxybutyrate from acetone and CO<sub>2</sub> using a combination of NAD<sup>+</sup> reduction system of triethanolamine, water-soluble zinc porphyrin, [Cp\*Rh(bpy)(H<sub>2</sub>O)]<sup>2+</sup> and a cell extract including dual-enzymes.

(4) The visible-light-driven production of biodegradable plastic precursors L-malate fumarate from bio-based pyruvate and CO<sub>2</sub> using a photoredox system consisting of an electron donor, a photosensitizer, an electron mediator and an enzyme-based biocatalyst.

In the future, it is expected that innovative technologies with a photo/biocatalytic hybrid system will be developed for the effective and practical use of the visible-light-driven production of biodegradable plastics and their precursors from gaseous CO<sub>2</sub> and small organic molecules. Therefore, the research introduced in this article contributes to the CO<sub>2</sub> fixation, and to alternative plastic or its precursor production for a sustainable society. These systems can fix gaseous CO<sub>2</sub> in small organic molecules and convert it into high-value-added materials, resulting in the long-term storage of CO<sub>2</sub> in molecules.
