# Beyond the three-state picture: when higher-lying excited states become quantitatively indispensable

Yue He and Daniel Escudero \*

Higher-lying excited states beyond  $S_1$  and  $T_1$  are widely recognized in many photophysical systems, including thermally activated delayed fluorescence (TADF). However, their explicit and quantitative impact on photophysical observables such as photoluminescence quantum yields (PLQY) and lifetimes is difficult to be attained experimentally and it has not been systematically assessed within a fully *ab initio* kinetic modeling framework. To address this gap, we developed KinLuv, a multistate excited state kinetic model that includes higher-lying excited states ( $S_2$ ,  $T_2$ ) and all possible monomolecular interconversion processes between all the electronic states, whose rate constants were computed using Fermi's golden rule (FGR) explicitly including the Herzberg–Teller (HT) vibronic coupling effect. We applied KinLuv to prototypical multi-resonance TADF (MR-TADF) emitters and their derivatives, as well as other representative organic chromophores, demonstrating its broad applicability across diverse photophysical playgrounds beyond TADF. The resulting simulations quantitatively reproduce key experimental observables, including PLQY and prompt/delayed fluorescence lifetimes. Beyond its predictive power, the present results establish clear criteria for identifying when higher-lying excited states influence the excited-state decay and when simplified models remain adequate. This framework enables rational selection of minimal kinetic models that balance physical insight with numerical robustness, with direct implications for the *in silico* design of high-performance organic emitters.

## 1 Introduction

Understanding the excited-state dynamics of organic chromophores has traditionally relied on a simplified three-state picture involving the ground state ( $S_0$ ) and the lowest singlet ( $S_1$ ) and triplet ( $T_1$ ) excited states. This approximation is generally valid when  $S_1$  and  $T_1$  are well separated in energy from higher-lying excited states ( $S_{n>1}$  and  $T_{n>1}$ ). However, advances in quantum-chemical methods and ultrafast spectroscopies have increasingly demonstrated the protagonist role of higher-lying excited states in a broad variety of photophysical and photochemical scenarios. Representative examples include emission<sup>1,2</sup> and photochemical reactions<sup>3</sup> originating from higher-lying excited states (*i.e.*, anti-Kasha photochemistry), triplet formation through  $S_1 \rightarrow T_{n>1}$  intersystem crossing (ISC) processes,<sup>4–7</sup> and internal conversion (IC) mediated by higher-lying excited states that enable access to pathways inaccessible from  $S_1$ .<sup>8,9</sup> In the above scenarios, a conventional three-state model becomes inadequate to model the excited-state dynamics of organic chromophores, as the explicit inclusion of higher-lying states may qualitatively and quantitatively alter the photophysical outcomes. From an experimental perspective,

unambiguously establishing their involvement remains challenging because it requires excitation-wavelength-dependent time-resolved spectroscopy combined with global kinetic analysis across multiple excited-state models and timescales.<sup>9–11</sup> Consequently, such tremendous efforts are rarely reported in the literature. For instance, employing coherence spectroscopy and wavepackets simulations in the context of the ultrafast excited state dynamics of dinuclear Pt(II) complexes, Chen *et al.*<sup>12–14</sup> provided an experimental and computational evidence of the spin-vibronic mechanism being at play and demonstrated the role of higher-lying excited state to accelerating ISC processes.

The above considerations are particularly relevant for thermally activated delayed fluorescence (TADF) materials,<sup>15</sup> for which a three-state picture is often assumed. However, increasing evidence indicates that more complex excited-state kinetics beyond this picture are not uncommon in TADF emitters.<sup>16–19</sup> In these systems, delayed fluorescence arises from reverse intersystem crossing (rISC) that upconverts triplet excited states ( $T_n$ ) to singlet excited states ( $S_n$ ), rendering observables such as photoluminescence quantum yield (PLQY) and prompt/delayed fluorescence lifetimes highly sensitive to the underlying excited-state decay pathways.<sup>20</sup> More recently, multi-resonance TADF (MR-TADF) emitters<sup>21</sup> have attracted considerable attention owing to their narrowband emission and efficient rISC enabled by short-range charge-transfer (SRCT)

Quantum Chemistry and Physical Chemistry Division, Department of Chemistry, KU Leuven, Celestijnenlaan 200F, 3001 Leuven, Belgium. E-mail: Daniel.Escudero@kuleuven.be

character and small singlet-triplet energy gaps.<sup>22–24</sup> As mentioned previously, increasing experimental and theoretical studies have suggested that higher-lying excited states may play a key mechanistic role in mediating ISC and rISC processes in these systems. Specifically, spin-vibronic coupling involving higher-lying triplet states has been shown to strongly enhance ISC and rISC processes especially when direct  $S_1 \rightarrow T_1$  or  $T_1 \rightarrow S_1$  coupling is symmetry-forbidden or intrinsically weak.<sup>25–28</sup> Computational studies by Olivier *et al.*<sup>16,17</sup> and Marian *et al.*<sup>18</sup> have further demonstrated that “dark” triplet states with distinct orbital characters can act as intermediate spin-mixing channels, facilitating efficient population transfer between  $S_1$  and  $T_1$ .

Despite these mechanistic insights, most quantitative kinetic analyses of TADF photophysics continue to rely predominantly on simplified three-state models. Experimentally, the transient photoluminescence measurements of TADF emitters are typically fitted by a biexponential decay profile, where the fast component is assigned to the prompt fluorescence and the slow one to the delayed fluorescence. Early kinetic models, such as those by Adachi *et al.*<sup>29</sup> and Dias *et al.*<sup>20</sup> estimated rISC rates under simplifying assumptions, *e.g.*, neglecting non-radiative decay or phosphorescence, whereas later approaches by Monkman *et al.*<sup>30</sup> and Tsuchiya *et al.*<sup>31</sup> have progressively relaxed these constraints and enabled direct extraction of all relevant kinetic parameters. Nevertheless, these models generally assume that ISC and rISC occur solely between  $S_1$  and  $T_1$ . From a mathematical perspective, the limited number of experimentally measurable quantities (*i.e.*, PLQY and fluorescence lifetimes) is insufficient to uniquely determine all unknowns in the excited-state decay kinetics. Consequently, the roles of higher-lying states cannot be unambiguously proved from experiment alone, making computational simulations indispensable for achieving a complete and quantitative description of the excited-state dynamics. Unlike the above-mentioned kinetic models that extract rate constants by fitting photoluminescence transient data, several theoretical studies have instead attempted to first compute rate constants and then use kinetic models to predict PLQY and fluorescence lifetimes.<sup>32</sup> Shizu *et al.*<sup>33,34</sup> have made significant contributions to the quantitative modeling of excited-state kinetics. They applied their method to molecules like DABNA-1, BNOO, BNSS, and BNSeSe. As with any theoretical framework, their methodology involves certain approximations that define its range of applicability. For example, they neglect Herzberg–Teller (HT) vibronic coupling effects in the rate constant calculations, leading to an underestimation of (r)ISC rate constants. This deficiency is evident from the calculated rISC  $T_1 \rightarrow S_1$  rate constants in DABNA-1 ( $2.5 \text{ s}^{-1}$  versus an experimental value of  $9.9 \times 10^3 \text{ s}^{-1}$ ) and BNOO ( $8.5 \text{ s}^{-1}$  versus  $4.3 \times 10^4 \text{ s}^{-1}$ ).

As a result, a fundamental gap remains in our understanding of the excited-state dynamics of organic chromophores, including TADF emitters: although higher-lying excited states are frequently invoked qualitatively, their explicit and quantitative impact on PLQY and excited-state lifetimes has not been systematically assessed within a fully *ab initio* kinetic modelling framework.

In this study, we address this gap by developing multistate kinetic models explicitly including higher-lying singlet and triplet states ( $S_2$  and  $T_2$ ) and incorporating HT vibronic coupling in the rate constant calculations. Our framework provides the community with a quantitative basis for determining when explicit inclusion of higher-lying excited states becomes essential and when a simplified kinetic model (*i.e.*, three-state picture) remains adequate. We first present a computational protocol that enables the calculation of all radiative and non-radiative rate constants involved in the interconversion between the electronically excited states. We then introduce KinLuv, a Python-based kinetic modeling program that computes prompt and delayed fluorescence lifetimes and PLQY from the calculated rate constants. To validate the proposed framework, we adopt a hierarchical strategy. DOBNA and DiKTA serve as prototypical MR-TADF systems, while DABNA-1 (a DOBNA derivative) and DQAO (a DiKTA derivative) assess the applicability of our approach to related derivatives. To further evaluate the generality of our methods, we additionally consider two non-TADF organic chromophores, namely dibenzothiophene (DBT) and bis-benzo-fused pyrano[3,2-*b*]pyran-2,6-dione (PPDs-1). DBT<sup>35</sup> and PPDs-1<sup>36</sup> were chosen as representative organic luminophores whose photophysical properties are strongly influenced by higher-lying excited states. In DBT, triplet formation through  $S_1 \rightarrow T_{n>1}$  ISC processes has been proved,<sup>37,38</sup> while preliminary investigations in our group show IC mediated by higher-lying excited states in PPDs-1. By systematically comparing multistate kinetic models of increasing complexity, this unified framework enables us to identify when higher-lying excited states play a significant role in their excited-state dynamics, to delineate the limitations of simplified kinetic models, and to quantify the trade-off between mechanistic completeness (inclusion of all physically accessible excited states and pathways) and quantitative necessity (inclusion required to reproduce experimentally observable quantities) with a fully *ab initio* kinetic modeling framework. This framework offers a principled strategy for constructing minimal yet robust kinetic models, thereby guiding the *in silico* design of high-performance organic emitters.

## 2 Results and discussion

### 2.1 Excited state kinetic models

If a molecule in its excited state is regarded as a distinct chemical species from that in its ground state, the interconversion between its involved electronic states can be formulated as a chemical reaction chain and analyzed with conventional kinetic methods. Within this framework, we systematically examined a hierarchy of excited state kinetic models with increasing complexity to evaluate the mechanistic relevance of higher-lying excited states in the quantitative calculation of PLQY and excited state lifetimes for both TADF and non-TADF organic chromophores.

Fig. 1 schematically summarizes the four kinetic models considered in this study, which differ in the number of electronic states and the possible interconversion processes between them. The two-state model considers the ground state

workflow enables a quantitative assessment of the validity and predictive capability of fully *ab initio* multistate kinetics models for functional organic chromophores, with particular emphasis on TADF systems, where both PLQY and prompt/delayed fluorescence lifetimes are of primary interest.

## 2.2 Excited-state energetics and decay rate constants

Six functional chromophores were deliberately selected as representative systems to examine the putative role of higher-lying excited states (Fig. 2). The selection follows a hierarchical design. We first focus on two prototypical MR-TADF emitters, DOBNA (Fig. 2a) and DiKTa (Fig. 2b), which serve as stringent benchmark systems for in-depth analysis. DOBNA

features a central boron atom as the electron acceptor and oxygen atoms as electron donors, while DiKTa uses carbonyl groups as electron acceptors instead of boron. To assess the generality and robustness of the proposed methodology, DABNA-1 (Fig. 2c) and DQAO (Fig. 2d) were subsequently selected as structurally related derivatives of these prototype MR-TADF emitters. These systems allow us to examine whether the conclusions drawn for DOBNA and DiKTa persist upon molecular modification, and to further evaluate the transferability of our approach. Finally, DBT (Fig. 2e) and PPDs-1 (Fig. 2f) were included as representative non-TADF organic chromophores, as previously mentioned to be inadequately described by simplified three-state models. Their incorporation enables the assessment of our approach beyond TADF and provides a critical control for assessing the role of higher-lying excited states. Table 1 summarizes the previously reported experimental results for all the investigated compounds.<sup>22,24,35,36,39,40</sup>

The optimized ground- and excited-state geometries of all systems are provided in Section 6 of SI: DOBNA and DiKTa (Fig. S3), DABNA-1 and DQAO (Fig. S4), and DBT and PPDs-1 (Fig. S5). In all cases, the structural changes associated with excitations are minimal (Root-Mean-Square Deviation well below 0.2 Å), thereby satisfying one of the prerequisites to apply the harmonic approximation and Fermi's golden rule (FGR) to calculate the excited state decay rate constants. The natural transition orbitals (NTOs) calculated with TD(A)-CAM-B3LYP involved in the excited states of selected compounds, *i.e.*, DOBNA and DiKTa, are shown in Section 5 of the SI. These NTOs were compared with those obtained with SCS-ADC(2). As

shown in Fig. S1 for DOBNA, the NTOs calculated using the CAM-B3LYP functional closely resemble those obtained from SCS-ADC(2). Similarly, for DiKta (Fig. S2), the CAM-B3LYP NTOs show good agreement with those from SCS-ADC(2) for most of the excited states, except for one hole NTO in the  $T_2$  state.

While geometries, Hessian matrix, and associated properties at the TD(A)-DFT level have been reported to be sufficiently accurate for excited state decay rate constant calculations, excitation energies are often insufficiently accurate.<sup>41,42</sup> To obtain refined adiabatic excitation energies and more accurate estimations of adiabatic energy gaps, we performed single-point SCS-ADC(2) calculations at the TD(A)-DFT optimized geometries. The comparison of the adiabatic excitation energies for the excited states calculated at the TD(A)-CAM-B3LYP and at the SCS-ADC(2) levels is shown in Section 7 of the SI. For instance, for the MR-TADF emitters, the adiabatic TD(A)-DFT excitation energies differ from the SCS-ADC(2) results by 0.1–0.8 eV (Fig. S6). Specifically, TD(A)-DFT tends to yield larger excitation energies for singlet states ( $S_n$ ) and smaller energies for triplet states ( $T_n$ ) compared to SCS-ADC(2), resulting in larger singlet-triplet energy gaps at the TD(A)-DFT level. Notably, this discrepancy is particularly pronounced for the  $T_2$  state of DOBNA and DABNA-1, highlighting the necessity of using a higher-level method such as SCS-ADC(2) to refine the excited-state energy gaps. In the case of the non-TADF systems DBT and PPDs-1, deviations between TD(A)-DFT and SCS-ADC(2) excitation energies remain below 0.5 eV. Table 2 lists the adiabatic excitation energies calculated with SCS-ADC(2) for all the compounds, obtained by subtracting the ground-state energy at its optimized geometry from the excited-state energies at their respective minima. For DOBNA, the calculated  $S_1$ - $T_1$  energy gap, *i.e.*,  $\Delta E_{ST}(S_1-T_1)$ , is 0.18 eV, which shows excellent agreement with the experimental value (Table 1). DiKta exhibits a slightly larger calculated  $\Delta E_{ST}(S_1-T_1)$  of 0.23 eV, which is within 0.05 eV of the experimental value, and comparable accuracy is obtained for DABNA-1 and DQAO. These results highlight the capability of the SCS-ADC(2) method to accurately determine the  $\Delta E_{ST}(S_1-T_1)$  values of MR-TADF emitters. In contrast, the calculated  $\Delta E_{ST}(S_1-T_1)$  values for the non-TADF emitters are sufficiently large (>0.7 eV), indicating a slowed down rISC process and consistent with the experimental observed absence of delayed fluorescence in these two compounds. Moreover, the  $\Delta E_{ST}(S_1-T_2)$  values for DiKta, DQAO, DBT and PPDs-1, in contrast to those of DOBNA and DABNA-1, are sufficiently small (within  $\pm 0.25$  eV) to

qualitatively suggest that triplet formation *via* higher-lying triplet excited states may be energetically feasible in these systems. However, this qualitative analysis is based solely on energetic considerations. In addition, a definitive quantitative assessment requires the approach developed here.

Thus, in the following section we focus on a detailed analysis of the calculated rate constants for DOBNA and DiKta, which serve as representative prototype examples of MR-TADF emitters with expected different behaviors. For completeness, the corresponding data for the other two MR-TADF derivatives, *i.e.*, DABNA-1 and DQAO, as well as for the two non-TADF emitters, are provided in Section 9 of SI. Fig. 3a and b present the calculated rate constants of (r)ISC between singlet states ( $S_n$ ) and triplet states ( $T_n$ ) for DOBNA (red) and DiKta (green), respectively. The calculated ISC rate constants for the individual sublevels are provided in Tables S1–S2 of the SI. As seen in Fig. 3a and b, DiKta exhibits larger (r)ISC rate constants than DOBNA for most transitions, with the exception of ISC  $T_1 \rightarrow S_0$ . In particular, the larger  $S_1 \rightarrow T_1$  ISC rate constant calculated for DiKta than for DOBNA cannot be explained by energetic considerations alone, as DOBNA has a slightly smaller  $\Delta E_{ST}(S_1-T_1)$  value of 0.18 eV compared to 0.23 eV for DiKta (Table 2). According to Marcus theory for ISC rate constants, two main factors account for this behavior: differences in spin-orbit coupling matrix elements (SOCMEs) or variations in the Marcus regime governing the ISC process (*i.e.*, normal or inverted regime). As shown in Tables S4–S5, both compounds feature a very small reorganization energy (*ca.* 0.02 eV) compared to their singlet-triplet gaps, indicating that the  $S_1 \rightarrow T_1$  ISC occurs within the same Marcus regime for both compounds. In contrast, the calculated SOCMEs at the reference FC geometry (Tables S6–S7) indicate that DiKta exhibits larger  $S_1 \rightarrow T_1$  SOCMEs than DOBNA. These results identify enhanced SOCMEs as the primary origin of the faster  $S_1 \rightarrow T_1$  ISC rate in DiKta. Still, the calculated ISC rate constants for both DiKta and DOBNA are exceptionally large, roughly ranging from  $10^5$  s<sup>-1</sup> to  $10^{11}$  s<sup>-1</sup>. Such high values cannot be rationalized solely based on calculated SOCMEs at FC geometry, nor by invoking simple empirical rules such as the heavy-atom effect<sup>43</sup> or El-Sayed rule.<sup>44</sup> The latter rule predicts faster ISC processes between states of different orbital characters (*e.g.*,  $n\pi^* \rightarrow \pi\pi^*$ ). However, analysis of the calculated NTOs (Fig. S1–S2) reveals that all relevant transitions are of  $\pi\pi^*$  character, with negligible  $n\pi^*$  contributions. Instead, the large (r)ISC rate constants stem from the vibronic coupling, as the HT effect is explicitly considered in the rate constant calculations. As shown in Tables S8–S9, the calculated (r)ISC rate constants are dominated by HT contributions for nearly all transitions. Unlike the FC approximation, the HT effect enables electronic transitions to couple with vibrational motions *via* a breakdown of the Condon approximation.<sup>45</sup> The vibrational motions of nuclei effectively increase the SOCMEs, thereby facilitating rapid ISC processes.

Fig. S7–S8 present the Huang-Rhys factors and reorganization energies per vibrational normal mode for key ISC processes of DOBNA and DiKta, revealing a strong mode dependence. For DOBNA, in-plane vibrations contribute the most to r(ISC) processes, as they have both the largest Huang-Rhys factors and

PPDs-1	3.66	3.97	2.51	3.68	1.15	-0.02

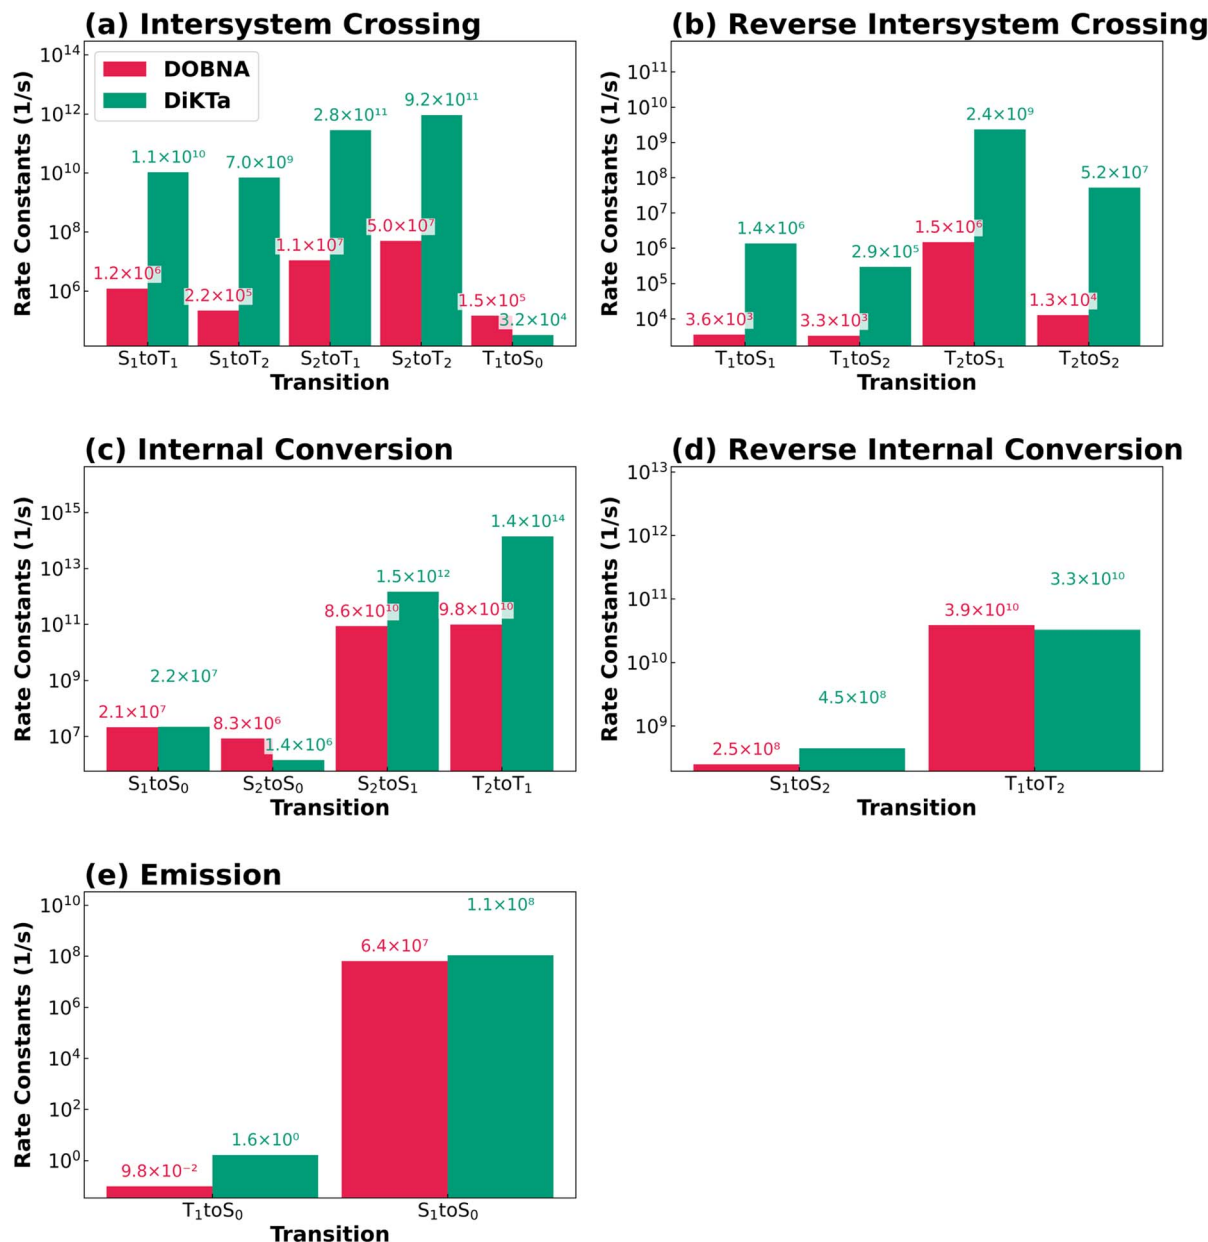

Fig. 3 Calculated rate constants of (a) intersystem crossing (ISC), (b) reverse intersystem crossing (rISC), (c) internal conversion (IC), (d) reverse internal conversion (rIC) and (e) emission for molecule DOBNA (red) and DiKTa (green). Calculations at SCS-ADC(2)/def2-TZVP//TDA-CAM-B3LYP/6-311G(d,p) level with the adiabatic Hessian, Franck-Condon/Herzberg-Teller (FC/HT) vibronic model and a 10 cm<sup>-1</sup> Lorentzian broadening.

the largest reorganization energies. Conversely, out-of-plane modes exhibit the largest Huang-Rhys factors for DiKTa, but in-plane modes still contribute the most to the reorganization energies. Overall, these results highlight that out-of-plane vibrational modes have more relevance for DiKTa than for DOBNA. To further elucidate the origins of the HT effects, Fig. S9 and S10 show the SOCMEs calculated at the reference FC geometry and at displaced geometries along specific vibrational modes corresponding to the HT regime for the key (r)ISC channels of DOBNA and DiKTa, respectively. Notably, the SOCMEs in the HT regime are significantly enhanced compared to those in the FC regime particularly for the S<sub>1</sub> → T<sub>1</sub> (Fig. S9a

and S10a) ISC and the T<sub>1</sub> → S<sub>1</sub> (Fig. S9e and S10e) rISC. Structurally, all atoms in DOBNA lie in a strictly planar configuration, leading to predominantly in-plane vibrational modes. In contrast, DiKTa exhibits a slight torsion between its molecular fragments, allowing out-of-plane vibrations that more effectively break molecular symmetry and enhance vibronic coupling.<sup>46</sup> This structural distinction likely contributes to the stronger HT effect observed in DiKTa (Fig. S9 and S10). This analysis demonstrates that vibronic couplings effectively enhance SOCMEs *via* the HT effect. All in all, vibrational contributions to HT-driven (r)ISC exhibit a strong dependence on molecular structure. For planar systems (*e.g.*, DOBNA), in-

plane vibrational modes dominate (Fig. S7 and S9), whereas in slightly twisted systems (*e.g.*, DiKTA), out-of-plane modes play a more significant role, as they more effectively break symmetry and enhance vibronic coupling (Fig. S8 and S10). Notably, the enhancement of SOCMEs arises from the collective contributions of multiple vibrational modes rather than from a single dominant mode.

Fig. 3c and d show the rate constants for IC and rIC; respectively, for DOBNA and DiKTA. The  $S_1 \rightarrow S_0$  IC rate constants are on the order of  $10^7 \text{ s}^{-1}$ . Notably, in DOBNA (Fig. 3d), the calculated rIC rate constant for  $T_1 \rightarrow T_2$  is comparable in magnitude to that of the  $T_2 \rightarrow T_1$  IC process and is significantly larger than those of  $T_2 \rightarrow S_1$  and  $T_1 \rightarrow S_1$  processes, indicating an efficient and nearly reversible population exchange between the two triplet states prior to population transfer back to the singlet manifold. Fig. 3e collects the values of the calculated radiative rate constants, which are *ca.*  $10^8 \text{ s}^{-1}$  for fluorescence and *ca.*  $1 \text{ s}^{-1}$  for phosphorescence, aligned to typical values for these compounds.

The calculated excited state decay rate constants for MR-TADF derivatives DABNA-1 and DQAO, as well as for the non-TADF systems (DBT, PPDs-1), are briefly summarized below. Calculated values are provided in Section 9 of the SI. DABNA-1,

being closely related to DOBNA shows similar trends in the computed rate constants. Both compounds generally possess smaller (r)ISC rate constants than DQAO, which is closely related to DiKTA and, in turn, also exhibits analogous rate constant trends (Tables S10 and S11). Importantly, by explicitly including HT contributions in the rate constant calculations, the rISC  $T_1 \rightarrow S_1$  rate constant of DABNA-1 ( $2.41 \times 10^4 \text{ s}^{-1}$ ) is obtained with a more reasonable accuracy with respect to the experimental one ( $9.9 \times 10^3 \text{ s}^{-1}$ ) than the one reported by Shizu *et al.*<sup>33</sup> ( $2.5 \text{ s}^{-1}$ ). This comparison highlights the indispensable role of vibronic coupling in accurately describing (r)ISC processes. Interestingly, the calculated rIC rate constant for  $T_1 \rightarrow T_2$  in DABNA-1 (Table S10) is comparable in magnitude to the  $T_2 \rightarrow T_1$  IC rate constant. This trend is also found in DOBNA as previously mentioned. These rate constant behaviors observed for the prototype emitters are consistently reproduced in their derivatives, indicating the generality of the underlying trends. In addition, the magnitudes of the ISC rate constants are also substantial for non-TADF compounds DBT and PPDs-1, where the large values arise primarily from HT contributions (Table S15). Both of them show a larger ISC  $S_1 \rightarrow T_2$  rate constant than that of  $S_1 \rightarrow T_1$ , indicating the non-negligible role of  $T_2$  in mediating ISC. At the same time, PPDs-1 shows

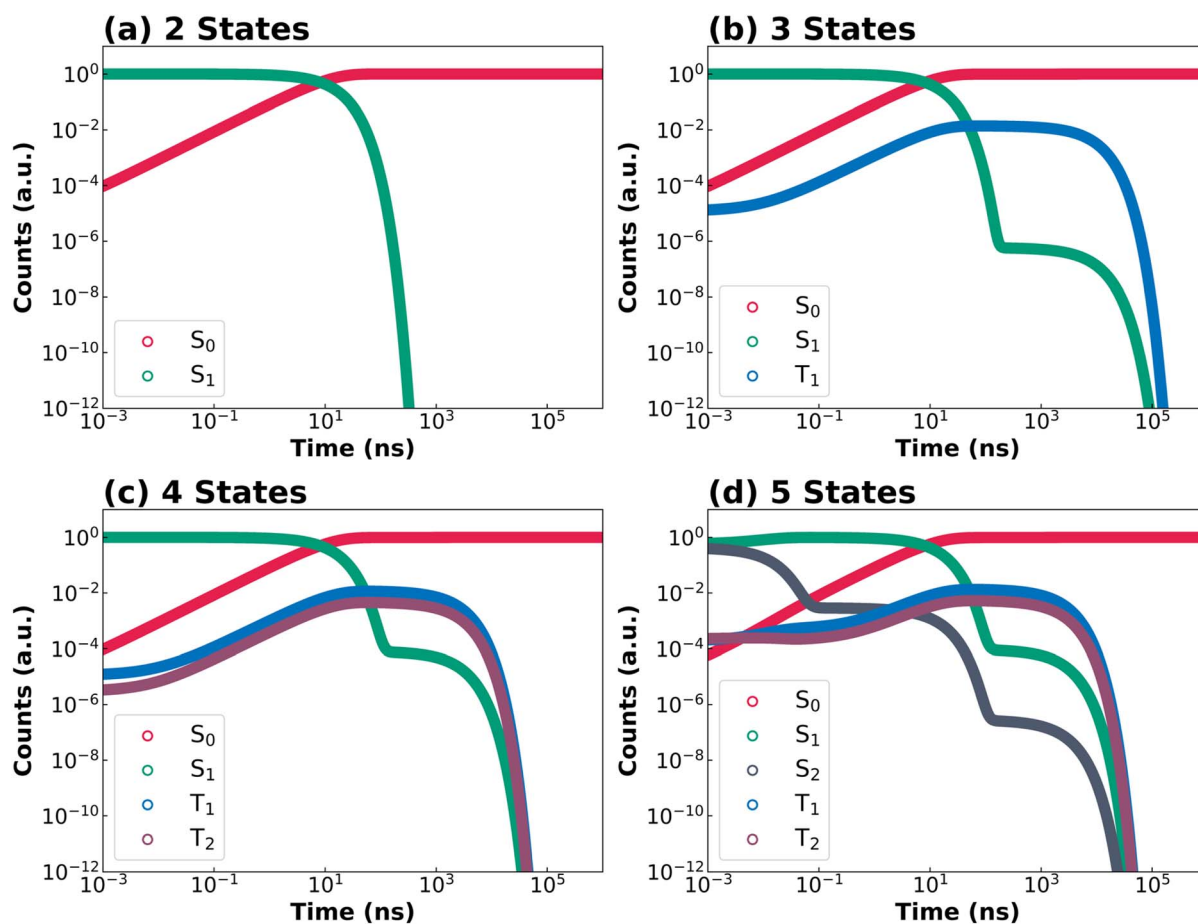

Fig. 4 Simulated population decay kinetics of DOBNA over a 1 ms timescale based on (a) two-state ( $S_0$ ,  $S_1$ ), (b) three-state ( $S_0$ ,  $S_1$ ,  $T_1$ ), (c) four-state ( $S_0$ ,  $S_1$ ,  $T_1$ ,  $T_2$ ), and (d) five-state ( $S_0$ ,  $S_1$ ,  $S_2$ ,  $T_1$ ,  $T_2$ ) kinetic models. The number of absorbed photons is set to 1, with the excitation pulse width of 10 ps. Both time (x-axis) and population (y-axis) are plotted on logarithmic scales.

a comparably large  $S_1 \rightarrow S_2$  rIC rate constant compared to  $S_2 \rightarrow S_1$  IC, indicating a significant population exchange between these two singlet states.

### 2.3 Excited-state kinetics simulation of MR-TADF

The following discussion focuses on excited-state decay kinetics and the quantitative determination of PLQY and lifetimes. The discussion first focuses on DOBNA and DiKTA, as prototype MR-TADF emitters, and then on their structurally related derivatives (DABNA-1 and DQAO). The remaining systems, PPDs-1 and DBT, where higher-lying excited states are also relevant, are discussed thereafter. The complete excitation and decay profiles directly generated by KinLuv for all compounds are provided in Section 12 of SI. Fig. 4 and 5 collect the simulated decay kinetics of DOBNA and DiKTA using kinetic models of increasing complexity, respectively. A logarithmic time scale is employed to simultaneously capture both prompt and delayed emission regimes within a single plot. Additionally, KinLuv can directly output the PLQY as well as the prompt and delayed fluorescence lifetimes. For the two- and three-state models, the decay of  $S_1$  population can be described by analytical expressions, whereas numerical solutions are employed for the four- and five-state models to ensure computational efficiency. The calculated

PLQY, prompt and delayed lifetimes for the four investigated MR-TADF emitters are summarized in Fig. 6.

DOBNA is first discussed as a representative example (Fig. 4). In the two-state model (Fig. 4a), after initial population of  $S_1$  (green), radiative and nonradiative decay to  $S_0$  (red) occur in the nanosecond regime, giving rise exclusively to prompt fluorescence. Incorporation of the  $T_1$  state in the three-state model (Fig. 4b) introduces an ISC pathway from  $S_1$  to  $T_1$  (blue), followed by rISC back to  $S_1$ . Consequently, two distinct regimes showing a marked decrease in  $S_1$  population are observed in Fig. 4b. The first regime corresponds to prompt fluorescence (as in the two-state model) while the second one (ranging between *ca.*  $10^2$  ns and *ca.*  $10^2$   $\mu$ s) stems from the delayed fluorescence *via* the  $T_1 \rightarrow S_1 \rightarrow S_0$  pathway. However, only a minute fraction of  $T_1$  population is accumulated because the  $S_1 \rightarrow T_1$  ISC rate constant ( $1.2 \times 10^6$  s $^{-1}$ ) is much smaller than the competing fluorescence ( $6.4 \times 10^7$  s $^{-1}$ ) and IC ( $2.1 \times 10^7$  s $^{-1}$ ) rate constants. Accordingly, the delayed decay of the  $S_1$  population originates from rISC of the  $T_1$  population and is characterized by a small onset amplitude of *ca.*  $10^{-6}$  (Fig. 4b). In the four-state model, inclusion of the higher-lying triplet state  $T_2$  leads to nearly overlapping  $T_1$  (blue) and  $T_2$  (purple) population curves (Fig. 4c and d), indicating synchronized population dynamics.

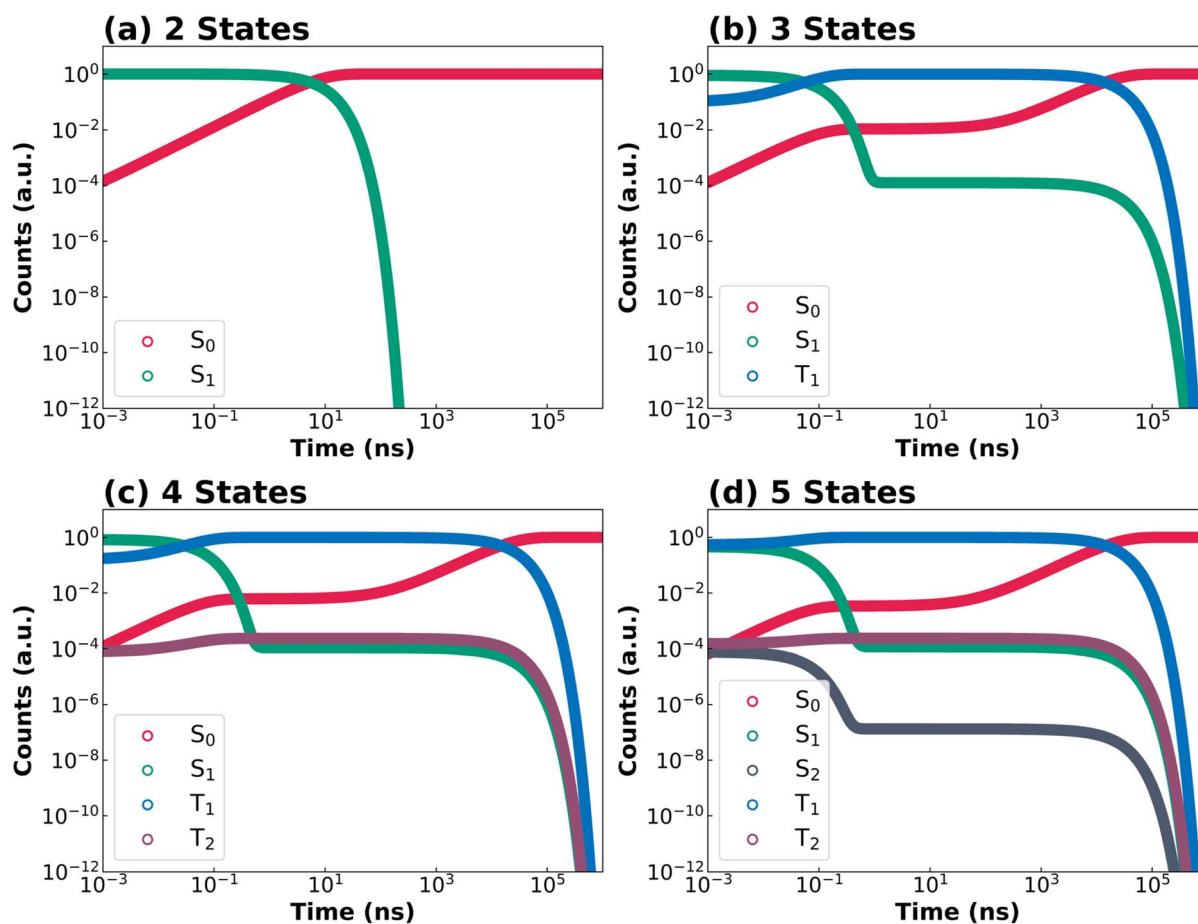

Fig. 5 Simulated population decay kinetics of DiKTA over a 1 ms timescale based on (a) two-state ( $S_0$ ,  $S_1$ ), (b) three-state ( $S_0$ ,  $S_1$ ,  $T_1$ ), (c) four-state ( $S_0$ ,  $S_1$ ,  $T_1$ ,  $T_2$ ), and (d) five-state ( $S_0$ ,  $S_1$ ,  $S_2$ ,  $T_1$ ,  $T_2$ ) kinetic models. The number of absorbed photons is set to 1, with the excitation pulse width of 10 ps. Both time (x-axis) and population (y-axis) are plotted on logarithmic scales.

## (a) PLQY

## (b) Prompt Lifetime

## (c) Delayed Lifetime

Fig. 6 Calculated (a) photoluminescence quantum yield (PLQY), (b) prompt fluorescence lifetime, and (c) delayed fluorescence lifetime for DOBNA (red), DABNA-1 (blue), DiKTa (green), and DQAO (purple) compared with experimental results.

This behavior arises from the comparable rIC rate constant for  $T_1 \rightarrow T_2$  ( $3.9 \times 10^{10} \text{ s}^{-1}$ ) and the  $T_2 \rightarrow T_1$  IC rate constant ( $9.8 \times 10^{10} \text{ s}^{-1}$ ), resulting in rapid thermal equilibration between these two states. Although  $T_2$  state introduces an alternative delayed fluorescence pathway ( $T_1 \rightarrow T_2 \rightarrow S_1 \rightarrow S_0$ ), the limited population accumulated in  $T_1$  restricts the overall impact of this pathway, increasing the onset amplitude of delayed  $S_1$  population only modestly, from *ca.*  $10^{-6}$  (in the three-state model) to *ca.*  $10^{-4}$ . In the five-state model, the initial population of the higher-lying singlet state  $S_2$  is followed by ultrafast IC to  $S_1$  ( $8.6 \times 10^{10} \text{ s}^{-1}$ ), which leads to negligible effect on the global excited-state dynamics of the emitter.

Despite the mechanistic differences between the three-, four- and five-state models, the calculated PLQY remains nearly constant at *ca.* 74% across all models (see red bars in Fig. 6).

The calculated prompt fluorescence lifetime reproduces the experimental value of 11.6 ns in the three-state model and shows only minor changes in the four- and five-state model. These results indicate that for DOBNA while the inclusion of higher-lying excited states is mechanistically important to provide a more complete description of the TADF pathways, it is not essential for accurately predicting experimentally observables such as PLQY, prompt and delayed fluorescence lifetimes. This can be attributed to the relatively slower timescales of (r) ISC processes compared to fluorescence and IC, which limit population accumulation in higher-lying triplets and thereby minimize their impact on the overall decay dynamics.

As a derivative of DOBNA, DABNA-1 exhibits excited-state dynamics that are very similar to those of DOBNA (Fig. S11). The calculated PLQY (82% *versus* experimental 88%) and

prompt fluorescence lifetime (8.4 ns *versus* 8.8 ns) remain essentially unchanged across the three-, four-, and five-state models (see blue bars in Fig. 6). By contrast, the delayed fluorescence lifetime decreases markedly from 41  $\mu\text{s}$  in the three-state model to 2.3  $\mu\text{s}$  in the four and five state model. Consistent with the behavior observed for DOBNA, higher-lying states may impact the TADF pathways mechanistically, yet the slow (r)ISC rates ensure a negligible effect on PLQY, prompt and delayed fluorescence. The consistency between DOBNA and its derivative DABNA-1 demonstrates that the conclusions drawn from the prototype system extend beyond a single molecule, thereby underscoring the robustness of our approach. Taken together, these results demonstrate that the adequacy of simplified three-state kinetic models is governed by both the magnitude of (r)ISC rate constants relative to fluorescence and IC and whether higher-lying excited states provide kinetically competitive rISC pathways. In systems such as DOBNA and DABNA-1, where (r)ISC processes are slow and the population of higher-lying states remains kinetically limited, their contribution to rISC is secondary, and three-state models remain sufficient to reproduce experimentally observable quantities, including PLQY and fluorescence lifetimes.

DiKTA (Fig. 5) exhibits significantly faster (r)ISC rate constants than DOBNA (Fig. 3a and b), leading to markedly distinct excited-state decay kinetics. In the three-state model (Fig. 5b), the  $T_1$  population becomes significantly larger than that of DOBNA (Fig. 4b) because of the much larger  $S_1$  to  $T_1$  ISC rate constant ( $1.1 \times 10^{10} \text{ s}^{-1}$ ) than that of DOBNA ( $1.2 \times 10^6 \text{ s}^{-1}$ ). Moreover, fast  $S_1 \rightarrow T_1$  ISC suppresses direct decay from  $S_1$  to  $S_0$ , causing a pronounced lag in  $S_0$  population growth. As  $S_1$  is gradually repopulated through rISC from  $T_1$ , the  $S_0$  population increases again, producing a characteristic sigmoidal profile which was not observed for DOBNA. When moving to the four-state model (Fig. 5c), the inclusion of a higher-lying triplet state  $T_2$  does not introduce an efficient delayed fluorescence pathway analogous to  $T_1 \rightarrow T_2 \rightarrow S_1 \rightarrow S_0$  observed for DOBNA. This is because IC rate constant for  $T_2 \rightarrow T_1$  ( $1.4 \times 10^{14} \text{ s}^{-1}$ ) is substantially faster than the rIC  $T_1 \rightarrow T_2$  rate constant ( $3.3 \times 10^{10} \text{ s}^{-1}$ ). Instead,  $T_2$  primarily provides a competing non-radiative pathway ( $S_1 \rightarrow T_2 \rightarrow T_1 \rightarrow S_0$ ) that effectively reduces the PLQY. In the five-state model, the higher-lying state  $S_2$  introduces an additional delayed fluorescence pathway ( $T_1 \rightarrow S_2 \rightarrow S_1 \rightarrow S_0$ ). However, this turns out to be a minor contribution that slightly increases the PLQY value, as the rISC rate constant for  $T_1 \rightarrow S_2$  ( $2.9 \times 10^5 \text{ s}^{-1}$ ) is smaller than that for  $T_1 \rightarrow S_1$  rISC rate constant ( $1.4 \times 10^6 \text{ s}^{-1}$ ).

Unlike DOBNA, the higher-lying states in DiKTA play a quantitatively important role in the excited-state kinetics. The calculated fluorescence PLQY decreases progressively from 83.1% in the two-state model to 28.6% in the three-state model and 25.4% and 26.5% in the four- and five-state model, the latter two models yielding PLQY values in excellent agreement with the experimental value of 26% (see the green bars in Fig. 6). Mechanistically, the computed decrease in the PLQY value when going from the three-state to the four-state and five-state models originates from the introduction of  $T_2$  as an additional non-radiative decay pathway, whereas  $S_2$  partially compensates

for this loss by providing an extra delayed fluorescence pathway. Overall, while the predominant delayed fluorescence pathway in DiKTA remains that of the three-state model, the inclusion of the higher-lying excited states improves the quantitative agreement with respect to the experiment. In addition, the predicted delayed fluorescence lifetime increases from 20.57  $\mu\text{s}$  in the three-state model to 21.50  $\mu\text{s}$  and 21.02  $\mu\text{s}$  in the four and five state models, the latter two in excellent agreement with the experimental value of 23  $\mu\text{s}$ . All in all, these results show that in DiKTA the inclusion of  $T_2$  is not only mechanistically important but also essential for quantitatively reproducing the experimental PLQY, owing to fast (r)ISC and substantial triplet state populations. In contrast,  $S_2$  primarily improves the mechanistic description of TADF pathways but it is not required to accurately predict the experimentally observable.

As a derivative of DiKTA, DQAO exhibits similar excited-state dynamics (Fig. S12). The calculated fluorescence PLQY decreases progressively from 77.5% in the two-state model to 66.1% in the five-state model. The comparison of the PLQY values for the three-state (49.3%) and the four-state model (60.7%) reveals that only after the inclusion of  $T_2$  in the kinetic models can we recover the experimental value of 59% (see the purple bars in Fig. 6). In addition, the delayed fluorescence lifetime decreases from 38.75  $\mu\text{s}$  in the three-state model to 22.92  $\mu\text{s}$  in the four-state model, and to 13.67  $\mu\text{s}$  in the five-state model. Consistent with the results obtained for DiKTA, the inclusion of  $T_2$  in DQAO is therefore essential for quantitatively reproducing the experimental PLQY, reflecting the fast (r)ISC processes and the dominant triplet state populations. Unlike in DiKTA,  $T_2$  in DQAO additionally mediates a minor alternative delayed fluorescence pathway ( $T_1 \rightarrow T_2 \rightarrow S_1 \rightarrow S_0$ ), as reflected in the changes in delayed fluorescence lifetime, rather than acting solely as a competing non-radiative decay pathway. The inclusion of  $S_2$  further refines the mechanistic description of the TADF process but has only a minor impact on the predicted experimentally observables. Overall, these results demonstrate that the adequacy of four-state kinetic models is likewise determined by the magnitude of (r)ISC rate constants relative to fluorescence and IC and by whether higher-lying triplet states provide kinetically competitive rISC pathways. In systems such as DiKTA and DQAO, where fast (r)ISC leads to substantial triplet state populations, the explicit inclusion of  $T_2$  is required to quantitatively reproduce experimentally observable quantities.

#### 2.4 Excited-state kinetics simulation beyond TADF emitters

As discussed above, higher-lying excited states may not only modify delayed fluorescence pathways but can also introduce additional nonradiative decay channels. Consequently, for certain non-TADF organic emitters, a three-state kinetic model is likewise insufficient. This behavior is illustrated below using DBT (see its excited state population dynamics in Fig. S13) and PPDs-1 (see its excited state population dynamics in Fig. S14).

For DBT, the three-state model already predicts a substantial population of  $T_1$  (Fig. S13b) from fast ISC  $S_1 \rightarrow T_1$  ( $2.13 \times 10^8 \text{ s}^{-1}$ ), giving rise to a nonradiative decay pathway  $S_1 \rightarrow T_1 \rightarrow S_0$ .

Consequently, the  $S_0$  population exhibits a sigmoidal temporal profile, similar to the one observed by DiKTA. When moving to the four-state model, the inclusion of  $T_2$  introduces an additional major non-radiative pathway ( $S_1 \rightarrow T_2 \rightarrow T_1 \rightarrow S_0$ ), because the ISC rate constant for  $S_1 \rightarrow T_2$  is also very large ( $2.65 \times 10^8 \text{ s}^{-1}$ ). In the five-state model, the higher-lying state  $S_2$  provides another nonradiative pathway ( $S_1 \rightarrow S_2 \rightarrow S_0$ ). However, its impact on the overall kinetics is of very minor relevance compared to the dominant ISC-mediated processes. As a result, the calculated PLQY progressively decreases from 73.3% in the two-state model to 17.1% in the three-state model and further to 8.8% in the four-state model and 8.5% in the five-state model (Fig. 7a). The PLQY of the four-state model is thus in good agreement with the experimental value of 9%. This highlights the necessity of including a higher-lying triplet excited state ( $T_2$ ) to attain quantitatively accurate PLQY estimates. In parallel, the calculated prompt fluorescence lifetime decreases from 15.4 ns in the two-state model to 1.8 ns in the four-state model and 2.6 ns in the five-states model, closely matching the experimental value of *ca.* 3 ns. All in all, the higher-lying  $T_2$  plays a crucial role by introducing competing nonradiative decay pathways ( $S_1 \rightarrow T_2 \rightarrow T_1 \rightarrow S_0$ ), which are essential for quantitatively reproducing both PLQY and prompt fluorescence lifetimes in systems dominated by fast ISC processes involving higher-lying triplets. Accordingly, the four-state model, explicit inclusion of  $T_2$  represents the minimal extension needed to achieve quantitative agreement for non-TADF organic emitters in which ISC processes involving higher-lying triplets are significant. We note, however, that the present analysis does not exclude the possible involvement of

higher-lying triplet states beyond  $T_2$  (e.g.,  $T_3$ ) in other molecular systems. In such cases, extensions of the present framework to include additional excited states may be required to achieve quantitative accuracy, which is beyond the scope of the present work.

For PPDs-1, the three-state model (Fig. S14b) predicts a low  $T_1$  population due to the relatively slow  $S_1 \rightarrow T_1$  ISC ( $4.61 \times 10^3 \text{ s}^{-1}$ ) relative to  $S_1 \rightarrow S_0$  IC ( $1.67 \times 10^7 \text{ s}^{-1}$ ) and fluorescence ( $3.74 \times 10^8 \text{ s}^{-1}$ ). In the four-state model, a faster ISC from  $S_1 \rightarrow T_2$  ( $4.07 \times 10^7 \text{ s}^{-1}$ ) increases the  $T_1$  population and introduces an additional nonradiative decay pathway ( $S_1 \rightarrow T_2 \rightarrow T_1 \rightarrow S_0$ ). In the five-state model, the presence of the higher-lying singlet state  $S_2$  opens up a highly efficient nonradiative decay channel,  $S_1 \rightarrow S_2 \rightarrow S_0$ . This pathway is important because the rIC  $S_1 \rightarrow S_2$  rate constant ( $3.15 \times 10^9 \text{ s}^{-1}$ ) exceeds that of the direct IC  $S_1 \rightarrow S_0$  ( $1.67 \times 10^7 \text{ s}^{-1}$ ), allowing a fraction of the  $S_1$  population to access  $S_2$  and subsequently undergo rapid IC ( $3.86 \times 10^{10} \text{ s}^{-1}$ ) to  $S_0$ . As a result, the calculated PLQY decreases progressively from 95.7% in the two-state model to 77% in the five-state model, while the calculated prompt fluorescence lifetime decreases from 2.56 ns in the two-state model to 2.09 ns in the five-state model. This clear trend indicates that  $T_2$  and  $S_2$  do indeed introduce additional nonradiative pathways and therefore play an important role. However, the experimental PLQY is reported to be 0.9%. To investigate the discrepancies between the simulations and the experiments in greater depth, we performed further analyses. First, we excluded the possibility that nonradiative decay pathways involving the higher triplet state  $T_3$  are operative, because both ISC ( $S_1 \rightarrow T_3$ ) ( $7.36 \times 10^4 \text{ s}^{-1}$ ) and ISC ( $S_2 \rightarrow T_3$ ) ( $9.87 \times 10^5 \text{ s}^{-1}$ ) are negligible compared to

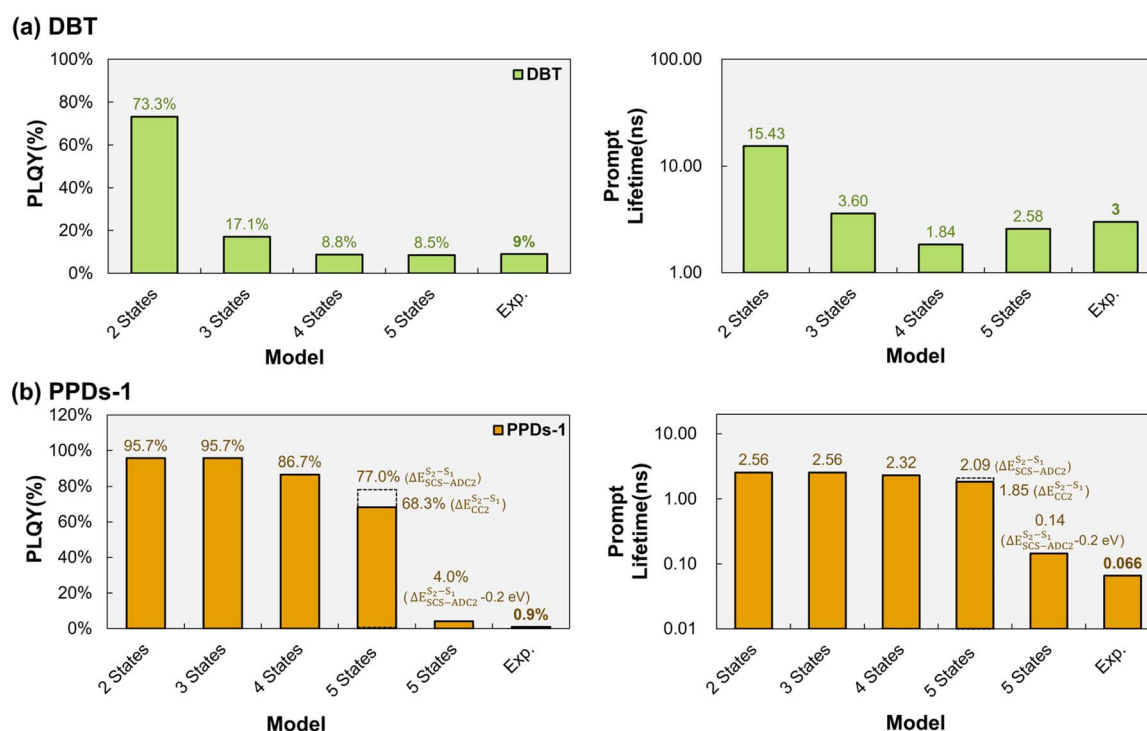

Fig. 7 Calculated photoluminescence quantum yield (PLQY) and prompt fluorescence lifetime for (a) DBT (light green) and (b) PPDs-1 (orange), compared with experimental results.

the fast (r)IC processes. Second, IC ( $S_2 \rightarrow S_1$ ) and rIC ( $S_1 \rightarrow S_2$ ) are extremely sensitive to the adiabatic energy gap  $\Delta E(S_2-S_1)$ . By subtracting 0.2 eV from the calculated  $\Delta E(S_2-S_1)$  value at the SCS-ADC(2) level (we note that  $\pm 0.2$  eV is the expected accuracy of SCS-ADC(2)), the calculated (r)IC rate constants significantly change by one to two orders of magnitude (Fig. S17). This leads to a reduction in the calculated PLQY to 4.0% and the lifetime to 0.14 ns (see fifth columns in Fig. 7b), bringing them substantially closer to the experimental values of 0.9% and 0.066 ns. Furthermore, we also calculated  $\Delta E(S_2-S_1)$  using the CC2 method, which is of comparable accuracy to ADC(2) but has been reported to provide more reliable excitation energies for valence excitations in benchmark studies<sup>47–49</sup> (both  $S_1$  and  $S_2$  of PPDs-1 are of  $\pi\pi^*$  character, see Fig. S18). CC2 predicts a smaller value of 0.23 eV compared to that obtained with SCS-ADC(2) (0.31 eV). Correspondingly, the calculated rIC  $S_1 \rightarrow S_2$  rate constant increases by approximately one order of magnitude, from  $3.15 \times 10^9 \text{ s}^{-1}$  (SCS-ADC(2)) to  $1.27 \times 10^{10} \text{ s}^{-1}$  (CC2), while the IC  $S_2 \rightarrow S_1$  rate constant increases more moderately, *i.e.*, from  $2.54 \times 10^{12} \text{ s}^{-1}$  (SCS-ADC(2)) to  $4.37 \times 10^{12} \text{ s}^{-1}$  (CC2). Consequently, the calculated PLQY and prompt fluorescence lifetime further decrease to 68.3% and 1.85 ns, respectively (see fourth columns in Fig. 7b), in closer agreement with the experimental results than those obtained using the calculated  $\Delta E(S_2-S_1)$  value at the SCS-ADC(2) level. Given the pronounced sensitivity of (r)IC rate constants to  $\Delta E(S_2-S_1)$  (see Fig. S17) and the likely overestimation of valence excitation energies by *ca.* 0.2 eV at the SCS-ADC(2) level, we consider the inaccuracy in the calculated  $\Delta E(S_2-S_1)$  value to be a major contributor to the remaining quantitative discrepancy with experiment (see also the discussion below in Section 2.5). These results demonstrate that higher-lying singlet states  $S_2$  can play a significant role by introducing efficient competing nonradiative decay pathways ( $S_1 \rightarrow S_2 \rightarrow S_0$ ), which are essential for quantitatively reproducing both PLQY and prompt fluorescence lifetimes in systems influenced by fast rIC processes. Accordingly, the five-state model, explicitly including both  $T_2$  and  $S_2$ , represents the minimal kinetic description beyond the three-state description required to achieve quantitative agreement for non-TADF emitters dominated by fast ISC and rIC processes.

## 2.5 Accuracy and limitations of our approach

Including higher-lying excited states in the kinetic models improves the mechanistic completeness of the excited state dynamic description and can yield more reliable predictions of PLQY and excited-state lifetimes by explicitly accounting for all relevant photophysical pathways in the solution of the rate equations. Nevertheless, achieving quantitative agreement with experiment from *ab initio* calculations remains highly challenging, largely due to uncertainties in the calculated excited-state decay rate constants. For instance, as illustrated in Fig. S15, even small variations in the calculated energy gaps  $\Delta E(S_1-S_0)$  can lead to orders-of-magnitude changes in the calculated  $S_1 \rightarrow S_0$  IC rate constants. Even when a very narrow Lorentzian broadening function is employed (HWHM  $\sim 0.001$  eV), the physical vibrational overlap becomes negligible once

the adiabatic energy lies beyond the inflection point. In such cases, the computed IC rate constant may be dominated by the tails of the broadening function, potentially leading to an overestimation. Consequently, extending the kinetic model to include additional excited states and pathways inevitably increases the number of rate constants that must be estimated, which can result in the accumulation and propagation of errors in the predicted observables.

For DOBNA and its derivative DABNA-1, the calculated delayed fluorescence lifetimes obtained from the four- and five-state kinetic models are underestimated by nearly one order of magnitude with respect to the experimental values. Even for the most rigid systems, errors of this size in the computed lifetimes are not uncommon. All in all, the deviations in the predicted PLQY and delayed fluorescence lifetime are to be unambiguously traced back to inaccuracies in some specific rate constant calculations. For DOBNA (Fig. S16a), gradually varying the value of the  $S_1 \rightarrow S_0$  IC rate constant over a range of  $10^7$ – $10^8 \text{ s}^{-1}$  while keeping all the other computed rate constants fixed leads to a pronounced change in the calculated PLQY, decreasing from approximately 80% to 40%, whereas the prompt and delayed fluorescence lifetimes remain essentially unaffected. This indicates that uncertainties in the calculated  $S_1 \rightarrow S_0$  IC rate constants are the primary source of the PLQY deviation. Furthermore, Fig. S16b demonstrates that variations in the  $T_1 \rightarrow S_0$  ISC rate constant strongly affect the delayed fluorescence lifetime, identifying this process as the dominant contributor to the inaccuracy in the predicted delayed lifetime for DOBNA. For its derivative DABNA-1 (Fig. S16c and S16d), the analysis indicates that uncertainties in the calculation of the  $S_1 \rightarrow S_0$  IC rate constant predominantly affect the predicted PLQY, whereas variations in the  $T_1 \rightarrow S_1$  ISC rate constant largely govern the accuracy of the delayed fluorescence lifetime.

For DiKTA and its derivative DQAO, the three-, four-, and five-state kinetic models all slightly underestimate the prompt fluorescence lifetime by nearly one order of magnitude. Among them, the four-state model yields the closest overall agreement with experiment when prompt and delayed fluorescence lifetimes and PLQY are considered simultaneously. In contrast to DOBNA and DABNA-1, the deviations observed for DiKTA and DQAO cannot be traced back to a single dominant rate constant but rather reflect the coupled and interdependent contributions of multiple excited-state decay processes. For the non-TADF emitters DBT, the calculated lifetimes and PLQY show deviations from the experimental data within an acceptable range. For PPDs-1, as discussed above, an overestimation of  $\Delta E(S_2-S_1)$  is the major contributor to the remaining discrepancy with the experiment (Fig. S17). Additionally, it is possible that the (r)IC process between  $S_1$  and  $S_2$  proceeds through a conical intersection (CI), resulting in ultrafast dynamics that cannot be adequately described by Fermi's golden rule within the harmonic approximation. This scenario merits further exploration using *e.g.*, nonadiabatic excited-state dynamics methods.

All in all, the above findings highlight a limitation of our fully *ab initio* kinetic modeling approach: the quantitative accuracy is ultimately determined by the accuracy in the state-of-the-art approaches to calculate excited state decay rate

constants. First, the static approach we used to calculate rate constants relies on the harmonic approximation, which may introduce non-negligible errors in systems with significant anharmonicity. In such cases, more advanced approaches, such as Morse-type potential<sup>50</sup> and time-dependent density matrix renormalization group theory (TD-DMRG),<sup>51</sup> may provide more reliable approaches to calculate rate constants. Second, nonadiabatic spin-vibronic effects remain challenging to incorporate within this static framework. These effects can be more naturally captured by *ab initio* excited-state dynamics methods (e.g., trajectory surface hopping<sup>52,53</sup>). However, their high computational cost generally restricts their application to short time windows. In contrast, kinetic modeling enables the simulation of population evolution over extended (nanosecond to microsecond) timescales, thereby providing a direct connection to experimental photophysical observables of rigid chromophores. The complementarity of these two approaches represents a promising direction for future studies in computational photochemistry. Specifically, static rate kinetic models can be used to construct a global photophysical picture of the excited-state population evolution over long time scales and to predict observables such as PLQY and lifetimes. In regimes where the static approach becomes inadequate, such as in the presence of strong anharmonicity, near conical intersections (CI), or under pronounced spin-vibronic coupling, *ab initio* excited-state dynamics simulations can offer highly accurate mechanistic insight into short-time population evolution.<sup>54,55</sup> Overall, this multiscale simulation framework, integrating both long- and short-time dynamics, represents a highly promising paradigm for the future of computational photochemistry. Nevertheless, despite the inherent uncertainties in the calculated rate constants, our investigations unambiguously highlight that a three-state model may be insufficient for some MR-TADF and non-TADF organic emitters, underscoring the need for more comprehensive excited-state kinetic models.

### 3 Conclusion

In this study, we developed KinLuv, a Python-based kinetic modeling package which explicitly includes higher-lying excited states ( $T_2$  and  $S_2$ ) into the excited state kinetic analysis. All rate constants were computed using Fermi's golden rule, explicitly including the HT vibronic coupling effect. Our approach was applied to prototypical MR-TADF emitters (DOBNA, DiKTa) and their derivatives (DABNA-1, DQAO), as well as to non-TADF organic emitters (DBT, PPDs-1). Key findings are summarized as follows:

(a) In the investigated organic emitters, fast (r)ISC is primarily governed by HT vibronic coupling, as revealed by the relative contributions of HT and FC mechanisms to the calculated rate constants.

(b) Mechanistically, inclusion of  $T_2$  state in the four-state model additionally mediates an additional delayed fluorescence pathway ( $T_1 \rightarrow T_2 \rightarrow S_1 \rightarrow S_0$ ) and a competing non-radiative decay pathway ( $S_1 \rightarrow T_2 \rightarrow T_1 \rightarrow S_0$ ). Inclusion of  $S_2$  state in the five-state model enables an additional delayed fluorescence pathway ( $T_1 \rightarrow S_2 \rightarrow S_1 \rightarrow S_0$ ) and introduces

further efficient competing nonradiative decay pathways ( $S_1 \rightarrow S_2 \rightarrow S_0$ ).

(c) Quantitatively, when (r)ISC processes are slow relative to fluorescence and IC, higher-lying excited states are not significantly populated and do not affect the overall decay dynamics; in this regime, a three-state description already reproduces the experimental observables (e.g., DOBNA and DABNA-1).

(d) When (r)ISC processes are fast leading to substantial triplet populations, and when the population of higher-lying triplet states become kinetically relevant; in this regime, explicit inclusion of at least  $T_2$  is required to achieve quantitative agreement (e.g., DiKTa, DQAO and DBT).

(e) When rIC processes dominate the excited-state dynamics, higher-lying singlet states become essential nonradiative decay channels; in this regime, explicit inclusion of  $S_2$  is required to reproduce the experimental observables (e.g., PPDs-1).

Overall, this unified framework clarifies that higher-lying excited states may play a mechanistically important role by introducing additional decay pathways and that their inclusion in the kinetic models may become necessary to attain quantitative accuracy in the calculated values of PLQY and fluorescence lifetimes. At the same time, increased mechanistic completeness does not inherently guarantee improved quantitative accuracy owing to the amplification of errors and uncertainties in the underlying calculation of *ab initio* rate constants. Further developments in FGR-based theories, including anharmonic effects, will be necessary to improve the quantitative accuracy of PLQY and fluorescence lifetimes. Regarding kinetic model selection, we suggest that higher-lying triplet states should be included explicitly when ISC is sufficiently fast to generate substantial populations in these states. Likewise, higher-lying singlet states become essential when rIC populates them more efficiently than nonradiative decay depletes the excited-state manifold. For more efficient model construction, simple descriptors may serve as preliminary indicators for assessing the importance of higher-lying states in future studies, thereby guiding model selection without requiring computationally intensive rate-constant calculations. Taken together, these insights establish a rational criterion for selecting minimal kinetic models that balance physical insight and numerical robustness, with direct implications for *in silico* design of high-performance organic emitters.
