# Engineering the electronic structure of Ni–Co bimetallic sites toward efficient electrochemical biomass upgrading and CO<sub>2</sub> reduction

Qing-Lian Yan,<sup>a</sup> Xun-Bin Lin,<sup>a</sup> Ji-dan Liu,<sup>a</sup> <sup>a</sup> Ting Ouyang<sup>\*a</sup> and Zhao-Qing Liu <sup>\*ab</sup>

Electrochemical coupling of the 5-hydroxymethylfurfural oxidation reaction (HMFOR) and CO<sub>2</sub> reduction reaction (CO<sub>2</sub>RR) offers a promising route to produce high-value chemicals while lowering the energy input. A critical bottleneck in the CO<sub>2</sub>-HMF coupled system is the poor ability of the anode catalyst to adsorb and desorb HMF and OH<sup>−</sup>, resulting in prohibitively high energy consumption. We construct an anode catalyst NiCo<sub>2</sub>O<sub>4</sub> by regulating the tetrahedral site to increase the ratio of Co<sup>3+</sup>/Co<sup>2+</sup>, which achieves a faradaic efficiency (FE) for 2,5-furandicarboxylic acid (FDCA) of 99.1% at 1.5 V vs. RHE. The CO<sub>2</sub>-HMF coupled system with NiCo<sub>2</sub>O<sub>4</sub> as an anode and Au as a cathode at a low cell voltage of 1.7 V affords a total energy conversion efficiency of 43.3%; the FE<sub>FDCA</sub> of the anode is 91.9%, and the FE of the cathode is 94.7% (66.1% for CO and 28.6% for H<sub>2</sub>). *In-situ* surface-enhanced Raman spectroscopy further elucidates the dynamic evolution of the surface state and intermediates of the integrated system: the NiCo<sub>2</sub>O<sub>4</sub> anode promotes HMF-to-FDCA conversion *via* potential-dependent formation of Ni<sup>3+</sup> and Co<sup>3+</sup> intermediates for OH<sup>−</sup> capture. Meanwhile, the key intermediate \*CO for CO<sub>2</sub>-to-CO conversion is detected at the cathode, and the simultaneous progress of the anodic and cathodic reactions significantly reduces the energy consumption of the coupled system. This work provides important theoretical support and a technical approach for the design and amplification of CO<sub>2</sub>-HMF coupled systems.

## Introduction

Electrochemical conversion technology provides a green solution for key issues in the field of energy and environment. Among them, water electrolysis hydrogen production (HER system) occupies a core position in the large-scale preparation of hydrogen energy due to the cheap and easy availability of raw materials.<sup>1</sup> Nevertheless, relying on a single method for hydrogen production is insufficient to address the complex challenges of carbon emission reduction and the high-value integration of resources. Using the electrocatalytic CO<sub>2</sub> reduction reaction (CO<sub>2</sub>RR) to obtain value-added chemicals represents a critical pathway toward global carbon neutrality.<sup>2–7</sup> However, the practical development of CO<sub>2</sub>RR electrolyzers is hindered by the high overpotential of the anodic oxygen evolution reaction (OER), which increases energy consumption and generates low-value byproduct O<sub>2</sub>.<sup>8–10</sup> A promising strategy to overcome these limitations involves replacing the OER with the electrooxidation of biomass-derived small molecules. These

oxidation reactions not only operate at lower overpotentials but also yield high-value products such as organic acids or fuels.<sup>11–13</sup> By integrating biomass oxidation with the CO<sub>2</sub>RR in a single electrolyzer, it could achieve dual benefits: enhanced energy efficiency and simultaneous production of valuable chemicals at both electrodes, thereby advancing sustainable electrochemical synthesis.<sup>14–16</sup>

An electrolyzer system with the anode producing liquid products and the cathode generating gas products is convenient for product detection, separation and collection.<sup>17</sup> A promising candidate for the anodic reaction is 5-hydroxymethylfurfural, an important and impressive biomass derivative.<sup>18</sup> Compared to the OER (4OH<sup>−</sup> + O<sub>2</sub> → 2H<sub>2</sub>O + 4e<sup>−</sup>, 1.23 V), the HMFOR (HMF + 6OH<sup>−</sup> → FDCA + 4H<sub>2</sub>O + 6e<sup>−</sup>, 0.3 V) shows a much lower theoretical potential and produces high-value chemicals.<sup>19–21</sup> HMF can be selectively oxidized or reduced to produce polymer monomers, chemicals and liquid fuels because its structure contains active hydroxyl groups and aldehyde groups. Notably, FDCA is one of the 12 sugar-based platform compounds listed by the U.S. Department of Energy and is obtained through the oxidation of HMF's two oxygen-containing groups into carboxyl groups (Table S1).<sup>18,22–24</sup> Accordingly, coupling the cathodic CO<sub>2</sub>RR with the anodic HMFOR is expected to simultaneously produce high value-added chemicals in an electrolytic cell. The half-cell and overall responses involved are shown below.

<sup>a</sup>School of Chemistry and Chemical Engineering, Institute of Clean Energy and Materials, Key Laboratory for Clean Energy and Materials, Huangpu Hydrogen Innovation Center, Guangzhou University, Guangzhou 510006, P. R. China. E-mail: ouyt@gzhu.edu.cn; lzqzu@gzhu.edu.cn

<sup>b</sup>School of Chemistry, South China Normal University, Guangzhou 510006, P. R. China

Notably, the development of the CO<sub>2</sub>-HMF coupled system has attracted considerable attention.<sup>25–27</sup> However, the integrated system of the HMFOR and CO<sub>2</sub>RR remains underexplored, with unresolved scientific challenges in understanding the reaction kinetics at both electrodes. Research on this system still faces a key challenge: the current research on the CO<sub>2</sub>-HMF coupled system mostly focuses on the independent development and performance optimization of anode and cathode catalysts. However, there is a lack of direct and *in situ* experimental evidence for the dynamic evolution of active sites at both ends of the catalyst, the formation and consumption of key reaction intermediates, and the dynamic synergy mechanism between them under actual working conditions. Co<sub>3</sub>O<sub>4</sub> as a HMFOR catalyst has garnered significant attention for its abundant octahedral Co (Co<sup>3+</sup> O<sub>h</sub>) active sites.<sup>28,29</sup> Co<sup>3+</sup> O<sub>h</sub> sites with their high oxidation state, optimized electronic structure, and stable lattice environment, serve as critical active centers for enhancing HMFOR activity and selectivity.<sup>30–32</sup> However, three key limitations hinder their practical application: (1) in the octahedral crystal field, the fully occupied t<sub>2g</sub><sup>6</sup> of low-spin Co<sup>3+</sup> O<sub>h</sub> sites results in excessively strong adsorption of HMF molecules, while the activation capability for OH<sup>−</sup> remains insufficient. This imbalance impedes the efficient deprotonation of intermediates (such as 5-hydroxymethyl-2-furancarboxylic acid (HMFA) and 5-formyl-2-furancarboxylic acid (FFCA)); (2) the HMFOR deprotonation process under alkaline conditions relies heavily on the dynamic supply of OH<sup>−</sup> on the surface of the catalyst. However, the weak adsorption and activation of OH<sup>−</sup> by Co<sub>3</sub>O<sub>4</sub> lead to sluggish reaction kinetics; (3) Co<sup>3+</sup> O<sub>h</sub> sites in the spinel structure tend to trigger the OER side reaction and significantly reduce the HMFOR selectivity.

To address the imbalance between HMF adsorption strength and OH<sup>−</sup> supply efficiency, doping Co<sub>3</sub>O<sub>4</sub> with transition metals (Fe, Zn, Ni...) has become an effective strategy to regulate the electronic and catalytic properties of Co<sup>3+</sup> O<sub>h</sub> sites.<sup>33–35</sup> In this work, a NiCo<sub>2</sub>O<sub>4</sub> catalyst was synthesized *via* Ni incorporation into Co<sub>3</sub>O<sub>4</sub>. Systematic electrochemical measurements, *in situ* spectroscopic studies, and theoretical calculations reveal that the Ni sites significantly enhance the concurrent adsorption and activation of HMF and OH<sup>−</sup>, thereby accelerating the dehydrogenation and electron-transfer kinetics during the rate-determining FFCA → FDCA step. Consequently, the NiCo<sub>2</sub>O<sub>4</sub> anode achieves an exceptional FE<sub>FDCA</sub> of 99.1% at 1.5 V vs. RHE, along with a low potential of 1.22 V vs. RHE to deliver a current density of 10 mA cm<sup>−2</sup>. A double-chamber membrane electrolytic cell, based on the CO<sub>2</sub>-HMF coupled system, was constructed. It features a gas diffusion electrode and an ion-selective membrane for the efficient separation of FDCA and CO. In the integrated coupled system, when the cell voltage of the NiCo<sub>2</sub>O<sub>4</sub> catalyst is 1.7 V, the FE<sub>FDCA</sub> of the anode is 91.9%,

the cathode FE is 94.7% (66.1% for CO and 28.6% for H<sub>2</sub>), and the total energy conversion efficiency is 43.3%, which proves that the combination of biomass pricing and the CO<sub>2</sub> conversion reaction is very important to reduce the cost of electricity and improve the economic efficiency and the great prospect of producing high value-added chemicals. Furthermore, *in-situ* surface-enhanced Raman spectroscopy (SERS) indicates that the NiCo<sub>2</sub>O<sub>4</sub> anode promotes HMF-to-FDCA conversion *via* potential-dependent formation of Ni<sup>3+</sup> and Co<sup>3+</sup> intermediates for OH<sup>−</sup> capture. Meanwhile, the evolution of key intermediates in the CO<sub>2</sub> to \*CO pathway is monitored at the cathode and directly reveals the dynamic evolution process of the surface state of the catalyst under operating conditions, confirming the high degree of kinetic synergy between the two ends of the reaction, thereby significantly reducing the overall energy consumption of the system. This work elucidates the synergistic mechanism of the two types of reaction kinetics *in situ* under coupling conditions for the first time, which provides a key experimental basis for optimizing the bifunctional electrocatalytic system and further exploring the coupling reaction mechanism. Through the above research, we aim to provide theoretical support and a technical path for the design and large-scale application of biomass-carbon dioxide co-electrolysis systems and promote the electrosynthesis technology towards the goal of high efficiency.

## Results and discussion

### Catalyst synthesis and characterization

Based on the above discussion, NiCo<sub>2</sub>O<sub>4</sub> supported on CC was synthesized by the hydrothermal-calcination method (Fig. S1). NiO and Co<sub>3</sub>O<sub>4</sub> were synthesized by the same method as that for the comparison sample. The crystal structure was characterized by X-ray powder diffraction (XRD). The diffraction peaks of NiO, Co<sub>3</sub>O<sub>4</sub> and NiCo<sub>2</sub>O<sub>4</sub> are consistent with the PDF standard cards of NiO (PDF # 44-1159), Co<sub>3</sub>O<sub>4</sub> (PDF # 43-1003) and NiCo<sub>2</sub>O<sub>4</sub> (PDF # 20-0781), respectively (Fig. S2), indicating that the materials were successfully synthesized. The morphology of the obtained electrocatalysts is observed by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). The SEM image of NiO shows that its structure is a linear cluster, and Co<sub>3</sub>O<sub>4</sub> shows a nanosheet array structure (Fig. S3b and c). NiCo<sub>2</sub>O<sub>4</sub> exhibits a nanoneedle array structure (Fig. S3a). HRTEM images enlarge the blue framed area of a single nanosheet and show clear lattice fringes with a spacing of 0.234 nm, which corresponds to the (111) crystal plane of NiCo<sub>2</sub>O<sub>4</sub> (Fig. S4). The selected area electron diffraction (SAED) patterns correspond to (111), (220), (311), (222) and (400) crystal planes (Fig. S5), which is consistent with the results of XRD and HRTEM. The corresponding element mapping image displays that the Ni, Co and O elements on the surface of the catalyst are evenly distributed (Fig. S6). The above analysis indicates the successful synthesis of NiCo<sub>2</sub>O<sub>4</sub>. Furthermore, it can be seen from TEM that the (222) crystal plane is the main unit cell of NiCo<sub>2</sub>O<sub>4</sub>. The analysis of the unit cell configuration of the (111) crystal plane of Co<sub>3</sub>O<sub>4</sub> and NiCo<sub>2</sub>O<sub>4</sub> in Fig. 1a preliminarily speculates that the octahedral interstitial Co<sup>3+</sup> with strong

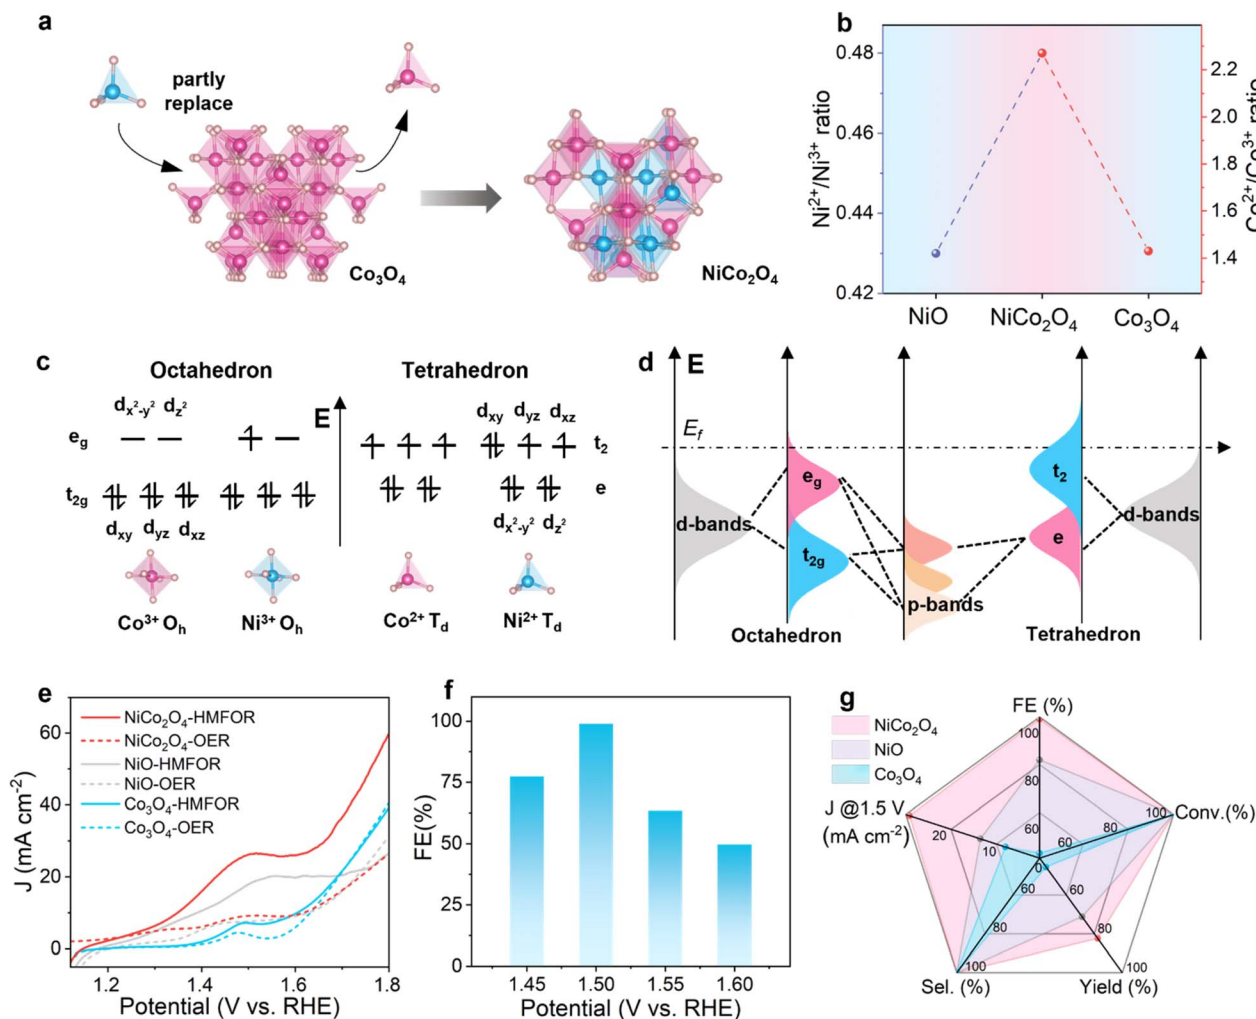

Fig. 1 (a) Lattice structures of  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$ . (b) The  $\text{Ni}^{2+}/\text{Ni}^{3+}$  ratio and the  $\text{Co}^{2+}/\text{Co}^{3+}$  ratio obtained from XPS for corresponding samples. (c) Schematic electron distribution of the tetrahedron coordination compared to octahedron coordination. (d) Interaction mode of Ni, Co-d and adsorbed molecule p-orbitals in octahedral and tetrahedral configurations. (e) LSV curves with and without 10 mM HMF. (f)  $\text{FE}_{\text{FDCA}}$  of the  $\text{NiCo}_2\text{O}_4$  at different potentials. (g) HMFOR performance comparison of NiO,  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$ .

adsorption to HMF, after the  $\text{Ni}^{2+}$  preferentially replaces the tetrahedral interstitial  $\text{Co}^{2+}$ . After that, the unit cell locally forms an 'octahedral interstitial  $\text{Co}^{3+}$ -tetrahedral interstitial  $\text{Ni}^{2+}$ ' adjacent coordination structure. Because the oxidation of  $\text{Co}^{3+}$  is much stronger than that of  $\text{Ni}^{2+}$ , in order to maintain the charge balance and reduce the lattice energy,  $\text{Ni}^{2+}$  will transfer the outer electrons to  $\text{Co}^{3+}$  through the  $\text{O}^{2-}$  bond, and finally  $\text{Co}^{3+}$  is reduced to  $\text{Co}^{2+}$  (still occupying the octahedral gap).  $\text{Ni}^{2+}$  may be oxidized to  $\text{Ni}^{3+}$  (maintaining the tetrahedral/octahedral gap), and the electrons realize the directional flow between the adjacent ions in the tetrahedral-octahedral gap. The increase in  $\text{Co}^{3+}$  electron cloud density further strengthens the adsorption of HMF, and the introduced high-energy d orbital of  $\text{Ni}^{2+}$  contributes to the desorption of the product. In order to investigate the effect of Ni introduction on the oxidation state of Co, X-ray photoelectron spectroscopy (XPS) measurements were performed on NiO,  $\text{Co}_3\text{O}_4$ , and  $\text{NiCo}_2\text{O}_4$  samples (Fig. S7). The Ni 2p spectra of NiO and  $\text{NiCo}_2\text{O}_4$  (Fig. S8a) show two spin-orbit

binaries (Ni 2p<sub>3/2</sub> and Ni 2p<sub>1/2</sub>), belonging to  $\text{Ni}^{3+}$  (855.5 eV and 873.7 eV) and  $\text{Ni}^{2+}$  (853.7 eV and 871.7 eV) peaks. The Co 2p spectra of  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$  (Fig. S8b) show two spin-orbit binary peaks (Co 2p<sub>3/2</sub> and Co 2p<sub>1/2</sub>), belonging to  $\text{Co}^{3+}$  (779.2 eV and 794.3 eV) and  $\text{Co}^{2+}$  (780.6 eV and 795.9 eV) peaks. As shown in Fig. 1b, the ratio of  $\text{Ni}^{2+}/\text{Ni}^{3+}$  (0.48/1) in  $\text{NiCo}_2\text{O}_4$  is higher than that in NiO (0.43/1). At the same time, the ratio of  $\text{Co}^{2+}/\text{Co}^{3+}$  in  $\text{NiCo}_2\text{O}_4$  (2.27) increases compared with  $\text{Co}_3\text{O}_4$  (1.43). The above results show that after introducing Ni into  $\text{Co}_3\text{O}_4$ , electrons can be transferred from Ni to Co and promote the reduction of  $\text{Co}^{3+}$  to  $\text{Co}^{2+}$ , and  $\text{Co}^{3+}$  reversely induces the equilibrium results of  $\text{Ni}^{2+}$  oxidation and Ni-induced  $\text{Co}^{3+}$  reduction. Next, the spinel cell composition of  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$  and the corresponding d-orbital electron filling are understood, which is conducive to the interpretation of the experimental results. The effect of Ni introduction on the molecular configuration of  $\text{Co}_3\text{O}_4$  was further explored. The d-orbital electron filling orbital distribution maps of the Ni and

Co tetrahedron and octahedron were  $\text{Co}^{3+} \text{O}_h$  ( $t_{2g}^6$ ),  $\text{Ni}^{3+} \text{O}_h$  ( $t_{2g}^6 e_g^1$ ),  $\text{Co}^{2+} T_d$  ( $e^4 t_2^3$ ), and  $\text{Ni}^{2+} T_d$  ( $e^4 t_2^4$ ) (Fig. 1c and d). It is worth noting that the energy level of the splitting d orbital in the octahedral field is  $t_{2g} (d_{xy}, d_{yz}, d_{xz}) < e_g (d_{x^2-y^2}, d_{z^2})$ , while the energy level of the splitting d-orbital in the tetrahedral field is opposite,  $e (d_{x^2-y^2}, d_{z^2}) < t_2 (d_{xy}, d_{yz}, d_{xz})$ . Compared with the octahedral coordination, the tetrahedral coordination has three high-energy  $t_2 (d_{xy}, d_{yz}, d_{xz})$  orbitals. More high-energy d-orbitals near the Fermi level provide more opportunities to interact with reactants and intermediates, thus providing a better ability to adjust the catalytic performance.<sup>36,37</sup>

### HMFOR performance evaluation

The HMFOR of NiO,  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$  was evaluated in a standard three-electrode system. The screening experiments of different concentrations of HMF show that the activity increased with the increase in the HMF concentration (0–40 mM), indicating that the reaction behavior is concentration-dependent (Fig. S9). In order to further study the electro-oxidation behavior and reaction mechanism, 10 mM HMF was selected. Fig. 1e shows the linear sweep voltammetry (LSV) curves of NiO,  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$  in the OER and HMFOR. For the OER (dotted line), the curves of  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$  both have a peak at 1.49 V vs. RHE, which corresponds to the oxidation of  $\text{Co}^{2+}$  to form high valence  $\text{Co}^{3+}$  species at potential. The peak at 1.44 V vs. RHE in the curve of NiO corresponds to the high valence  $\text{Ni}^{3+}$  species formed by the oxidation of  $\text{Ni}^{2+}$  at the potential.<sup>38</sup> When 10 mM HMF is introduced into the electrolyte, the  $\text{NiCo}_2\text{O}_4$  electrode reaches 10  $\text{mA cm}^{-2}$  at 1.35 V vs. RHE, which is lower than that of NiO (1.39 V) and  $\text{Co}_3\text{O}_4$  (1.6 V), indicating that the HMFOR performance of  $\text{NiCo}_2\text{O}_4$  is better. When the feed ratio of Ni:Co is 1:1, compared with the morphology and LSV response of  $\text{NiCo}_2\text{O}_4$  (Fig. S10 and S11), it further indicates that the introduction of Ni greatly improves the HMFOR performance of  $\text{Co}_3\text{O}_4$ . Under the same conditions, the Tafel slope of  $\text{NiCo}_2\text{O}_4$  (255  $\text{mV dec}^{-1}$ ) is smaller than that of  $\text{Co}_3\text{O}_4$  (398  $\text{mV dec}^{-1}$ ) and NiO (400  $\text{mV dec}^{-1}$ , Fig. S12), which also verifies that the HMFOR performance of  $\text{NiCo}_2\text{O}_4$  is better than that of  $\text{Co}_3\text{O}_4$  and NiO from the kinetic point of view.  $\text{NiCo}_2\text{O}_4$  was evaluated by measuring the electrochemical double layer capacitance ( $C_{dl}$ ), where a larger  $C_{dl}$  means a larger specific surface area and, consequently, more exposed active sites under set conditions.  $\text{NiCo}_2\text{O}_4$  shows a higher  $C_{dl}$  value (3.78  $\text{mF cm}^{-2}$ ) than NiO (2.65  $\text{mF cm}^{-2}$ ) and  $\text{Co}_3\text{O}_4$  (1.88  $\text{mF cm}^{-2}$ , Fig. S13). The larger ECSA value indicates that  $\text{NiCo}_2\text{O}_4$  has more specific surface area of reaction, which is beneficial for the improvement of HMFOR activity.

The  $\text{FE}_{\text{FDCA}}$  of  $\text{NiCo}_2\text{O}_4$  was tested at 1.45–1.60 V vs. RHE (Fig. 1f). With the increase in potential, the  $\text{FE}_{\text{FDCA}}$  decreases gradually due to the emergence of the competitive OER. It is worth noting that the highest  $\text{FE}_{\text{FDCA}}$  is 99.1% at 1.5 V vs. RHE. The substances present and composition of the electrolyte at this potential were determined by HPLC-MS. The results show that there is only one substance present (FDCA), indicating that HMF is completely converted into FDCA, and the electro-oxidation process does not stay in the intermediate product

step, further indicating the reliability of the data (Fig. S14). A complete comparison of the current density, HMF conversion, FDCA and FE yields and selectivity at 1.5 V vs. RHE is revealed in the radar plot (Fig. 1g), indicating that  $\text{NiCo}_2\text{O}_4$  in NiO,  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$  has significant HMFOR activity. The current density on the  $\text{NiCo}_2\text{O}_4$  electrode reaches 26.2  $\text{mA cm}^{-2}$  at 1.5 V vs. RHE, which is much higher than the same voltage on the  $\text{Co}_3\text{O}_4$  electrode (7.05  $\text{mA cm}^{-2}$ ) and the NiO electrode (18  $\text{mA cm}^{-2}$ ). This result indicates that  $\text{NiCo}_2\text{O}_4$  significantly boosts HMFOR efficiency and facilitates electron transfer. The conversion of HMF on NiO,  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$  electrodes is 100%, but it is worth noting that the  $\text{FE}_{\text{FDCA}}$  is 99.1% and the yield is 82.44%, which are higher than those of the NiO electrode (82%/71.24%) and  $\text{Co}_3\text{O}_4$  electrode (43.09%/45.58%). According to the FE of  $\text{Co}_3\text{O}_4$  which is less than the yield, it is preliminarily speculated that it is more conducive to the formation of intermediate products, namely hydroxyl oxidation. The FE of NiO is lower than its yield, which is more conducive to the formation of FDCA, namely aldehyde oxidation. From the perspective of product collection, the introduction of Ni changes the configuration of  $\text{Co}_3\text{O}_4$ , which greatly improves the HMFOR efficiency of  $\text{NiCo}_2\text{O}_4$ .

### Corroboration of the reaction pathway

At present, there are two main oxidation pathways of the HMFOR in alkaline electrolyte: 2,5-diformylfuran (DFF) and HMFCFA (Fig. 2a).<sup>16,39</sup> In the DFF-directed pathway, the hydroxyl groups of HMF are preferentially oxidized to form DFF, and DFF is further oxidized to FFCA by aldehyde oxidation. In the HMFCFA-oriented pathway, HMF is preferentially oxidized by the aldehyde group to form HMFCFA and then oxidized by the hydroxyl group to form FFCA. Finally, FDCA is obtained by deep oxidation of FFCA. The  $\text{NiCo}_2\text{O}_4$ -catalyzed HMFOR was used to elucidate the reaction pathways involved at 1.5 V vs. RHE, and traces of HMF consumption and product (HMFCFA, FFCA, DFF and FDCA) accumulation were tracked by HPLC (Fig. 2b and S15). In 1 M KOH containing 7.7 mM HMF (15 mL), a decrease in HMF and an increase in FDCA are observed with the accumulation of charge, indicating that HMF could be converted into FDCA by  $\text{NiCo}_2\text{O}_4$  (Fig. S16 and S17). The color change of the reaction solution during the specific experiment also confirmed the complete conversion process (Fig. S18). In addition to HMF and FDCA, the intermediate products HMFCFA and FFCA can be clearly detected, confirming that the conversion of HMF to FDCA follows the HMFCFA-oriented pathway ( $\text{HMF} \rightarrow \text{HMFCFA} \rightarrow \text{FFCA} \rightarrow \text{FDCA}$ ). In order to further determine the conversion pathway of the HMFOR catalyzed by  $\text{NiCo}_2\text{O}_4$ , potential- and time-dependent *in situ* FTIR spectroscopy was used.<sup>40–42</sup> As shown in Fig. 2c–e,  $\text{NiCo}_2\text{O}_4$  has a band at 1654  $\text{cm}^{-1}$  (HMF), indicating that HMF is consumed first and then adsorbed, while the downward band of  $\text{Co}_3\text{O}_4$  has the largest change, and NiO has no obvious change, indicating that  $\text{Co}_3\text{O}_4$  has the largest adsorption of HMF and NiO has no adsorption. At the same time, fork-like bands at 1523 and 1541  $\text{cm}^{-1}$  are observed, indicating the formation of intermediate HMFCFA (Fig. S19). With time, a new peak appeared at 1700  $\text{cm}^{-1}$ , which

Fig. 2 (a) Two possible reaction pathways for the HMFOR. (b) HPLC chromatogram of oxidation products during the HMFOR at 1.5 V vs. RHE. *In situ*-FTIR spectra of NiCo<sub>2</sub>O<sub>4</sub> (c), Co<sub>3</sub>O<sub>4</sub> (d) and NiO (e) samples. Bode plots of Co<sub>3</sub>O<sub>4</sub> (f), NiCo<sub>2</sub>O<sub>4</sub> (g) and NiO (h) samples for the HMFOR.

belongs to the carboxylate group, which is related to the formation of FDCA. NiCo<sub>2</sub>O<sub>4</sub> has the most obvious change in the descending section, indicating that the formation of FDCA is the fastest. These results indicate that the introduction of Ni with strong desorption of weakly adsorbed reactants on Co<sub>3</sub>O<sub>4</sub>, which has strongly adsorbed reactants and difficult to desorb products, can result in the HMFOR with efficient multi-electron transfer and dual-site synergistic catalysis of strong adsorption of Co and strong desorption of Ni. In particular, the absence of the DFF signal once again confirms the dominant position of the HMFO pathway in the NiCo<sub>2</sub>O<sub>4</sub>-catalyzed HMFOR, which is consistent with the results of HPLC analysis. As mentioned, the absence of DFF features is likely to be caused by spontaneous conversion in strongly alkaline solutions.<sup>43,44</sup> In addition, NiCo<sub>2</sub>O<sub>4</sub> shows excellent catalytic stability and can be recycled four times continuously (Fig. S20a and b), and the conversion rate, yield and FE are all greater than 95%, which can be attributed to its good structural integrity. After the HMFOR test, the stability of the structure and composition was evaluated by a number of characterization studies. The SEM image shows that the overall outline of the needle-like array structure of

NiCo<sub>2</sub>O<sub>4</sub> is well maintained (Fig. S21), and the results show that NiCo<sub>2</sub>O<sub>4</sub> has a stable microstructure. The XRD pattern shows that NiCo<sub>2</sub>O<sub>4</sub> retained the original characteristic diffraction peak, and no new peak appeared (Fig. S22), indicating that the crystal structure of the catalyst did not change significantly after the HMFOR. The surface state of the elements was studied by XPS analysis. The subtle changes in the high-resolution XPS spectra of Co and Ni indicate a subtle change in the surface chemical state of NiCo<sub>2</sub>O<sub>4</sub> (Fig. S23). All these analyses demonstrate the excellent robustness of NiCo<sub>2</sub>O<sub>4</sub> in the HMFOR.

*In-situ* electrochemical impedance spectroscopy (EIS) tests were performed on NiO, Co<sub>3</sub>O<sub>4</sub> and NiCo<sub>2</sub>O<sub>4</sub> in 1 M KOH or 1 M KOH + 10 mM HMF under a potential gradient of 1.1–1.6 V vs. RHE. The HMFOR and OER processes of NiO, Co<sub>3</sub>O<sub>4</sub> and NiCo<sub>2</sub>O<sub>4</sub> show similar trends in the high-frequency and medium-frequency regions (10–10<sup>5</sup> Hz) (Fig. 2f–h and S24a–c). During the OER process, the Bode plots of NiO, Co<sub>3</sub>O<sub>4</sub> and NiCo<sub>2</sub>O<sub>4</sub> show characteristic peaks in the low-frequency region (0.1–10 Hz). When the potential increases to 1.5 V vs. RHE, an inflection point appears in the low frequency region, which may

be related to the adsorption of hydroxyl groups on the surface and surface oxidation, because the initial potential of the OER is in this potential range. The relevant equivalent circuit and Nyquist diagram and the fitted  $R_{ct}$  values are shown and summarized (Fig. S25, S26 and Tables S2–S7). By comparison, the introduction of Ni into  $\text{Co}_3\text{O}_4$  effectively reduces the transfer resistance and results in a faster reaction rate.

### In-depth understanding of HMFOR performance

The oxidation of HMF in alkaline solution requires the participation of  $\text{OH}^-$  species.<sup>45,46</sup> The adsorption and conversion of  $\text{OH}^-$  is an essential step in the HMFOR, similar to the first step of electrocatalytic water oxidation in an alkaline environment. Therefore, it is necessary to clarify the transformation behavior of  $\text{OH}^-$  by exploring the OER performance of the material. The Tafel slope of  $\text{NiCo}_2\text{O}_4$  ( $373 \text{ mV dec}^{-1}$ ) is larger than that of  $\text{Co}_3\text{O}_4$  ( $207 \text{ mV dec}^{-1}$ ) and  $\text{NiO}$  ( $320 \text{ mV dec}^{-1}$ ) (Fig. S27), indicating that the introduction of Ni inhibits the OER kinetics of  $\text{NiCo}_2\text{O}_4$ , that is, inhibits the conversion of  $\text{OH}^-$  on the surface of  $\text{NiCo}_2\text{O}_4$ . The O 1s XPS spectra of different samples can be deconvoluted into three parts (Fig. 3a and b), which are surface adsorbed water molecules ( $530.2 \text{ eV}$ ), oxygen vacancies ( $528.3 \text{ eV}$ ) and lattice oxygen atoms combined with metal ions ( $526.8 \text{ eV}$ ). Compared with the high-resolution spectra of  $\text{NiO}$  and  $\text{Co}_3\text{O}_4$ , the proportion of lattice oxygen ( $526.8 \text{ eV}$ ) in  $\text{NiCo}_2\text{O}_4$  is significantly reduced, and the proportion of adsorbed water ( $530.2 \text{ eV}$ ) is significantly increased, which confirms the existence of abundant oxygen vacancies in  $\text{NiCo}_2\text{O}_4$ . The ratio of lattice oxygen to adsorbed oxygen in  $\text{NiCo}_2\text{O}_4$ ,  $\text{Co}_3\text{O}_4$  and  $\text{NiO}$  samples is 2.6 : 1, 6.7 : 1 and 9.2 : 1, respectively. The results show that the proportion of adsorbed oxygen species in  $\text{NiCo}_2\text{O}_4$  is significantly higher than that in  $\text{Co}_3\text{O}_4$  and  $\text{NiO}$ , indicating that  $\text{NiCo}_2\text{O}_4$  may have better adsorption capacity for oxygen-containing species  $\text{OH}^-$ , which is more conducive to the HMFOR. In the *in-situ* FTIR spectra (Fig. 3c), in the range of  $3100\text{--}3600 \text{ cm}^{-1}$ ,  $\text{NiO}$  shows little change in the intensity of the O–H vibration peak and  $\text{NiCo}_2\text{O}_4$  shows higher O–H vibration peak intensity than  $\text{Co}_3\text{O}_4$ , indicating that more  $\text{OH}^-$  species are formed or accumulated on the surface of  $\text{NiCo}_2\text{O}_4$  during the reaction, while there is no  $\text{OH}^-$  accumulation on the surface of  $\text{NiO}$ . At the same time, it is detected that when the voltage was turned off at the end, the O–H characteristic signals of  $\text{Co}_3\text{O}_4$ ,  $\text{NiCo}_2\text{O}_4$  and  $\text{NiO}$  did not decrease or disappear (Fig. S28). The peak intensity, peak shape and peak position remain stable, which is completely consistent with the characteristics in the process of electrification. This indicates that this process does not involve the physical adsorption of free OH in the electrolyte, but involves the process of chemical combination of active sites on the catalyst surface with OH to form M–OH. The generated M–OH is part of the chemical structure of the catalyst surface and has a stable chemical bonding state. Next,  $\text{NiCo}_2\text{O}_4$  and  $\text{Co}_3\text{O}_4$  were further explored, and the adsorption activity of  $\text{OH}^-$  was also determined in an  $\text{OH}^-$  deficient environment (1 M PBS). The results show that the OER performance of  $\text{NiCo}_2\text{O}_4$  is much higher than that of  $\text{Co}_3\text{O}_4$  (Fig. 3d), which also proves that the introduction of Ni is particularly beneficial

for the capture of  $\text{OH}^-$ . In Fig. 3e,  $\text{NiCo}_2\text{O}_4$  ( $-27.5 \text{ mV}$ ) shows a more negative zeta potential value than  $\text{Co}_3\text{O}_4$  ( $-9.5 \text{ mV}$ ) in the KOH environment, representing more  $\text{OH}^-$  in the inner Helmholtz layer, which also supports the above conclusion. In addition, in the cyclic voltammetry (CV) curve (Fig. 3f, g and S29), an obvious oxidation peak can be observed in the potential range of  $0.8\text{--}1.05 \text{ V vs. RHE}$ , indicating the adsorption of  $\text{*OH}$ . At the same time, the linear fitting results show that the process is an adsorption control process (Fig. S30 and S31).

Open circuit potential (OCP) was measured to detect changes in the internal organic adsorbent content of the Helmholtz layer. When 10 mM HMF is injected, although the OCP change of  $\text{NiCo}_2\text{O}_4$  ( $0.536 \text{ V}$ ) is close to that of  $\text{Co}_3\text{O}_4$  ( $0.548 \text{ V}$ ), the OCP potential of  $\text{Co}_3\text{O}_4$  of  $\text{NiCo}_2\text{O}_4$  is significantly smaller, indicating that more HMF molecules are inherently adsorbed in the inner Helmholtz layer. As shown in Fig. 3h, the OCP of  $\text{NiCo}_2\text{O}_4$  decreases faster after the addition of HMF, which also means that the introduction of Ni is beneficial for the dynamic adsorption of HMF. The evidence of whether  $\text{Co}^{3+}$  is the active site of the HMFOR is further investigated. Therefore, we conducted a  $\text{Co}^{3+}$  elimination time test to explore the function of  $\text{Co}^{3+}$  species in the HMFOR. As shown in Fig. 3i,  $\text{NiCo}_2\text{O}_4$  is first oxidized to form  $\text{Co}^{3+}$  species and accumulate at an oxidation potential of  $1.1 \text{ V vs. RHE}$ , resulting in the enrichment of  $\text{Co}^{3+}$ , which is completed in 1 M KOH + 10 mM HMF. When accumulated to a certain extent, the potential is converted to OCP, and the potential gradually decreases, indicating the attenuation of  $\text{Co}^{3+}$ . When an additional amount of HMF (50 mM) is introduced into the backward system in the first 10 s, the decay rate of  $\text{Co}^{3+}$  increases sharply, and the decay time is shortened from about 284 s to 55 s, indicating that  $\text{Co}^{3+}$  is the active site of the HMFOR.

### Density functional theory calculations

In order to further reveal the introduction of Ni, that  $\text{NiCo}_2\text{O}_4$  has a significant improvement in the selectivity and performance of HMF oxidation to FDCA and the internal promotion mechanism for the integration of  $\text{NiCo}_2\text{O}_4$  in the HMFOR, we performed DFT calculations.<sup>47</sup> According to the optimized stable structures of  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$ , the (111) crystal plane of the catalyst sample is selected for calculation. After adsorption of HMF (Fig. 4a),  $\text{NiCo}_2\text{O}_4$  ( $0.143 \text{ e}^-$ ) transferred more electrons to HMF than  $\text{Co}_3\text{O}_4$  ( $0.112 \text{ e}^-$ ), indicating a stronger interaction with HMF. Considering that the appropriate adsorption behavior of  $\text{OH}^-$  and HMF is critical to the HMFOR performance, the bonding strength of  $\text{OH}^*$  and  $\text{HMF}^*$  at different sites on the sample was evaluated (Fig. 4b, S32 and Tables S8, S9). For the adsorption of  $\text{OH}^*$ , the Co sites of  $\text{NiCo}_2\text{O}_4$  ( $-1.14 \text{ eV}$ ) show a smaller bonding strength than the Ni sites of  $\text{NiCo}_2\text{O}_4$  ( $-0.70 \text{ eV}$ ) and the Co sites of  $\text{Co}_3\text{O}_4$  ( $-1.05 \text{ eV}$ ). However, for the adsorption of HMF, the Co sites of  $\text{NiCo}_2\text{O}_4$  ( $-2.55 \text{ eV}$ ) exhibit more negative adsorption energy than the Ni sites of  $\text{NiCo}_2\text{O}_4$  ( $-1.84 \text{ eV}$ ) and the Co sites of  $\text{Co}_3\text{O}_4$  ( $-1.96 \text{ eV}$ ), indicating that the introduction of Ni enhances the adsorption behavior of HMF and  $\text{OH}^*$  on the Co sites of  $\text{NiCo}_2\text{O}_4$ , while the Ni sites of  $\text{NiCo}_2\text{O}_4$  exhibit worse

**Fig. 3** (a) Relative content of oxygen vacancies, M-O, and adsorbed oxygen groups in the above samples. (b) High-resolution O 1s XPS spectra of NiO,  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$ . (c) The *in-situ* FTIR spectra of NiO,  $\text{Co}_3\text{O}_4$  and  $\text{NiCo}_2\text{O}_4$  samples recorded at 1.5 V vs. RHE for 30 min in the HMFOR. HMF and  $\text{OH}^*$  adsorption behavior than the Co sites of  $\text{Co}_3\text{O}_4$ , which just balances the competitive adsorption of HMF molecules and  $\text{OH}^-$  species, a reaction conducive to subsequent steps. In addition, the total density of states (TDOS) of  $\text{NiCo}_2\text{O}_4$  near the Fermi level (EF) is significantly higher than that of  $\text{Co}_3\text{O}_4$  due to the introduction of Ni (Fig. 4c and d), indicating that the conductivity of  $\text{NiCo}_2\text{O}_4$  is enhanced, which is conducive to achieving faster interfacial electron transfer in the electrocatalytic process, thus effectively promoting the elementary steps involved in multi-electron transfer in the HMFOR, especially the rate-determining step. The smoother electron supply directly reduces the electron transfer energy barrier, thereby improving the overall reaction kinetics. The partial density of states (PDOS) analysis shows that both Co-3d and Ni-3d orbitals have a major contribution to TDOS, and there are strong peaks and signals near EF, indicating that Ni as an active site promotes electron transfer and has a lower energy

barrier. After the introduction of Ni, the d-band center ( $-2.796$  eV) of Co in  $\text{NiCo}_2\text{O}_4$  is slightly shifted upward compared with  $\text{Co}_3\text{O}_4$  ( $-2.814$  eV), indicating that its interaction with adsorbed oxidation intermediates is strengthened, which is consistent with the strengthening of  $\text{OH}^*$  adsorption behaviour. Then, the reaction state of the HMFOR process on the sample was studied (Fig. 4e–g, S33 and Tables S10–S14), which shows the specific adsorption configuration with the lowest energy path and the corresponding intermediate. Since the HMFOR is an exothermic reaction from  $\text{HMF} \rightarrow \text{HMF}^* \rightarrow \text{HMFC}^* \rightarrow \text{FFCA}^* \rightarrow \text{FDCA}^*$  and  $\text{HMF} \rightarrow \text{HMF}^* \rightarrow \text{DFF}^* \rightarrow \text{FFCA}^* \rightarrow \text{FDCA}^*$ , and the last step  $\text{FDCA}^* \rightarrow \text{FDCA}$  is an endothermic reaction, the HMF adsorption and FDCA desorption steps are determined as the reaction rate-determining steps (RDSs). For HMF adsorption, the Co sites of  $\text{NiCo}_2\text{O}_4$  adsorb HMF to form  $\text{HMF}^*$  with the lowest energy. Combined with the comparison of adsorption configurations, it can be seen that the Co sites of

Fig. 4 (a) The calculated charge density difference (CDD) of HMF adsorbed on  $\text{Co}_3\text{O}_4$  (111) (left) and  $\text{NiCo}_2\text{O}_4$  (111) (right) surfaces, which was calculated using the following equation:  $\Delta\rho = \rho(\text{total}) - \rho(\text{surface}) - \rho(\text{HMF})$ . The yellow region represents electron accumulation, while the blue region represents electron depletion. (b) The adsorption energies of  $\text{HMF}^*$  and  $\text{OH}^*$  on Ni sites and Co sites of  $\text{NiCo}_2\text{O}_4$  and Co sites of  $\text{Co}_3\text{O}_4$ . The density of states (DOS) of  $\text{NiCo}_2\text{O}_4$  (c) and  $\text{Co}_3\text{O}_4$  (d). The Gibbs free energy diagrams of the HMFCa (e) and DFF (f) paths of the HMFOR on the Ni and Co sites of  $\text{NiCo}_2\text{O}_4$  and the Co sites of  $\text{Co}_3\text{O}_4$ . (g) The adsorption configurations of HMFOR intermediate HMFCa on Ni sites and Co sites of  $\text{NiCo}_2\text{O}_4$  and Co sites of  $\text{Co}_3\text{O}_4$ .

$\text{NiCo}_2\text{O}_4$  adsorb from the side of HMF. The Ni sites of  $\text{NiCo}_2\text{O}_4$  and the Co sites of  $\text{Co}_3\text{O}_4$  are adsorbed from the front of HMF, and the steric hindrance is large, indicating that the Co sites of  $\text{NiCo}_2\text{O}_4$  are more conducive to the formation of  $\text{HMF}^*$  to accelerate the reaction, which is consistent with the previous *in situ* FTIR analysis. Compared with the HMFCa path and the DFF path, the Co site of  $\text{HMF}^* \rightarrow \text{HMFCa}^*$  is more exothermic than the Co site of  $\text{HMF}^* \rightarrow \text{DFF}^*$ , which is more conducive to the generation of  $\text{HMFCa}^*$ , further confirming that the main path is the HMFCa path. Since  $\text{FDCA}^*$  is endothermically desorbed to obtain FDCA, the Ni sites of  $\text{NiCo}_2\text{O}_4$  are superior to the Co sites of  $\text{NiCo}_2\text{O}_4$  and the Co sites of  $\text{Co}_3\text{O}_4$ . Combined with the adsorption configuration, it can be seen that the conversion of  $\text{FDCA}^*$  to FDCA requires desorption from adjacent metal atoms, and the Ni adsorption capacity is poor, indicating that the Ni sites of  $\text{NiCo}_2\text{O}_4$  are more favorable for

$\text{FDCA}^*$  to form FDCA. The results show that the introduction of Ni and the synergistic effect on  $\text{NiCo}_2\text{O}_4$  are beneficial to accelerate the reaction conversion rate in the RDS and HMFOR processes, thereby promoting the improvement of product selectivity and yield.

#### Electrocatalytic performance of the $\text{CO}_2$ -HMF coupled system reaction

Based on  $\text{NiCo}_2\text{O}_4$ , a paired electrolysis system was developed with the prepared  $\text{NiCo}_2\text{O}_4$  as the HMFOR anode and Au nanoparticles as the  $\text{CO}_2\text{RR}$  cathode (Fig. 5a and S34).<sup>8,14,25</sup> For comparison, the  $\text{CO}_2\text{RR}$  system was also compared with the traditional anode OER. The LSV curve shown in Fig. 5b shows that at the same current density, the voltage required for the  $\text{CO}_2$ -HMF coupled system is lower than that of the OER- $\text{CO}_2\text{RR}$  system ( $\Delta E = 275$  mV), indicating that the use of biomass small

molecule oxidation instead of the OER can reduce the energy consumption required for the electrolysis process. The cathode and anode products of the coupled system were analyzed at 1.5–1.8 V (Fig. 5c and d). The FE<sub>FDCA</sub> at the anode is higher than 86%, and the highest value reached 91.9% at 1.7 V. The selectivity of the cathode to CO also reached 69.8% at 1.7 V, the FE for CO was 66.1%, and the FE of H<sub>2</sub> was 28.6%. These results are among the top records for both the FE of CO<sub>2</sub> and HMF (Table S15). Energy efficiency (EE) is the percentage of the energy retained in the target product to the total energy input into the electrolysis system.<sup>48</sup> It can be used to measure the effectiveness of the reaction process that converts the input electric energy into valuable chemical products and stores it in the form of chemical energy. We calculate EE for further evaluation, and it can be seen that the total energy conversion efficiency is stable at about 43% at 1.5–1.8 V (Fig. S35). At 1.7 V, the total energy

conversion efficiency is 43.3% (22.2% for FDCA, 15.9% for CO, and 5.2% for H<sub>2</sub>), which has a good effect on achieving high energy conversion efficiency at low potential (Table S16). High EE is essential to reduce electricity costs and improve the economic benefits of the CO<sub>2</sub>RR. In the potentiostatic electrolysis process (Fig. 5e), the change in cell current with time showed a significant difference between HMFOR-CO<sub>2</sub>RR and OER-CO<sub>2</sub>RR pairing systems in a H-type cell. The average current required for the CO<sub>2</sub>-HMF coupled system is 4 mA cm<sup>-2</sup>, and the average current required for the OER-CO<sub>2</sub>RR system is 2 mA cm<sup>-2</sup>. In the early stage of electrolysis of the CO<sub>2</sub>-HMF coupled system, the current density changes rapidly. However, in the later stage, due to the consumption of HMF, the OER dominates and the current change converges with the OER. In this case, the kinetic rate of the anodic reaction becomes slow with the decrease of the reactant concentration. For the OER-

CO<sub>2</sub>RR system, the continuous decrease in current is due to the consumption of OH<sup>-</sup> by the OER. In addition, the system has excellent catalytic stability (Fig. 5f and S36), and the total FE exceeds 190% after 6 cycles of the stability test, and the FE<sub>FDCA</sub> is stable between 86.4% and 97.6%. At the same time, the total FE of the cathode is stable at more than 86%, including CO (57.1–66.6%) and H<sub>2</sub> (24.2–32.6%). The stability of its structure and composition was evaluated by a series of characterization studies. In the SEM images it can be seen that the needle-like array structure of NiCo<sub>2</sub>O<sub>4</sub> and the overall contour of Au nanoneedles are well maintained (Fig. S37). The XRD pattern shows that the anode cathode catalyst still shows the original characteristic diffraction peak, and no new peaks appear, indicating that the crystal structure of the catalyst does not change significantly after the CO<sub>2</sub>-HMF coupled system reaction (Fig. S38).

### *In situ* Raman spectroscopy of the coupled system

In order to detect and track the dynamic evolution of the intermediate products at both ends of the CO<sub>2</sub>-HMF coupled system in real time, *in situ* Raman spectroscopy (SERS) can not only monitor the changes of the intermediates at both ends of the CO<sub>2</sub>-HMF coupled system, but also analyze the changes of the surface state of the catalysts at both ends. For the HMFOR (Fig. 5g), there are two obvious peaks at 479 and 555 cm<sup>-1</sup>, which are attributed to the e<sub>g</sub> bending ( $\delta$ ) and A<sub>1g</sub> stretching ( $\nu$ ) modes of Ni<sup>3+</sup>-O, respectively. With the increase of applied potential, abundant NiOOH species are formed and accumulated on the electrode surface.<sup>20,49</sup> This phenomenon also implies that the generated Ni<sup>3+</sup>-O species is an active intermediate; two obvious peaks at 487 and 606 cm<sup>-1</sup> are attributed to CoOOH, which accumulates with the increase of applied potential as NiOOH species, while the signal peak of CoO<sub>2</sub> is almost undetectable, indicating that Co<sup>3+</sup> is the active site of the HMFOR.<sup>31</sup> At the same time, with the increase of the potential, the HMF (1653 cm<sup>-1</sup>) peak gradually increases, indicating that the adsorption of HMF is continuously enhanced, which is consistent with the previous characterization results. The peak of FDCA (982 cm<sup>-1</sup>) also gradually increases, and the generation of FDCA is positively correlated with the applied potential, which is consistent with Fig. 5d.<sup>50,51</sup> This shows that the two-site synergy of NiCo<sub>2</sub>O<sub>4</sub> is applied to high-efficiency HMFOR, which further confirms the reliability of the theoretical calculation results. For the CO<sub>2</sub>RR (Fig. 5h), the peaks at 195 and 388 cm<sup>-1</sup> correspond to the restricted rotation and Au-CO stretching of adsorbed CO, respectively.<sup>52</sup> As the potential increases, the CO coverage decreases and Au accelerates CO desorption. No \*CO peak at 2100 cm<sup>-1</sup> verifies this conjecture. At the same time, \*CO<sub>2</sub><sup>-</sup> (1394 cm<sup>-1</sup>) and \*COOH (1563–1686 cm<sup>-1</sup>) are necessary intermediates for the formation of \*CO.<sup>53,54</sup> As the potential increases, the peak intensity decreases, which is related to the decrease of CO selectivity, which is consistent with the Fig. 5c results. Overall, in the CO<sub>2</sub>RR-HMFOR coupled system, the NiCo<sub>2</sub>O<sub>4</sub> anode promotes HMF-to-FDCA conversion *via* potential-dependent formation of Ni<sup>3+</sup> and Co<sup>3+</sup> intermediates for OH<sup>-</sup> capture. Meanwhile, the key intermediates of the CO<sub>2</sub>-to-

CO conversion are observed at the cathode. The simultaneous progress of these anodic and cathodic reactions significantly reduces the overall energy consumption of the process.

## Conclusions

In summary, we present a cobalt-based spinel anode catalyst with a Ni-Co dual-site synergistic effect, which achieves efficient and stable electrochemical HMFOR under alkaline conditions, delivering a high FE<sub>FDCA</sub> of 99.1% at 1.5 V vs. RHE. Comprehensive characterization confirms that the introduction of Ni significantly enhances the adsorption and conversion capability of the catalyst towards HMF and OH<sup>-</sup> species. This enhancement is particularly crucial in the key FFCA → FDCA conversion step, effectively facilitating dehydrogenation and electron transfer processes. In the coupled system, at a cell voltage of 1.7 V, the anode maintains a high FE<sub>FDCA</sub> of 91.9%, while the cathode FE is 94.7% (CO is 66.1% and H<sub>2</sub> is 28.6%), and the total energy conversion efficiency is 43.3%. SERS and DFT are used to reveal the dynamic catalytic mechanisms in the CO<sub>2</sub>-HMF coupled system. The NiCo<sub>2</sub>O<sub>4</sub> anode promotes HMF-to-FDCA conversion *via* potential-dependent formation of Ni<sup>3+</sup> and Co<sup>3+</sup> intermediates for OH<sup>-</sup> capture. Meanwhile, the key intermediates of the CO<sub>2</sub>-to-CO conversion are observed at the cathode, offering a real-time experimental basis for optimizing such integrated electrocatalytic systems for concurrent CO<sub>2</sub> and biomass conversion. This work provides compelling experimental evidence for the co-production of high-value chemicals *via* the upgrading of biomass-derived platform molecule HMF and CO<sub>2</sub> conversion. More importantly, the adopted electronic structure regulation strategy and the established *in situ* dynamic monitoring method provide a universal research paradigm and technical path for the design and optimization of other coupled electrosynthesis systems (such as glycerol, ethanol, benzyl alcohol, *etc.*) involving organic molecule oxidation and CO<sub>2</sub> reduction.
