Enhancing multi-enzymatic CO₂ conversion via reactor engineering: effects of mass transfer on sustainable and green metrics

Sady Roberto Rodriguez,  Marina Guillén  and Oscar Romero *

The global energy transition toward decarbonization requires highly efficient Carbon Capture and Utilization (CCU) technologies that combine economic feasibility, operational stability and environmental sustainability. A key factor for successful CCU is efficient CO₂ gas–liquid transfer, which can be optimized through tailored reactor designs to maximize yields and utilization. Technological advances such as CO₂-specific sensors have enabled accurate monitoring of CO₂ mass balance enhancing the efficiency of its conversion. This work addresses an in-depth analysis of CO₂ mass transfer in a stirred-tank reactor, focusing on the impact of volumetric gas flow rate on gas–liquid transfer during the multi-enzymatic conversion of CO₂ into high-value compounds using a co-immobilized biocatalyst of formate dehydrogenase and glycerol dehydrogenase enzymes. The volumetric mass transfer coefficient (k_La) was determined at different gas flow rates (1, 0.5 and 0.1 vvm) from a 24% CO₂ gas mixture, with the reaction carried out at 0.1 vvm achieving an outstanding formate production of 66.1 ± 1.4 mM (3 g L^{-1}), due to near-neutral pH conditions that improved the reaction conditions and enhanced biocatalyst stability by at least 1.8-fold compared with high gas flow rate (1.0 vvm). Furthermore, a remarkable CO₂ capture efficiency of $93.3 \pm 2.1\%$ was achieved at 0.1 vvm, along with a high selectivity toward formate and glycerol carbonate, reflecting a complete CO₂ conversion into target products. Finally, the environmental impact of the reaction at 0.1 vvm showed a lower contribution to climate change, reaching 13.2 kg CO₂ eq. per kg products. These results underscore enzymatic CO₂ reduction as an effective and sustainable approach for the development of bio-based industrial processes with a markedly reduced environmental footprint.

Green foundation

1. This work advances green chemistry as the first enzymatic Carbon Capture and Utilization (CCU) report using environmental metrics to support carbon-neutral manufacturing. It valorises industrial emissions and renewable feedstocks into high-value chemicals, significantly reducing the environmental footprint for climate change.
2. The system achieved a record 66.1 mM formate production, 93.3% capture efficiency, and complete conversion into high-value products. This achievement demonstrates high process selectivity and a remarkably low Global Warming Potential (GWP) of 13.2 kg CO₂ eq. per kg of product.
3. Future work should focus on: (1) optimizing FDH catalytic efficiency (k_{cat}/K_m) via protein engineering or bioprospecting to overcome kinetic bottlenecks, and (2) enhancing CO₂ mass transfer through synergy with Carbonic Anhydrase (CA).

1. Introduction

Carbon dioxide (CO₂) is gaining increasing recognition as a valuable carbon feedstock as the global energy landscape shifts toward decarbonization. In this context, CO₂ conversion technologies offer a strategic approach to simultaneously enhance energy storage, contribute to global climate objectives, and promote the development of a circular carbon

economy.¹ However, scaling up these technologies to industrial processing plants requires comprehensive optimization to ensure economic viability and operational stability.² Despite significant advances to develop more efficient catalysts for CO₂ reduction and translating these processes to larger scales, studies focusing on reactor engineering aspects to optimize these catalytic processes remain limited.³

For conventional chemical reactions, including catalytic conversions, reactor engineering has long provided a robust and effective framework for achieving maximum productivity while minimizing cost and energy losses.⁴ Moreover, this approach is crucial for enhancing reaction performance, facili-

tating efficient mass and heat transfer, improving product selectivity and increasing overall process efficiency.^{4,5} Under these principles, a fundamental requirement for the success of both CO₂ capture and utilization processes is the efficient transfer from the gas to the aqueous phase, enabling effective mitigation.⁶ Therefore, evaluating CO₂ mass transfer through tailored reactor configurations is essential to advance industrial deployment of CCU technologies.

Under this context, the volumetric mass transfer coefficient ($k_L a$) is a key parameter that quantifies the rate of gas movement to the liquid phase, directly influencing reaction kinetics and overall performance in inter-phase systems. $k_L a$ is commonly used to assess reactor efficiency, optimize the design and operation of mixing and sparging equipment, and plays a critical role in process scale-up.⁷ In many processes involving the direct conversion of gases such as CO₂ or oxygen (O₂), mass transfer may be slower than the reaction rate; therefore, the rate of gas-liquid transfer becomes the limiting step of the entire process, and its optimization is therefore crucial.⁸ Furthermore, in the case of CO₂ there is an additional step during this transfer, the chemical reaction rate at which CO₂ reacts with water to form various inorganic carbonate species in equilibrium.⁹ Therefore, assessing the volumetric mass transfer coefficient of CO₂ in the biocatalytic reaction is crucial for evaluating reaction rates, improving process efficiency, optimizing reactor performance and enabling successful scale-up.

CO₂ gas-liquid transfer has been typically considered as analogous to O₂ transfer by applying correction factors to account for differences in diffusion coefficients between the two gases.¹⁰ This approach stems from the extensive availability of O₂ sensors, the ease of measuring O₂ transfer, and the abundance of published data.¹¹ However, modern

advances have enabled the development of CO₂-specific sensors that directly measure gas-liquid transfer by detecting pH changes caused by inorganic carbon species,⁷ as the digital in-line CO₂ sensor used in this work. In addition, most CO₂ mass-transfer studies have focused on low pH conditions, where its equilibrium concentration is higher, while only few have evaluated its $k_L a$ at neutral or higher pH.¹²

Consequently, by applying mass transfer analysis and reactor engineering principles, it is possible to integrate instrumentation such as sensors and control systems that generate reliable data to evaluate the overall process balance, ensuring favorable economics when all reactor components perform optimally. Furthermore, adjusting the gas supply rate to maintain the dissolved CO₂ concentration near the optimum for the reaction conditions can reduce unnecessary gas expenditure and maximize the fraction effectively converted into product.¹³

In this study, we investigate the mass transfer of CO₂ in a multi-enzymatic reduction system for the simultaneous production of three high value-added compounds: formate, dihydroxyacetone (DHA) and glycerol carbonate (GC) (Fig. 1). In our previous work, the multi-enzymatic system was developed using the enzymes formate dehydrogenase (FDH) and glycerol dehydrogenase (GlyDH) in their free form,¹⁴ as well as co-immobilized on the Ni²⁺-ReliZyme carrier (bifunctional biocatalyst).¹⁵ FDH enzyme has been considered a key model for the design of CO₂ fixation systems, enabling the production of the only CO₂-derived product currently manufactured at industrial scale, formic acid or formate.¹⁶ This compound finds a wide range of industrial applications, serving as a chemical feedstock, in the textile and leather industries, and as a food additive.¹⁷ To complement this reaction, GlyDH was selected to enable *in situ* cofactor regeneration through glycerol valorization, which is abundantly generated as a byproduct of the bio-

Fig. 1 Overview of the multi-enzymatic system for CO₂ reduction to high-value compounds. The co-production of formate and DHA – from CO₂ and glycerol – is enzymatically catalyzed by formate dehydrogenase (FDH) and glycerol dehydrogenase (GlyDH) enzymes co-immobilized on the Ni²⁺-ReliZyme carrier, allowing the *in situ* NADH regeneration. Likewise, the synthesis of the by-product glycerol carbonate (GC) from CO₂ and glycerol is catalyzed by the nickel (Ni²⁺) present in the bifunctional biocatalyst (prepared on Ni²⁺-ReliZyme carrier) and zinc (Zn²⁺) in the active site of GlyDH from *Bacillus stearothermophilus*.

diesel industry, making it an industrially relevant and low-cost feedstock.¹⁸ From this, DHA is produced, a compound utilized as a tanning agent in the cosmetic industry and as a building block in pharmaceutical synthesis.¹⁹ This FDH–GlyDH synergy has ensured efficient NADH cofactor recycling while simultaneously coupling two thermodynamically challenging reactions and adding value to industrial feedstocks like CO₂ and glycerol.¹⁴ Additionally, GC is formed as a byproduct through the direct carboxylation of CO₂ and glycerol²⁰ [reaction mechanism in Fig S2, SI], catalyzed by metals such as nickel (Ni²⁺) on the immobilization carrier and zinc (Zn²⁺) in the active site of metalloenzyme GlyDH from *Bacillus stearothermophilus*.²¹ This is another high-value chemical with applications in the polymer, pharmaceutical, and cosmetic industries, as well as a versatile intermediate in green chemistry and sustainable synthesis.²⁰

For this work, through reactor engineering, the setup of the multi-enzymatic reaction enabled the development of a mass balance to quantify CO₂ captured and converted at different gas flow rates using an *in situ* sensor system. Likewise, the environmental impact of this bioprocess was assessed through its contribution to climate change (GWP: Global Warming Potential). These findings represent a novelty in the study of CO₂ mass transfer in biocatalytic processes and provide a framework to support the development of sustainable and environmentally friendly systems that combine the capture of CO₂ gas emissions and their subsequent conversion into valuable compounds in a single step.

2. Experimental

2.1. Materials

All reagents were purchased from Sigma Aldrich® (St Louis, MO, USA) and PanReac Quimica S.L.U. (Barcelona, Spain). The cofactors NADH and NAD⁺ were purchased from GERBU Biotechnik GmbH (Heidelberg, Germany). ReliZyme™ EP403S resin was purchased from Resindion S.r.l. (Binasco, Italy). All samples and buffers were prepared in Milli Q water (18.2 MΩ cm, Merck Millipore, USA). The gas mixture 24% CO₂ and 76% N₂ was obtained from Carbueros Metalicos (Barcelona, Spain). Formate dehydrogenase (EC 1.17.1.9) and glycerol dehydrogenase (EC 1.1.1.6) enzymes were produced and purified by the research group according to the procedures reported by the authors.¹⁴

2.2. Determination of the CO₂ volumetric mass transfer coefficient ($k_L a$)

The volumetric mass transfer coefficient ($k_L a$) for CO₂ was determined in a stirred-tank reactor (SpinChem, Sweden) with 200 mL of phosphate buffer 100 mM (pH 7.5) as reaction medium, temperature of 30 °C and stirring set at 300 rpm. A gas mixture composed of 24% CO₂ in nitrogen, similar to the off-gases composition from blast furnaces in the iron and steel industry (24.5% CO₂)²² was employed. The dissolved CO₂ concentration was monitored using a digital in-line CO₂ sensor

InPro5000i/12/220 (Mettler Toledo S.A.E., Barcelona, Spain). This sensor was immersed in the liquid at the same depth for all experiments and the data was collected by an Analytical Transmitter M400 Type 3 (Mettler Toledo S.A.E., Barcelona, Spain). The volumetric gas flow rate per volume of liquid per minute (vvm) was assessed at 0.1, 0.5, 1.0, and 1.5 vvm. Additionally, the effect of the immobilization carrier (Ni²⁺-ReliZyme) resuspended in the medium was evaluated by applying loadings of 5%, 10%, 15%, and 20% of the total reaction volume. Sensor response time was assessed by equilibrating the CO₂ concentration in the medium and then transferring the sensor to a CO₂-free medium, according to the equation in section S5 in the SI. The $k_L a$ was calculated using the following equation, applying a nonlinear model with the Solver tool (Microsoft® Excel):

$$C_{\text{mes}} = C^* + \frac{C^* - C_0}{1 - \tau k_L a} \left[\tau k_L a \exp\left(-\frac{t}{\tau}\right) - \exp(-k_L a t) \right] \quad (1)$$

where: C_{mes} : CO₂ concentration measured by the sensor at certain time t ; C^* : equilibrium or saturation CO₂ concentration in the liquid phase; C_0 : initial dissolved CO₂ concentration in the medium; $k_L a$: the volumetric mass transfer coefficient (min⁻¹); τ : sensor response time; t : time at which the CO₂ concentration is measured.

2.3. Multi-enzymatic reduction of CO₂ by assessing different volumetric gas flow rates

The multi-enzymatic reduction of CO₂ was performed in a stirred-tank reactor using a co-immobilized bifunctional biocatalyst, with *in situ* NADH regeneration and continuous gas supply. As reaction medium, phosphate buffer 100 mM (pH 7.5) was used with NADH 1 mM, glycerol 100 mM, and gas continuously bubbled at volumetric flow rates of 0.1, 0.5, and 1 vvm from a gas mixture with 24% CO₂ in nitrogen, using a mass flow controller EL-FLOW (Bronkhorst, Netherlands). A total of 20 g of biocatalyst (containing approximately 40 mg g⁻¹ of GlyDH and 10 mg g⁻¹ FDH) were suspended in 200 mL of reaction medium. The preparation of this biocatalyst is detailed in SI (section S1).

To monitor the CO₂ inlet and outlet of the reactor, two BCP-CO₂ gas analyzers were installed for *in situ* CO₂ measurements (measured every 5 min). The data were collected and analyzed using the BlueVis software. (BlueSens GmbH, Germany). A digital in-line CO₂ sensor InPro5000i/12/220 was also incorporated to measure its dissolved concentration (measured every 2 min) and the data was collected by an Analytical Transmitter M400 Type 3 (Mettler Toledo S.A.E., Barcelona, Spain). Additionally, a Syntrode pH electrode, connected to a 916 Ti-Touch titrator (Metrohm Hispania, S.L.U., Spain), was installed to continuously monitor the pH throughout the reaction, measuring every hour. Fig. 2 shows the full flow diagram of the reaction setup with the sensors involved. The experiments were conducted in duplicate at 30 °C with constant stirring at 300 rpm over 80 h. Samples were taken

Fig. 2 Flow diagram of the setup for the multi-enzymatic reduction of CO₂ to high value chemicals. (1) Gas mixture 24% CO₂ in N₂. (2) Gas flowmeter. (3) Gas humidification. (4) CO₂ input sensor. (---) Data collection.

periodically to analyze substrate and product concentrations, as well as enzyme activity (sections S2 and S4, SI).

2.4. CO₂ mass balance analysis

The mass balance of CO₂ during the reaction was determined through the sensor-based system integrated into the experimental setup previously detailed. First, the amount of CO₂ at the inlet and outlet of the reactor per unit of time (h) was calculated following eqn (S2) and (S3). Accordingly, the mass of CO₂ captured was calculated using the following equation:

$$\text{CO}_2 \text{ captured (g h}^{-1}\text{)} = \text{CO}_2 \text{ inlet (g h}^{-1}\text{)} - \text{CO}_2 \text{ outlet (g h}^{-1}\text{)} \quad (2)$$

Afterwards, the total amount of CO₂ (in g) that entered the reactor and the amount captured throughout the reaction were calculated by estimating the area under the curve according to eqn (S4) in SI.

For CO₂ converted to formate and glycerol carbonate (GC), only the fraction of CO₂ atoms incorporated into each product was considered. As reported by Gao *et al.*,²³ all CO₂ atoms participate in forming the linear carbonate intermediate during glycerol carbonate synthesis, as well as in formate synthesis. Therefore, correction factors were calculated based on the molecular weights of CO₂ and each product, as described by eqn (S5) in SI. These factors were then incorporated into the subsequent equation to determine the mass of CO₂ converted into product:

$$\text{CO}_2 \text{ converted (g)} = \text{amount of product (g)} \times \text{CF} \quad (3)$$

where: CF formate = 0.978; CF glycerol carbonate = 0.373.

The total amount of CO₂ converted corresponds to the sum of the CO₂ incorporated into each product.

The product yields obtained per g of CO₂ captured were calculated based on the total mass of each molecule produced

and expressed as g g⁻¹ (dimensionless). The following equation was employed:

$$\text{Product yield (g g}^{-1}\text{)} = \frac{\text{total mass of formate or GC produced (g)}}{\text{mass of CO}_2 \text{ captured (g)}} \quad (4)$$

Finally, two CO₂ conversion performance metrics commonly employed in the green chemistry were considered. First, process selectivity refers to the system's ability to direct captured CO₂ toward the desired product, reflecting the reaction efficiency under the given conditions. The following equation was applied:

$$\text{Selectivity (\%)} = \frac{\text{moles product (formate or GC)}}{\text{moles CO}_2 \text{ captured}} \times 100 \quad (5)$$

The sum of the selectivity toward each product represents the global process selectivity.

On the other hand, carbon efficiency indicates how effectively carbon introduced into a process is incorporated into the final product, accounting indirectly for losses in by-products or emissions and providing a key measure of process sustainability and economic efficiency. The carbon efficiency equation used in this work was adapted from Belsa *et al.*²⁴ and Constable *et al.*,²⁵ indicating the sum of the yields of the final CO₂-derived products, formate and glycerol carbonate (GC):

$$\text{Carbon efficiency} = \frac{\sum C_x n_x}{n_{\text{CO}_2}} \times 100 \quad (6)$$

where C_x = number of carbons from CO₂ in each product x (one single carbon); n_x = number of moles of each product (formate or GC); n_{CO_2} = number of moles of CO₂ that entered the system.

2.5. Environmental impact assessment

To assess the environmental impact of this process on climate change, the global warming potential (GWP) was determined for each reaction performed at different volumetric flow rates. The GWP was calculated based on the product mass (eqn (7)) and the energy consumed (eqn (8)), following the equations proposed by Domínguez de María:²⁶

$$\text{GWP (water(wwtp))} = \frac{0.073 \times \% \text{water treated}}{\text{conv.} \times [\text{SL}]} \quad (7)$$

$$\text{GWP (water(energy))} = \left(\frac{0.037 \times \Delta T}{\text{conv.} \times [\text{SL}]} \right) + t \left(\frac{0.0056 \times \Delta T}{\text{conv.} \times [\text{SL}]} \right) \quad (8)$$

where: wwtp = wastewater treatment plant; conv.: CO₂ conversion (%); [SL]: product concentration expressed in kg L⁻¹. *t*: reaction time (80 h).

Considerations: 100% of the residual water was assumed to be treated in a WWTP. Room temperature was set at 25 °C.

3. Results and discussion

3.1. Determination of the volumetric mass transfer coefficient (*k_La*) of CO₂ in a stirred-tank reactor

To study CO₂ mass transfer, its volumetric mass transfer coefficient (*k_La*) was determined in the stirred-tank reactor used for the multi-enzymatic CO₂ reduction reaction. Estimating *k_La* for CO₂ is crucial in bioreactor design, as it assesses reactor efficiency and guides scale-up, especially in processes requiring continuous CO₂ supply, such as in several chemical processes and in some fermentations.²⁷ Moreover, optimizing CO₂ transfer also reduces costs by supplying only the necessary gas amount, thereby improving resource efficiency.²⁸ However, understanding CO₂ chemical equilibrium in water is essential to evaluate its mass transfer in aqueous systems. CO₂ interacts with water to form carbonic acid, bicarbonate, and carbonate, following this dissociation equilibria at pH 7.0 and 30 °C:²⁹

According to some reports, the Total Inorganic Carbon (TIC), which reflects the distribution of these species as a function of the medium's pH, is a key parameter for studying CO₂ gas-liquid transfer, since it not only estimates the amount of CO₂ absorbed but also identifies the dominant form in which it is present.¹² This parameter can be determined using conventional methods such as alkalinity titration or specialized techniques like Non-Dispersive Infrared (NDIR) analysis.³⁰ However, in this study, *k_La*(CO₂) was determined using a dynamic method that requires continuous real-time tracking of the dissolved CO₂ concentration. For that, a digital in-line CO₂ sensor was employed, which measures only dissolved CO₂

(mg L⁻¹). This provides a simplified methodology and enables immediate *in situ* tracking of concentration changes, which are essential for the accurate and rapid determination of *k_La* throughout the process. The operating principle of this sensor, based on the Severinghaus principle, is illustrated in Fig. S1 in SI.

In general, *k_La* determination depends on reactor type and volume, operating conditions (temperature, pH, pressure, agitation), flow rate, immersion depth, suspended solids and the properties of the gas and liquid phases, among other factors.³¹ In this work, the agitation speed was set at 300 rpm to prevent biocatalyst damage at higher stirring rates. Consequently, other factors such as gas flow rate and resuspended solids (immobilization carrier), were examined. As an initial step, the response time of the dissolved CO₂ sensor (*τ*) was assessed according to eqn (S1) in SI. Fig. S3 in the SI provides a graphical illustration and a brief discussion of the sensor's response to a CO₂-free medium, yielding a response time of 0.93 min (56 s).

Fig. 3 shows the *k_La*(CO₂) values obtained by evaluating different volumetric flow rates of the 24% CO₂ mixture, along with the immobilization carrier (Ni²⁺-ReliZyme) present at 10% of the total volume are plot. As expected, the CO₂ gas-liquid transfer rate increased with the volumetric flow rate from 0.1 to 1 vvm, while no further increase was observed at 1.5 vvm, indicating that the mass transfer limit had been reached (Fig. 3A). In experiments with 10% resuspended carrier, *k_La*(CO₂) increased compared to assays without carrier, particularly at higher flow rates such as 1 vvm (Fig. 3A). Suspended solids likely enhance gas-liquid transfer by increasing turbulence and dispersing gas bubbles, expanding the surface area for solubilization.³² As before, no further increase was observed at 1.5 vvm.

Table S1 in the SI summarizes the parameters evaluated for *k_La*(CO₂) in the experiments described. Across flow rates from 0.1 to 1 vvm, the data were well described by a linear model (*R*² > 0.99). Under these conditions, a CO₂ gas-liquid transfer rate of 7.35 ± 0.44 mg L⁻¹ min⁻¹ (0.17 ± 0.02 mM min⁻¹) was achieved with 10% resuspended carrier at 1 vvm. The *k_La*(CO₂) was also determined with pure CO₂. As expected, a highest transfer rate was observed, yielding a *k_La* of 0.32 ± 0.03 min⁻¹ (10.75 mg L⁻¹ min⁻¹, Table S1), due to the higher partial pressure driving faster gas-liquid transfer.

Finally, varying the resuspended carrier at 1 vvm (Fig. 3B) showed that concentrations above 10% caused a linear decrease in *k_La*(CO₂), likely due to interface saturation and increased fluid viscosity limiting bubble mobility.³³ Minimal differences were observed between 5% and 10%, suggesting a negligible effect within this range. Hence, a carrier concentration in that range (from 10–20%) and volumetric flow rate from 0.1–1.0 vvm from the gas mixture 24% CO₂ may represent the optimal operating conditions for this multi-enzyme system.

Compared to oxygen (O₂), for which *k_La* is typically measured, CO₂ generally has a lower *k_La* under standard conditions (25 °C and 1 atm). Under similar reaction conditions in this same reactor, *k_La*(O₂) can reach values up to an order of

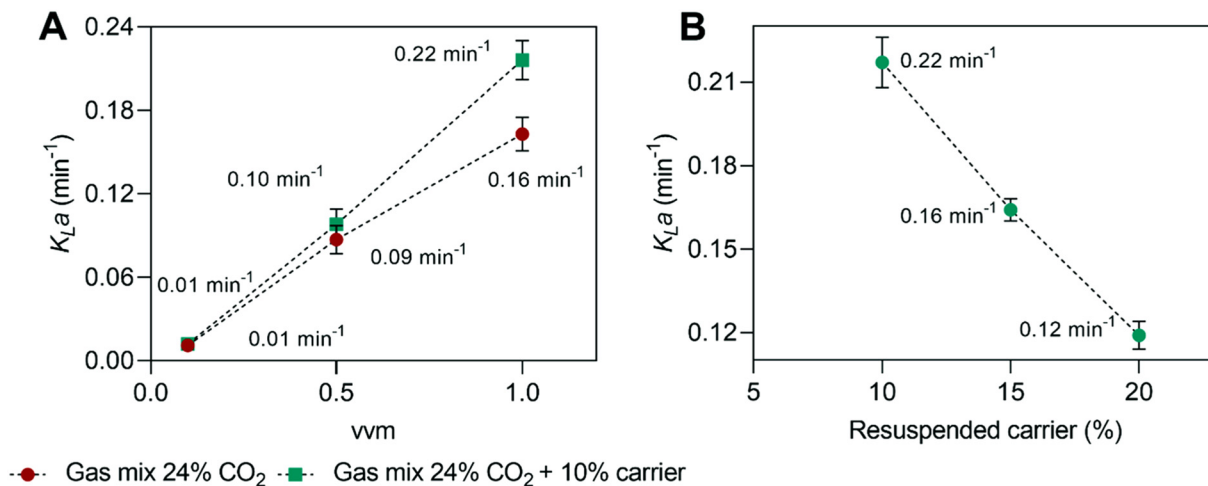

Fig. 3 (A) Gas–liquid CO₂ transfer rate ($k_L a$) by varying the volumetric flow rate (vvm) from the gas mixture 24% CO₂ in nitrogen and with a fixed amount of suspended carrier in the liquid (10%). (B) Gas–liquid CO₂ transfer rate ($k_L a$) by varying the percentage of resuspended Ni²⁺-ReliZyme in the medium at 1 vvm from the gas mixture 24% CO₂.

magnitude higher than $k_L a_{(\text{CO}_2)}$ when air is directly bubbled into the system. Although CO₂ is more soluble than O₂ in water (0.033 vs. 0.001 mol L⁻¹) under standard conditions,³⁴ this results not only from physical dissolution but also from chemical interactions forming inorganic species that prolong CO₂ retention.⁷ However, despite its higher solubility, CO₂ diffuses more slowly than O₂ due to its larger molecular size, and chemical reactions that reduce the free CO₂ available for transfer, leading to lower $k_L a_{(\text{CO}_2)}$ values.³⁵

In contrast, O₂ transfer is often limited by agitation, as increased stirring produces smaller bubbles and greater gas–liquid contact. In the case of CO₂, its transfer is also limited by agitation, but even more so by the gas flow rate, as higher flow rates continuously renews the gas–liquid concentration gradient, thereby enhancing mass transfer and leading to higher $k_L a_{(\text{CO}_2)}$ values.³⁶ However, at lower flow rates, mass transfer is slower, but rapid gas saturation is avoided, maintaining the concentration gradient longer and allowing more efficient gas utilization. In addition, gas bubbles also remain in contact with the liquid for a longer time, promoting more effective CO₂ utilization.^{7,37} Although some studies suggest estimating $k_L a_{(\text{CO}_2)}$ by multiplying $k_L a_{(\text{O}_2)}$ by 0.91 attributed to physico-chemical differences,³⁸ these gases have demonstrated different diffusion coefficients, so their transfer and absorption kinetics can differ even when bubbled together.³⁹ However, in this study, $k_L a_{(\text{CO}_2)}$ was successfully determined in a stirred-tank reactor using a potentiometric sensor, enabling accurate and reliable measurements.

Importantly, this study of gas–liquid mass transfer provides a foundation for potentially incorporating key parameters into reactor-scale simulations for dynamic mass balance and reaction kinetics modeling. The measured $k_L a$ values describe CO₂ transfer, allowing prediction of dissolved CO₂ profiles as a function of operating variables. These results pave the way for implementing gas–liquid mass transfer studies in other enzy-

matic CO₂ transformation including lactic acid production²² and carboxylation, where reaction kinetics depend strictly on CO₂ mass transfer and pH levels. Furthermore, this approach can be extended to other enzymatic processes involving gaseous substrates, such as oxidation reactions, which rely on maintaining optimal dissolved oxygen concentrations in the reaction medium.

3.2. Multi-enzymatic CO₂ reduction by evaluating different gas volumetric flow rates

The multi-enzymatic reduction of CO₂ into high-value compounds was assessed in a stirred-tank reactor by testing different volumetric flow rates (0.1, 0.5, and 1.0 vvm) of a gas mixture containing 24% CO₂, which corresponds to the typical CO₂ content reported for the off-gases from blast furnaces in the iron and steel industry.²² Although the effect of different immobilization carrier loadings on the determination of $k_L a_{(\text{CO}_2)}$ was also evaluated, a 10% carrier-to-volume ratio was used in all these following reactions to ensure good distribution of the carrier in the liquid and to avoid the effect of excessive solids on CO₂ gas–liquid mass transfer. The concentrations of both enzymes (GC-GlyDH and FDH) in the biocatalyst were previously optimized by the authors, for both their free¹⁴ and co-immobilized on Ni²⁺-ReliZyme forms.¹⁵

As a first point of comparison, it is important to understand the strong relationship between CO₂ flow rate and the pH resulting in the reaction medium. As previously explained, CO₂ reacts with water to form carbonic acid, which partially dissociates, releasing protons (H⁺) and thereby modulating the pH of the medium.⁴⁰ Therefore, higher CO₂ flow rates lead to increased CO₂ mass transfer rate and a more pronounced decrease in pH compared to lower flow rates. However, this close relationship is also influenced by key factors in the reaction medium, including buffer capacity, temperature and partial pressure.⁴¹ Fig. S4 in SI shows a comparison of pH evol-

ution over time for reactions at different vvm. At 1 vvm, the pH dropped sharply from 7.5 to 6.7 within one hour, then stabilized around pH 6.6. At 0.5 vvm, pH fell from 7.5 to 6.9 within one hour, then gradually to pH 6.7. At 0.1 vvm, the initial drop was minor, decreasing slowly from pH 7.3 to 7.0. Thus, the CO₂ dissolution rate governs pH changes over time, indicating that the three reactions occurred at different pH levels, which could potentially affect the reactions' microenvironment. Notably, accounting for the CO₂-carbonate equilibrium is also essential for accurately predicting dissolved CO₂ concentrations as a function of medium pH, mass transfer rate and other operating parameters, particularly when extrapolating these effects to potential reactor-scale simulations. This approach has previously been validated for the development of mass transfer models, highlighting gas flow rate and CO₂ loading as the key factors influencing the mass transfer rate⁴²

as well as for models based on mechanistic enzymatic kinetic models, such as those describing carbonic anhydrase, under a range of operating conditions including temperature, CO₂ partial pressure and concentration.^{43,44}

Regarding the multi-enzymatic CO₂ conversion reaction, Fig. 4 presents the concentrations of formate, DHA, and glycerol carbonate, along with glycerol conversion, obtained after 80 h of reaction for the three evaluated volumetric flow rates. The time courses of the three reactions are illustrated in Fig. S5 (SI). As observed, a linear correlation ($R^2 > 0.99$) was found between the gas volumetric flow rate and each product concentrations, as well as glycerol conversion across all experiments, suggesting that CO₂ input and its concentration in the medium are key factors for the performance and efficiency of this multi-enzymatic system. Formate production was inversely proportional to CO₂ input, with lower flow rates resulting in

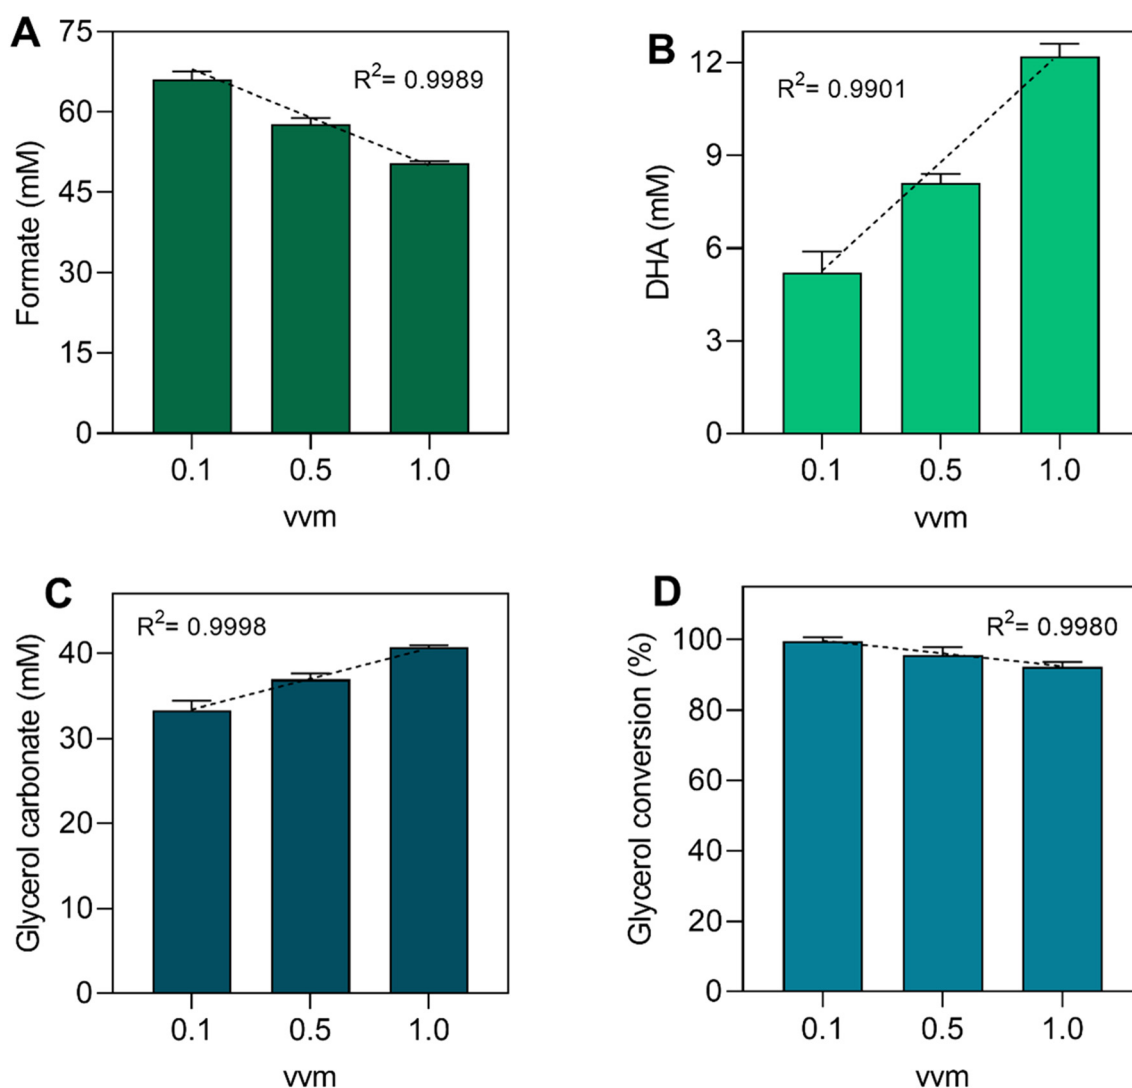

Fig. 4 Multi-enzymatic reduction of CO₂ to high-value compounds using a bifunctional co-immobilized biocatalyst with *in situ* cofactor regeneration, evaluating three different gas volumetric flow rates from a 24% CO₂ gas mixture. (A) Formate [mM]. (B) DHA [mM]. (C) Glycerol carbonate [mM]. (D) Glycerol conversion [%]. The DHA concentrations shown in this figure correspond only to the soluble fraction (not adsorbed onto the biocatalyst).

higher concentrations (Fig. 4A). At the lowest flow rate (0.1 vvm), and therefore at a pH closer to neutral (pH 7.0), the highest formate concentration was achieved, 66.1 ± 1.4 mM (equivalent to 3 g L^{-1}). This represents a 31.2% increase compared to the reaction conducted at 1 vvm (50.4 ± 0.3 mM). This result represents up to an 8.5-fold improvement over previous reports on enzymatic CO_2 reduction and cofactor regeneration platforms.^{45–47} Similarly, this formate production is comparable to electrochemical and bioelectrocatalytic studies, where reported concentrations are similar or lower than those achieved in this work,^{48–50} highlighting the enhanced efficiency of the developed system. This milestone was accompanied by a 1.5-fold increase in the formate synthesis rate (0.66 mM h^{-1} at 1 vvm vs. 0.96 mM h^{-1} at 0.1 vvm), indicating enhanced catalytic performance under lower gas flow conditions. Accordingly, this constitutes the highest formate concentration reported to date *via* enzymatic synthesis.

For DHA, its concentration in the medium decreased as the gas volumetric flow rate was reduced (Fig. 4B), however, its low quantification in the liquid phase is attributed to its adsorption onto the biocatalyst with an adsorption capacity of $140.8 \text{ mg DHA per g}$, as previously documented by the authors.¹⁵ This effect arises from strong interactions between DHA and protein amino groups through the Maillard reaction.⁵¹ Compared to the reaction at 1 vvm, which yielded a soluble DHA concentration of 12.2 ± 0.4 mM, the reaction at 0.1 vvm showed only 5.2 ± 0.7 mM, indicating that 92.1% of DHA produced was adsorbed onto the bifunctional biocatalyst (based on the equimolar formate co-production). This behavior may result from changes in the local microenvironment, such as reactor pressure, pH, or dissolved gas concentration, which can shift adsorption equilibria.⁵² Despite this significant adsorption, the authors also have reported the saturation of the biocatalyst over several reaction cycles, allowing greater accumulation of DHA in the liquid phase. Likewise, its desorption directly from the biocatalyst has also been demonstrated under mild conditions, achieving desorption yields of up to $27.2 \pm 1.8\%$.¹⁵ However, further studies are needed to clarify the mechanisms driving this DHA adsorption and the contribution of each variable under these conditions.

Regarding glycerol carbonate, its concentration decreased as the gas flow rate was reduced (Fig. 4C). This may result from the multi-enzymatic reaction favoring formate synthesis at lower dissolved CO_2 levels, leading glycerol to be preferentially consumed for DHA production rather than glycerol carbonate synthesis. However, no significant differences were observed in the GC production rate, suggesting that the intrinsic reaction kinetics for this compound were not substantially affected by the gas flow conditions. This indicates that the reaction was not limited by the gas–liquid mass transfer of CO_2 . In the case of glycerol, its conversion increased with decreasing gas flow rate, reaching $99.5 \pm 1.2\%$ at 0.1 vvm (Fig. 4D). Thus, optimizing reaction conditions can enhance substrate conversion and orientate the system toward improved formate and DHA enzymatic co-production.

Table S2 in SI presents some performance metrics obtained from the three reactions. At 0.1 vvm, a space-time yield (STY)

for formate of $37.2 \pm 2.2 \text{ mg L}^{-1} \text{ h}^{-1}$ was determined, representing a 1.3-fold improvement compared to the reaction at 1 vvm. A similar improvement was observed in catalyst yield, which reached $29.8 \pm 1.7 \text{ mg formate per g of biocatalyst}$. In the case of DHA and GC, these metrics decreased as the volumetric flow rate was reduced due to enhanced DHA adsorption on the biocatalyst and the shift of the reaction conditions to favor the co-production of formate and DHA while minimizing GC formation.

These remarkable findings can also be attributed to the sustained operational stability of the co-immobilized biocatalyst throughout the reaction, as observed in Fig. 5. Notably, enzyme stability increased as the gas flow rate decreased, suggesting reduced inactivation at lower gas flow rate and dissolved CO_2 levels. At 0.1 vvm, GC-GlyDH and FDH retained $80.2 \pm 2.1\%$ and $96 \pm 1.6\%$ activity after 80 h, representing 1.9- and 1.8-fold improvements over the operational stability of the biocatalyst in the reaction at 1 vvm. This demonstrates the high biocatalyst's robustness and potential for reuse for consecutive reaction cycles under low dissolved CO_2 conditions. In addition, as mentioned earlier, changes in the reaction microenvironment can vary with gas supplementation, affecting parameters such as pH (Fig. S4 in SI). Since pH depends on dissolved CO_2 concentration, this can significantly influence enzyme stability. At slightly acidic pH (6.5–7.0), free GlyDH can lose up to 30% of its activity compared to pH 7.5, whereas free FDH loses only about 10%.¹⁴ Additionally, even when immobilized, the enzymes may show slight pH-dependent inactivation, but much less than in their free form.⁵³ Consequently, lower dissolved CO_2 helped maintain near-neutral pH, enhancing enzyme stability and biocatalytic efficiency for formate production.

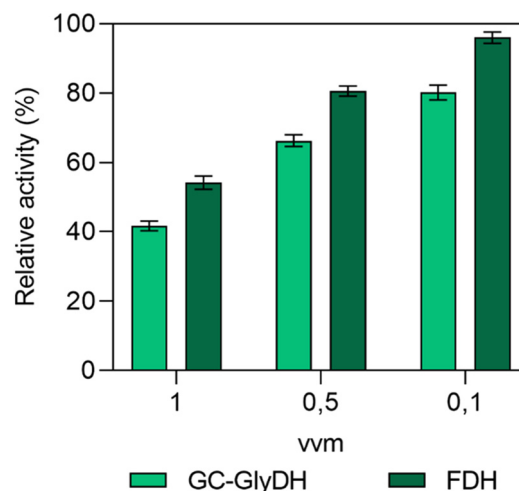

Fig. 5 Operational stability of the bifunctional biocatalyst after 80 h of reaction corresponding to the multi-enzymatic reduction of CO_2 to high-value chemicals by evaluating three different gas volumetric flow rates using a 24% CO_2 gas mixture (1, 0.5 y 0.1 vvm). 100% relative activity was considered as the activity at the initial reaction time (time zero).

3.3. Carbon flow analysis in the CO₂ capture and utilization system

After evaluating the multi-enzymatic system at different gas flow rates, a mass balance was performed to quantify the CO₂ captured and converted, representing the fraction of emissions not released into the atmosphere. The setup included inlet, outlet, and dissolved CO₂ sensors, providing real-time measurements throughout the reaction. Fig. S6 in SI shows the corresponding time-course data. At 1 vvm, dissolved CO₂ concentrations remained stable between 227–247 mg L⁻¹ (Fig. S6A), indicating high gas turnover and steady substrate supply. At 0.5 vvm, the maximum CO₂ concentration was ~232 mg L⁻¹ but it gradually declined after 50 h, reaching 145 mg L⁻¹ by the end of the reaction. A similar behavior was observed at 0.1 vvm, where the maximum CO₂ concentration was only ~214 mg L⁻¹, followed by a steady decline at 48 h and stabilizing during the final two h at around ~36 mg L⁻¹, reflecting a slower gas renewal rate. Despite this, CO₂ remained sufficient to sustain the multi-enzymatic reaction (Fig. S5, SI). Regarding the decline in dissolved CO₂ concentrations observed at 0.5 and 0.1 vvm, it likely reflects CO₂ consumption exceeding gas replenishment, unlike at 1 vvm where renewal maintains stable levels (Fig. 6A).⁵⁴ Furthermore, as the reaction proceeds, rising fluid viscosity and foam formation can further limit gas-liquid mass transfer, especially at low gas flow rates.⁵⁵

Regarding the gas inlet and outlet sensors, they operate *via* dual-wavelength infrared (IR) absorption to quantify CO₂ in the gas phase. As shown in Fig. S6B, the inlet CO₂ proportion remained steady at 24.4 ± 0.2%, matching the gas mixture used in all experiments. However, although the inlet CO₂ percentage was the same in all reactions, the actual amount of CO₂ supplied varied with the gas flow rate. At 1 vvm, the outlet CO₂ fraction remained stable at ~21.1 ± 0.1%, indicating ~3.4 ± 0.5% of CO₂ was continuously dissolved into the medium. At 0.5 vvm, the outlet CO₂ was ~19.8 ± 0.9% during the first 30 h, then gradually declined to ~16.4 ± 0.5%, reflecting more CO₂ accumulation in the reaction system over time. At 0.1 vvm, the outlet CO₂ initially increased to ~8.4 ± 0.4% and then steadily decreased after 30 h, reaching complete capture after 55 h, with no CO₂ detected at the system outlet. This behavior reflects lower gas turnover, allowing more efficient CO₂ capture and progressive consumption.

Based on the data collected from the gas sensors, the amount of non-emitted CO₂ (captured fraction) throughout the reaction was determined. Table 1 summarizes the overall CO₂ mass balance, including the amounts of CO₂ supplied, captured, and converted (to formate and/or glycerol carbonate), as well as the yields at each stage. As observed, only 13.8 ± 1.3% of the CO₂ supplied was captured within the system during the reaction conducted at 1 vvm, whereas at 0.5 vvm the CO₂ retention nearly doubled to 24.4 ± 0.9%. This implies that some CO₂ remains in the system, either physically trapped, chemically absorbed (mainly as bicarbonate and other inorganic species), or unconverted due to reaction limitations. In the case of the reaction at 0.1 vvm, an exceptional capture efficiency of 93.3 ± 2.1% was achieved, indicating that the decreased gas-liquid interfacial saturation at low volumetric flow rates resulted in a significant improvement in CO₂ retention within the system for its subsequent conversion. Under these conditions, conversion performance was also favored, where nearly the entire amount of CO₂ captured was converted into the target products, reaching production yields of 0.84 ± 0.07 g of formate and 1.09 ± 0.06 g of GC (as the total molecule) per g of CO₂ captured at 0.1 vvm. Thus, although more CO₂ is captured at 1 vvm, the multi-enzymatic system was favored by the improved biocatalyst performance at near-neutral pH at 0.1 vvm, thereby maximizing the utilization of the captured CO₂. Despite this, the amount of CO₂ converted into products was similar across all reactions, suggesting that conversion is the limiting step of this system.

Based on CO₂ conversion to the target products, Table 2 summarizes key performance metrics for this stage. As observed, enzymatic selectivity for formate increases as the gas flow rate decreases (82.5 ± 2.4% at 0.1 vvm), showing more efficient enzymatic CO₂ utilization at neutral pH. In the case of GC, its non-enzymatic production was less selective, especially at 0.1 vvm, where formate yield was roughly twice that of GC. At 0.1 vvm, all captured CO₂ was efficiently converted into formate and GC, obtaining an overall selectivity of 123.1 ± 2.2%. This apparent overestimation likely arises from the error linked to the determination of captured CO₂ (0.72 ± 0.12 g) which represents almost a 17% of error, combined with the accuracy of the flow meter and gas sensors, particularly when operating at low flow rates. Nonetheless, despite this, the global selectivity in each reaction

Table 1 Material balance and performance metrics for CO₂ capture and conversion in the multi-enzymatic reduction process to high value-added compounds

Volumetric gas flow rate (vvm)	Supplied CO ₂ (g)	Captured CO ₂ (g)	Capture efficiency (%)	Converted CO ₂ ^a (g)	Product yield ^b (g product per g CO ₂)	
					Formate	GC
1	7.74 ± 0.23	1.07 ± 0.18	13.8 ± 1.3	0.81 ± 0.13	0.43 ± 0.09	0.90 ± 0.08
0.5	3.87 ± 0.14	0.95 ± 0.08	24.4 ± 0.9	0.84 ± 0.14	0.56 ± 0.04	0.92 ± 0.09
0.1	0.77 ± 0.11	0.72 ± 0.12	93.3 ± 2.1	0.89 ± 0.08	0.84 ± 0.07	1.09 ± 0.06

Experiments were conducted at three different volumetric gas flow rates using a 24% CO₂ gas mixture in a stirred-tank reactor with a 200 mL reaction volume. GC: glycerol carbonate. ^a Corresponding to the fraction of CO₂ atoms incorporated into formate and glycerol carbonate. ^b Based on the total mass of each product.

Table 2 Performance metrics of CO₂ conversion into high-value products, formate and glycerol carbonate (GC), evaluated at different volumetric gas flow rates (1, 0.5 and 0.1 vvm) of a 24% CO₂ gas mixture in a multi-enzymatic system

Volumetric gas flow rate (vvm)	Selectivity (%)		Global process selectivity (%)	Carbon efficiency (%)
	Formate	GC		
1	42.4 ± 1.3	33.5 ± 0.8	75.9 ± 1.1	10.5 ± 0.7
0.5	55.1 ± 1.7	34.4 ± 1.5	89.5 ± 1.6	21.8 ± 1.1
0.1	82.5 ± 2.4	40.6 ± 1.8	123.1 ± 2.2	114.7 ± 1.6

was considerably high, as the system allowed for the maximization of CO₂ utilization to produce both products.

In terms of carbon efficiency, only 10.5 ± 0.7% of the supplemented CO₂ at 1 vvm was converted into the target products (formate and GC), while at 0.5 vvm roughly doubled to 21.8 ± 1.1%. Remarkably, at 0.1 vvm, all supplied CO₂ was converted into the target products (114.7 ± 1.6%), indicating maximal utilization of the total supplemented CO₂. The slight overestimation likely reflects the previously mentioned sources of errors. Under these conditions, glycerol was also almost completely consumed, with a conversion yield of 99.5 ± 1.2% (Fig. 4D). Therefore, the inclusion of an additional CO₂ and glycerol valorization route in this multi-enzymatic system, the synthesis of glycerol carbonate, enhanced the overall carbon efficiency and expanded the products portfolio of this process, thus also contributing to overall process sustainability by generating an additional high-value product from the same feedstocks. Likewise, the potential for developing reactor-scale predictive models based on these operation conditions requires explicit consideration of pH-dependent CO₂ speciation when coupling gas-liquid mass transfer with reaction kinetics. As result, this would enable a more realistic description of CO₂ behavior and availability within the system, ensuring adequate gas supply for the reaction while maximizing conversion efficiency in greener biocatalytic processes.

Several studies have shown successful CO₂ capture and conversion into value-added products. Zhou *et al.* demonstrated the production of methane from CO₂ with complete capture and conversion efficiency (100%) using a fixed-bed reactor packed with adsorbents specifically designed for CO₂.⁵⁶ The same reactor, operated in different configurations, has also been widely used to produce various chemicals and fuels from industrial gas streams, achieving capture efficiencies over 85%.⁵⁷ On the other hand, CO₂ capture using the regenerative ammonia method has reported efficiencies exceeding 90% for the direct production of fertilizers from CO₂,⁵⁸ and capturing CO₂ as carbamic acid from amino acid salts has also been shown to be a feasible strategy for CO₂ utilization to produce compounds such as oxazolidinones.⁵⁹ Additionally, among the simplest capture methods, solvent-based approaches have achieved efficiencies above 90% using solvents like monoethanolamine (MEA), 2-amino-2-methyl-1-propanol (AMP), and piperazine (PZ).⁶⁰ However, CO₂ conversion in these systems is often limited by solvent degradation, impurities, and the reduced reactivity of CO₂ caused by the formation of stable amine complexes.⁶¹ Finally, although electrochemical systems

often achieve high CO₂ conversion rates exceeding 95%, this performance frequently comes at the expense of low selectivity, increased energy requirements and CO₂ supplementation with low capture efficiencies.^{62,63}

In the case of enzymatic processes, CO₂ conversion rates are often not reported, mainly due to measurement challenges, the involvement of other inorganic substrates, and the common practice of estimating yields from NADH consumption, as typically done in FDH-catalyzed reactions. However, a study reported a CO₂ conversion to formate efficiency of 80.5% using FDH immobilized on metal-organic frameworks (MOFs), markedly improving the enzyme's catalytic performance.⁶⁴ Additionally, complete (100%) conversion of CO₂ from industrial off-gases to formate by FDH was also reported, highlighting the potential of these systems for efficient valorization of gas emissions, even at low CO₂ concentrations.⁶⁵ In multi-enzymatic systems, CO₂ reduction has been successfully applied to produce compounds such as pyruvate, achieving conversion of 81%.⁶⁶ In contrast, methanol production generally shows much lower CO₂ conversion efficiencies, mainly due to the complexity of multiple sequential enzymatic reduction steps, with reported values ranging from 3% to 25%,^{67,68} highlighting the challenges in optimizing these multi-step biocatalytic processes. Finally, carbonic anhydrase has been shown to selectively accelerate CO₂ capture up to 20-fold, while also promoting its conversion into compounds such as carbon monoxide and carbonates, reaching yields of approximately 80% or higher.^{6,69} In addition, its synergy with FDH enzymes has been effectively demonstrated to enhance the CO₂ conversion to formate.^{46,47} Overall, enzymes represent a feasible biocatalytic tool for the development of sustainable processes aimed at CO₂ capture and conversion into value-added industrial products.

3.4. Environmental implications of the multi-enzymatic CO₂ reduction system

Once the CO₂ conversion performance was evaluated, the environmental impact of these processes was also analyzed. As extensively reported, the enzymatic reduction of CO₂ represents a green and sustainable catalytic route for mitigating greenhouse gas emissions.^{70,71} Since enzymes originate from renewable biological systems, they are inherently biocompatible and environmentally benign, offering a safer alternative to heavy-metal and synthetic complex catalysts. Consequently, enzymatic catalysis stands out as a key strategy for advancing carbon-neutral bioprocessing and sustainable industrial chem-

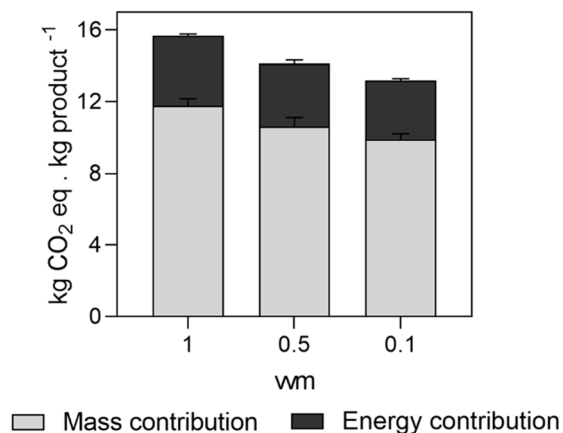

Fig. 6 Total global warming potential (GWP) assessment of the multi-enzymatic reduction of CO₂ to high value-added compounds (accounting for formate, DHA and GC), varying the inlet volumetric gas flow rate from a 24% CO₂ gas mixture.

istry.⁷² However, to the best of our knowledge, only few reports have evaluated the environmental impact of these enzymatic processes. Therefore, to evaluate the greenness of this multi-enzymatic reaction, the Global Warming Potential (GWP) was estimated both in terms of the materials used for the production and the energy invested in each reaction carried out at different volumetric gas flow rates (Fig. 6).

A clear correlation was observed between the applied volumetric gas flow rate and the global warming contribution. At the lowest flow rate (0.1 vvm), CO₂ conversion was highest, indicating that maximizing multi-enzymatic carbon utilization can significantly reduce the environmental footprint of the process due to more efficient use of resources. In this reaction, a total GWP of 13.2 ± 0.2 kg CO₂ eq. per kg of product was obtained. Compared to electrochemical CO₂ reduction platforms, some processes can exhibit an environmental impact at least 1.5 times greater than that observed in this study.^{73–75}

This is mainly due to their high energy consumption, the materials required for electrodes and electrolytes, and their rapid degradability, which generates additional waste. However, in some cases, the optimization of these processes at industrial scales can substantially improve their environmental footprint (up to four times lower than in this study).^{76,77} Regarding these enzymatic platforms, information on their environmental performance remains limited; nevertheless, the present study provides a foundational dataset that can be used to further develop a comprehensive Life Cycle Assessment (LCA).

On the other hand, the energy demand and conversion losses associated with fossil-based processes can lead to a higher global warming impact compared to CO₂-based processes, where different amounts of products can be obtained directly from CO₂,⁷⁸ as demonstrated in this study. Consequently, renewable-based systems are considered the most promising candidates for achieving negative greenhouse gases (GHG) emissions.⁷⁹ As a result, a CO₂ capture

and conversion system was successfully developed by investigating the gas–liquid mass transfer of CO₂ and implementing a sensor-based approach to accurately quantify the amount of CO₂ that was prevented from being emitted into the atmosphere and effectively converted into valuable industrial molecules. These findings pave the way for the development of large-scale sustainable multi-enzymatic systems and the establishment of benchmarks such as industrial feedstock valorization, CO₂ capture and conversion efficiency, robust biocatalyst stability, and reduced environmental impact, which could serve as key criteria for identifying promising strategies that make a substantial contribution to GHG mitigation and advance green chemistry and CCU technologies.

4. Conclusions

The gas–liquid transfer of CO₂ in the multi-enzymatic system was successfully evaluated in a stirred-tank reactor using reactor engineering to gain insights into CO₂ mass transfer during the stages of capture and conversion and enabling a first assessment of the sustainability of this type of bioprocess. The volumetric mass transfer coefficient ($k_L a$) was determined with a digital in-line CO₂ sensor based on pH under different gas flow rates from a 24% CO₂ gas mixture, showing that higher flow rates increased CO₂ transfer when the system operated with 10% immobilization carrier resuspended. At the lowest volumetric gas flow rate (0.1 vvm), the multi-enzymatic reaction achieved the highest formate concentration reported to date by an enzymatic route, 66.1 ± 1.4 mM. This was attributed to pH shifts from CO₂ dissolution, which improved biocatalyst stability at near-neutral pH and revealed a strong correlation between pH and CO₂ transfer rate, significantly influencing the biocatalytic transformation. Finally, the mass balance showed that a portion of the supplied CO₂ was effectively retained, avoiding its release to the atmosphere, with the highest capture efficiency at 0.1 vvm ($93.3 \pm 2.1\%$). Moreover, although a higher amount of CO₂ was captured at 1 vvm, all CO₂ captured at 0.1 vvm was selectively converted into value-added products (formate and glycerol carbonate) demonstrating the high efficiency of the multi-enzymatic system for CO₂ valorization, facilitated by significantly improved reaction conditions at 0.1 vvm. Thus, evaluating gas flow rate provided key insights into CO₂ gas–liquid transfer, directly enhancing enzyme-driven carbon utilization at low CO₂ concentrations. These insights provide a foundation for further reactor-scale simulations predicting CO₂ behavior based on pH-dependent speciation, mass transfer rates, and other key operating variables under these conditions. Furthermore, the environmental impact assessment highlights enzymatic CO₂ reduction systems as promising and viable strategies for industrial implementation within conventional manufacturing processes, achieving a substantial reduction in the environmental impact of this system, afforded by maximal CO₂ utilization for the production of the target products.

Author contributions

S. R. R. contributed to data curation, formal analysis, investigation and writing the original draft. The project, conceptualized by M. G. and O. R., involved activities such as funding acquisition, project administration, and methodological development. Additionally, M. G. and O. R., were actively engaged in validating, supervising, visualizing, reviewing, and editing this manuscript.
