This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.

ARTICLE

Loosely Packed Catalyst Layers Promote Gas Transport and Flooding Resistance in Gas Diffusion Electrodes for Electrochemical CO₂ Reduction

Acidic CO₂ electrolysis enables high CO₂ utilization through carbonate protonation and high C₂₊ selectivity due to the elevated local alkalinity, yet its lifetime remains limited by gas diffusion electrode flooding. In this study, we reveal that a loosely packed, house-of-cards structure can be obtained by incorporating 2D-structured graphene nanoplatelets (GNPs) with Cu-based catalysts, effectively mitigating flooding. With an optimal GNP content below 9 wt.%, this structure enhances CO₂ diffusion and significantly improves electrode lifetime, reaching 10 hours at a high current density of 600 mA cm⁻². Excessive GNP content leads to catalyst layer densification and accelerates flooding, highlighting the importance of a structure sufficiently thick to accommodate liquid seepage but also sufficiently porous to allow CO₂ access throughout the entire thickness. Our findings provide insights into a practical microstructural strategy for developing efficient and stable CO₂ electrolysis systems.

Keywords: Catalyst layer, CO₂ reduction, electrocatalysis, flooding, house-of-cards structure.

Introduction

The electrochemical carbon dioxide reduction reaction (eCO₂RR) – occurring at room temperature and ambient pressure and involving the direct use of electricity – represents a promising strategy for mitigating CO₂ emissions^{1,2}. This reaction between CO₂ and water shows potential for the storage of renewable energy in the form of valuable chemical feedstocks, such as hydrocarbons^{3,4}. The reaction activity and product selectivity depend on the choice of catalysts and the reaction conditions^{5,6} and can be regulated via, for example,

catalyst development, designing/tailoring the interfacial environment, and systems engineering. In the eCO₂RR, the local microenvironment around the catalyst has a significant effect on the Faradaic efficiency (FE) towards CO₂RR products relative to the competing hydrogen evolution reaction (HER). Due to the limited solubility of CO₂ in water, the eCO₂RR is typically conducted at a neutral pH, ensuring a balance that minimises the HER (favoured by an excess of protons) while also avoiding the formation of carbonate species (which occurs under conditions of excess OH⁻)⁷.

Flow cell reactors, in which CO₂ is fed from the rear of a gas diffusion electrode (GDE), effectively address the challenge of the limited solubility of CO₂ in aqueous electrolytes⁸. Catalysts are typically drop-cast, spray-coated, or directly grown on a hydrophobic microporous layer (MPL), which sits atop a gas diffusion layer (GDL) composed of carbon cloth. The CO₂, introduced from the rear of the GDE, diffuses first through the GDL and subsequently through the MPL before reaching the catalyst layer (CL). This rear-fed configuration reduces the

diffusion distance of CO₂ in the liquid phase (on the order of micrometres), thereby enhancing the local CO₂ concentration near the catalyst surface compared to H-cell setups. Flow cells can thus operate at current densities of hundreds of mA·cm⁻², significantly higher than the tens of mA·cm⁻² typically achievable in H-cells.

Nevertheless, while a flow cell enables operation at high current densities, it often faces a trade-off in terms of a limited operational timeline due to various degradation mechanisms, such as flooding, species evolution in the catholyte and anolyte, membrane degradation, and catalyst reconstruction⁹. Among these, flooding is one of the most critical issues, limiting the operational time to only several hours^{9,10}. Under a high current density, the potential-driven off-equilibrium conditions often cause the electrolyte to penetrate the MPL, which can then lead to salt crystallisation (upon reaching the solubility limit) due to water evaporation¹¹. These salt crystals typically accumulate in the MPL, blocking CO₂ access to the CL. Once flooding begins, the reduced CO₂ diffusion to the catalyst is reflected in a decrease in the CO₂RR selectivity and an increase in the HER¹². From the onset of flooding to its progression to severe flooding, salt crystals progressively spread within the GDL, not only blocking CO₂ access to the catalyst but also preventing the gas products from leaving the reaction site, indicating the complete degradation of the GDE.

Strategies for modifying the GDE to improve its resistance to flooding include GDL, MPL, and CL engineering^{10,13–15}. A common approach for all three components is tuning their wettability by adding hydrophobic materials or ionomers to their structures^{11,16}. The wetproofing of the GDL can be adjusted to achieve optimal CO₂RR selectivity versus the HER; for example, 10% wetproofing allows for maximal CO FE on an Ag catalyst, as it provides the ideal balance between hydrophobicity and electrical conductivity¹⁷. The resistance to flooding can also be improved by incorporating a PTFE/carbon black layer between the GDL and MPL via vacuum-assisted infiltration¹⁸. The hydrophobicity of the CL is usually improved by mixing the catalyst with hydrophobic binders (e.g., PTFE or PDMS)^{19–21}, fluorinated silane, or hydrophobic ionomers such as PFSA^{8,22}. Compared to the MPL, which serves as a potentially highly hydrophobic barrier to repel water and enable CO₂ flow, the CL must ensure adequate ionic conductivity and water

activity while avoiding full flooding to maintain sufficient CO₂ access. Often, increasing the hydrophobicity comes at the expense of electrical conductivity and the electrochemical surface area; thus, the type and amount of the hydrophobic additive must be optimised²³. While insufficient hydrophobicity can lead to the complete flooding of the metal-based CL and long CO₂ diffusion pathways, an excessive quantity of hydrophobic material, combined with capillary forces, requires a high capillary pressure to wet the CL, resulting in only the partial hydration of the catalyst. Therefore, the catalysts should ideally be covered with a thin layer of electrolyte without the full flooding of the pores, which might be achieved with larger hydrophobic pores²⁴. While some studies have focused on bridging the gap in the hydrophobicity between the MPL and CL by tuning the MPL through, for example, the creation of a hydrophobicity gradient zone within the MPL^{25,26}, research efforts on designing the CL itself, to the best of our knowledge, are limited. A notable approach to increasing the pore size is the incorporation of two-dimensional (2D) structures, such as nanosheets derived from exfoliated layered double hydroxides, which can assemble into a house-of-cards architecture to enhance pore connectivity and create larger voids²⁷. However, the primary focus of such works has been to enable catalyst loadings as high as 5.82 mg cm⁻² by improving gas and electrolyte transport.

Herein, we employ the house-of-cards structural design to create larger pores within the CL, enhancing CO₂ diffusion through it. By combining a high-void-fraction architecture with a thin hydrophobic binder layer, the CL maintains an optimal “wet-but-not-flooded” state, thereby extending the gas–liquid interaction zone. In this configuration, the selectivity towards C₂₊ products reaches 70% in the acidic reaction environment due to the high local alkalinity at the catalytic sites, while the house-of-cards scaffold improves the resistance to flooding and increases the operational lifetime of the GDE from 2 to 10 hours.

Results and Discussion

Acidic CO₂RR Over Highly Porous CuO Catalysts

The Cu-based catalyst herein, synthesised using a similar protocol to previous works, involves Cu(II) oxide^{19,28}, showcasing a highly porous network morphology (Figure 1a). The catalyst primarily comprises nanoparticles assembled into high-aspect-ratio needles that are 200 to 500 nm long and 15 to 30 nm wide (Figures 1a, b and S1). High-resolution transmission electron microscopy (HR-TEM) images, along with the corresponding fast Fourier transform (FFT) patterns and their rotational average intensity, indicate a polycrystalline copper oxide structure, with diffraction peaks matching those of PDF 04-007-0518 (Figure 1c). In our prior work, this catalyst demonstrated >25% selectivity towards H₂ in 0.1 M KHCO₃ within an H-cell. Considering these results, we hypothesised that using an acidic electrolyte would yield a higher FE for H₂¹⁹. Consequently, CO₂ electrolysis was exclusively conducted under acidic conditions in a flow cell. A single-pass configuration was used to mitigate OH⁻ and liquid product recirculation, as previously demonstrated²⁹.

Figure 1. Acidic CO₂ reduction reaction (CO₂RR) over CuO catalysts. (a) SEM image (scale bar: 500 nm), (b) bright-field TEM image, and (c) high-resolution TEM image with the corresponding FFT pattern and its

rotationally averaged intensity profile of the synthesised CuO catalysts. (d) Product distribution of flow-cell CO₂RR at 600 mA cm⁻² and pH values of 1, 2, 3, and 14. (e) Operando Raman spectra of CuO at 10, 20, 30, and 50 mA cm⁻² in a catholyte of pH 2.

At a current density of 600 mA cm⁻², the CO₂RR product distribution on CuO across three acidic pH conditions (3 M KCl adjusted to pH 1, 2, and 3 with H₃PO₄) and in an alkaline environment (1 M KOH, pH 14) was compared. The FE for H₂ remains approximately 10% under all acidic conditions, while the CO₂RR products account for around 90%, demonstrating the effective suppression of H₂ evolution in acidic electrolytes by the added K⁺ ions (Figure 1d)^{22,30,31}. Across all acidic pH values, the FE for H₂ remains stable with an increasing current density; the product distribution, however, shifts from CO to C₂H₄, likely due to higher overpotentials at elevated current densities (Figure S2). The FE for C₂₊ products ranges from 45 to 55% at 200 mA cm⁻² and increases to 65–75% at 800 mA cm⁻² (Figure S2). When operating the cell at high current densities (e.g., 600 and 800 mA cm⁻² at pH 1 and 800 mA cm⁻² at pH 2), the FE for C₂₊ products exceeds 70% and approaches 76%, the value achieved with a flow cell using 1 M KOH¹⁹.

The product distribution in acidic electrolytes is notably similar to that observed in 1 M KOH using the same catalyst and experimental setup, suggesting that the local pH at the reaction sites is alkaline even when an acidic catholyte is used. The alkaline surface pH is further confirmed by the presence of the CuO_x/(OH)_y peak in the operando Raman spectra, acquired at current densities ranging from 10 to 50 mA cm⁻² to minimise the accumulation of gas bubbles on the GDE surface (Figure 1e). At an applied current density of 10 mA cm⁻², one can note the disappearance of the characteristic CuO phase peaks at 298 and 348 cm⁻¹ and that of a broad peak at 540–660 cm⁻¹, along with the appearance of the CuO_x/(OH)_y peak at 385–390 and 525–535 cm⁻¹³². When probing at the same location on the GDE, the area under the CuO_x/(OH)_y peak increases correspondingly as the current density is raised to 20, 30, and 50 mA cm⁻², indicating a higher concentration of OH⁻. Peaks corresponding to the bicarbonate and carbonate phases at 1020 and 1060 cm⁻¹ begin to appear at current densities above 30 mA cm⁻², confirming the reaction between CO₂ and local OH⁻ to form adsorbed bicarbonate and carbonate species^{33,34}. The alkaline

surface pH, as demonstrated in previous studies, is favourable for C–C coupling and C₂₊ product formation, explaining the observed selectivity towards C₂₊ products despite the use of an acidic catholyte³⁵. Varying the CO₂ flow rate between 14.5 and 62.9 mL min⁻¹ has a minimal effect on the CO₂RR selectivity in the catholyte at pH 2: the H₂ FE remains below 10%, while the C₂₊ FE lies between 63% and 70% (Figure S3). The single-pass carbon conversion efficiency for C₂₊ products is 3.3% at a current density of 600 mA cm⁻², obtained at a CO₂ flow rate of 14.5 mL min⁻¹ (Supporting Information S1).

Prolonged Lifetime of Carbon-Based GDEs on a GNP–CuO Scaffold

Under acidic CO₂RR conditions (pH 2) at 600 mA cm⁻², the lifetime of the CuO–GDE ranges from 3 to 4 hours using a single-pass catholyte setup, as demonstrated recently²⁹. The CuO catalysts were mixed with 2D structured graphene nanoplatelets (GNPs) to extend the lifetime of the GDE. The CuO–GNP combinations were prepared at four different GNP:CuO mass ratios: 0.05:1, 0.1:1, 0.25:1, and 1:1. In all GNP–CuO combinations, the CuO loading was maintained at approximately 0.2 mg cm⁻² in the preparation of the GDEs, as confirmed by inductively coupled plasma–optical emission spectroscopy (Table S1). The product selectivity of these GNP–CuO mixtures at 600 mA cm⁻² is shown in Figure 2a. All samples exhibit similar product distributions to the GDE loaded with 0.2 mg cm⁻² of CuO. This indicates that the integration of GNP with CuO does not alter the CO₂RR selectivity and that CuO remains the primary active phase for the reaction. In a densely packed CL, for example one composed only of catalyst, it has previously been demonstrated that there are selectivity gradient zones within the CL³⁶. The zone far from the MPL and close to the electrolyte mainly produces H₂ due to low CO₂ concentration and high proton activity, whereas the zone close to the MPL mainly produces C₂₊ products due to the opposite trend. Similar

significant changes in selectivity were observed with a dense CL composed solely of CuO catalysts; for example, the H₂ FE approximately doubled when the CuO loading increased from 0.2 to 1.25 mg cm⁻² (Figure S4). Here, the slight differences in selectivity observed when varying the GNP:CuO ratios further emphasize the advantage of the house-of-cards structure, highlighting that the role of the GNP is simply to disperse the same amount of catalyst within a thicker CL. The house-of-cards structure provided by the GNP further expands the interface between the catalyst, electrolyte, and CO₂ across the CL, enabling homogeneous selectivity throughout the catalyst layer thickness.

Figures 2b and 2c show the C₂H₄ and H₂ selectivities over time for GDEs with different GNP-to-CuO ratios, and Figure S5 presents the full product distributions. Two distinct deactivation modes were observed. The first is characterised by a gradual increase in the HER and a corresponding decrease in C₂H₄ production, as observed with the CuO-only composition and the GNP:CuO ratios of 0.05:1 and 0.1:1. This is attributed to catholyte penetration into the rear side of the GDE, which restricts CO₂ (reactant) access to the catalyst and promotes water splitting^{37,38}. In the second deactivation mode, observed in the samples with GNP:CuO ratios of 0.25:1 and 1:1, the reaction was forced to stop after detecting no gas at the outlet. This is induced by salt crystal formation from the penetrated catholyte, which blocks the escape pathways for the gas products. As a result, these products are unable to diffuse through the GDE and reach the gas outlet. In this scenario, flooding occurs with no changes in the H₂ and C₂H₄ selectivities, as the blockage primarily affects the gas products rather than the CO₂ reactant. Both deactivation modes occur randomly across all samples, depending on the progression of catholyte seepage, and no specific mode can be consistently associated with a particular GNP-to-CuO ratio.

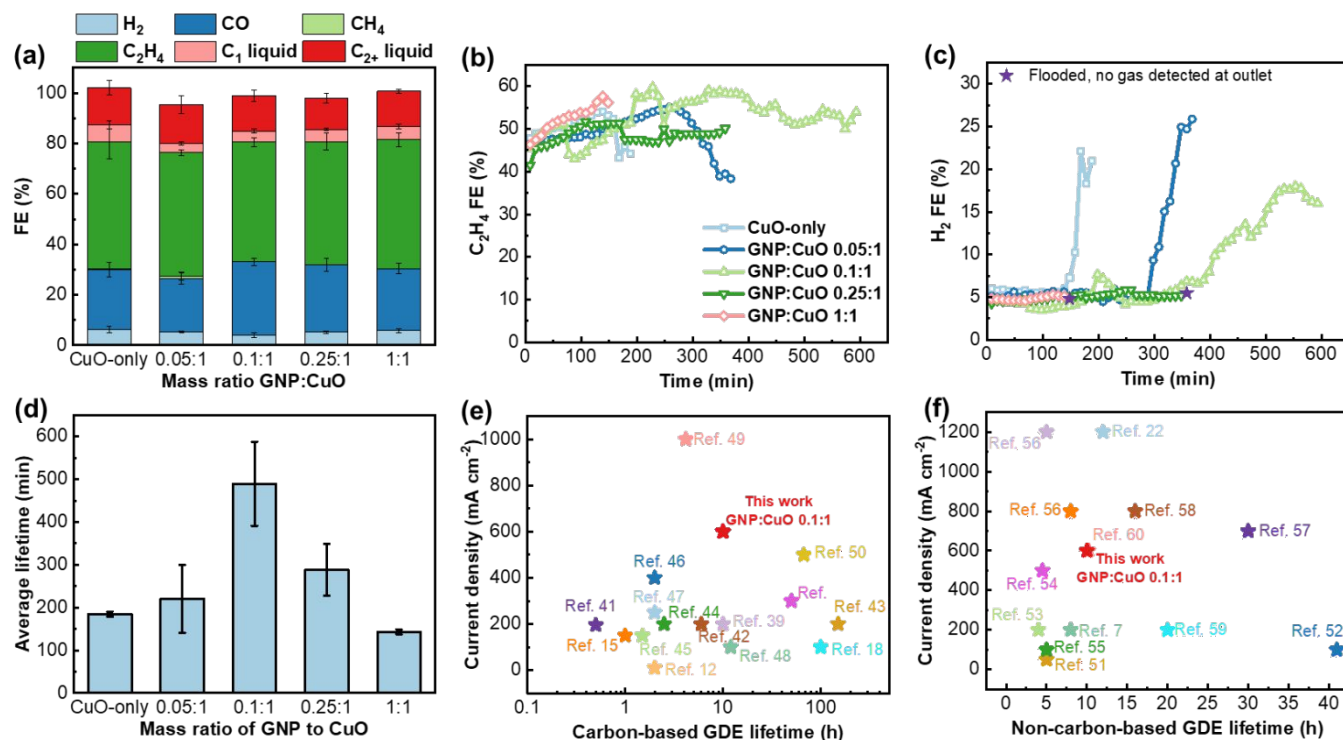

Figure 2. Acidic CO₂RR selectivity and stability of CuO-only and GNP–CuO gas diffusion electrodes (GDEs). (a) Product distribution of flow-cell CO₂RR in the catholyte at pH 2 and 600 mA cm⁻² for the CuO-only GDE and GNP–CuO GDEs with varying GNP-to-CuO mass ratios. Evolution of (b) C₂H₄ and (c) H₂ faradaic efficiency (FE) over time for the GNP–CuO GDEs; the curves correspond to the samples with the longest lifetimes. (d) Average lifetimes of CuO-only and GNP–CuO GDEs; the error bars represent standard deviations from at least three independent samples. Comparison of lifetime–current density merit of the GNP:CuO 0.1:1 GDE with values reported in the literature for (e) carbon-based and (f) non-carbon-based GDEs.

The addition of GNP improves the lifetime of the GDE without affecting the product selectivity (Figure 2d). In this study, the average lifetime and standard deviation were calculated from at least three independent samples (Figures S5–S10). The time at which the H₂ FE exceeds 20% was defined as the “dead time” of the GDE. The average GDE lifetime increases slightly from 185 minutes for the CuO-only system to 230 minutes for the sample with 5 wt% GNP, reaching a maximum of 490 minutes at 10 wt% GNP. However, further increases in the GNP content lead to a decline in the average lifetime, which drops to 290 and 140 minutes for the remaining (higher) GNP loadings. The lifetimes of carbon-based GDEs reported in the literature at different current densities for various catalysts are summarised in Figure

2e^{12,15,18,39–50}, with further details presented in Table S2. Stability tests on carbon-based GDEs are typically conducted at current densities between 100 and 200 mA cm⁻², with the lifetime reaching 150 hours at 200 mA cm⁻². In comparison, our GNP:CuO 0.1:1 sample demonstrates a carbon-based GDE lifetime of 10 hours at a significantly higher current density of 600 mA cm⁻² (Figure S5), outperforming many GDEs from previous studies that achieved similar lifetimes though at lower current densities (100–200 mA cm⁻²). This lifetime–current density merit is comparable to that of other PTFE-based GDEs and self-supported porous Cu GDEs, which are generally more durable than carbon-based ones (Figure 2f)^{7,22,51–60}. Further details are provided in Table S3. Notably, our CuO loading is only

0.2 mg cm⁻², and further optimisation of the GNP:CuO 0.1:1 surface loading may prolong the GDE lifetime.

To elucidate the degradation mechanism in the CuO and GNP–CuO GDEs, the reaction time was fixed at 150 minutes. This duration is shorter than the lifetimes of the two less durable samples (CuO and GNP:CuO 1:1) yet sufficiently long to observe differences in the GDEs after operation under CO₂RR conditions at 600 mA cm⁻². We first evaluated the degree of flooding based on the change in mass of the GDE, which reflects the amount of salt retained in the pores of the CL, MPL, and GDL. After a reaction time of 150 minutes, the used GDE was rinsed on the catalyst side to remove residual electrolyte and on the backside to eliminate large droplets that had fully crossed over and visible salt crystals. This procedure ensured that only the salt that had infiltrated into the pore structure was evaluated. Only a 0.26-mg increase in mass can be observed for GNP:CuO 0.1:1, indicating minimal flooding in this sample (Figure 3a). Slightly higher mass changes were observed for GNP:CuO 0.05:10 (0.53 mg) and GNP:CuO 0.25:1 (0.79 mg). The most severe flooding,

as indicated by the highest mass gains, is exhibited by the CuO-only (1.75 mg) and GNP:CuO 1:1 (1.98 mg) samples. All samples initially exhibit a similar degree of hydrophobicity, as reflected by the water contact angles (WCAs), ranging from 153° to 158° (Figures S11 and S12). However, after a reaction time of 150 minutes at a current density of 600 mA cm⁻², the loss in hydrophobicity varies among the samples (Figures 3b and S13–S17). Figure 3c presents the average WCA, measured at three (at the minimum) different locations (Figures S13–S17) on the used GDE. In the GNP:CuO 0.1:1 sample, the WCA remains relatively high (136°). In contrast, the WCA decreases to 81.5°, 86.6°, and 80.8° for the GNP:CuO ratios of 0.05:1, 0.25:1, and 1:1, respectively. The most significant loss in hydrophobicity was observed for the CuO-only sample, with a WCA of only 52°. This reduction in hydrophobicity is closely correlated with the mass gain due to flooding, suggesting that a greater loss in hydrophobicity is a key factor contributing to more severe flooding in the GDE.

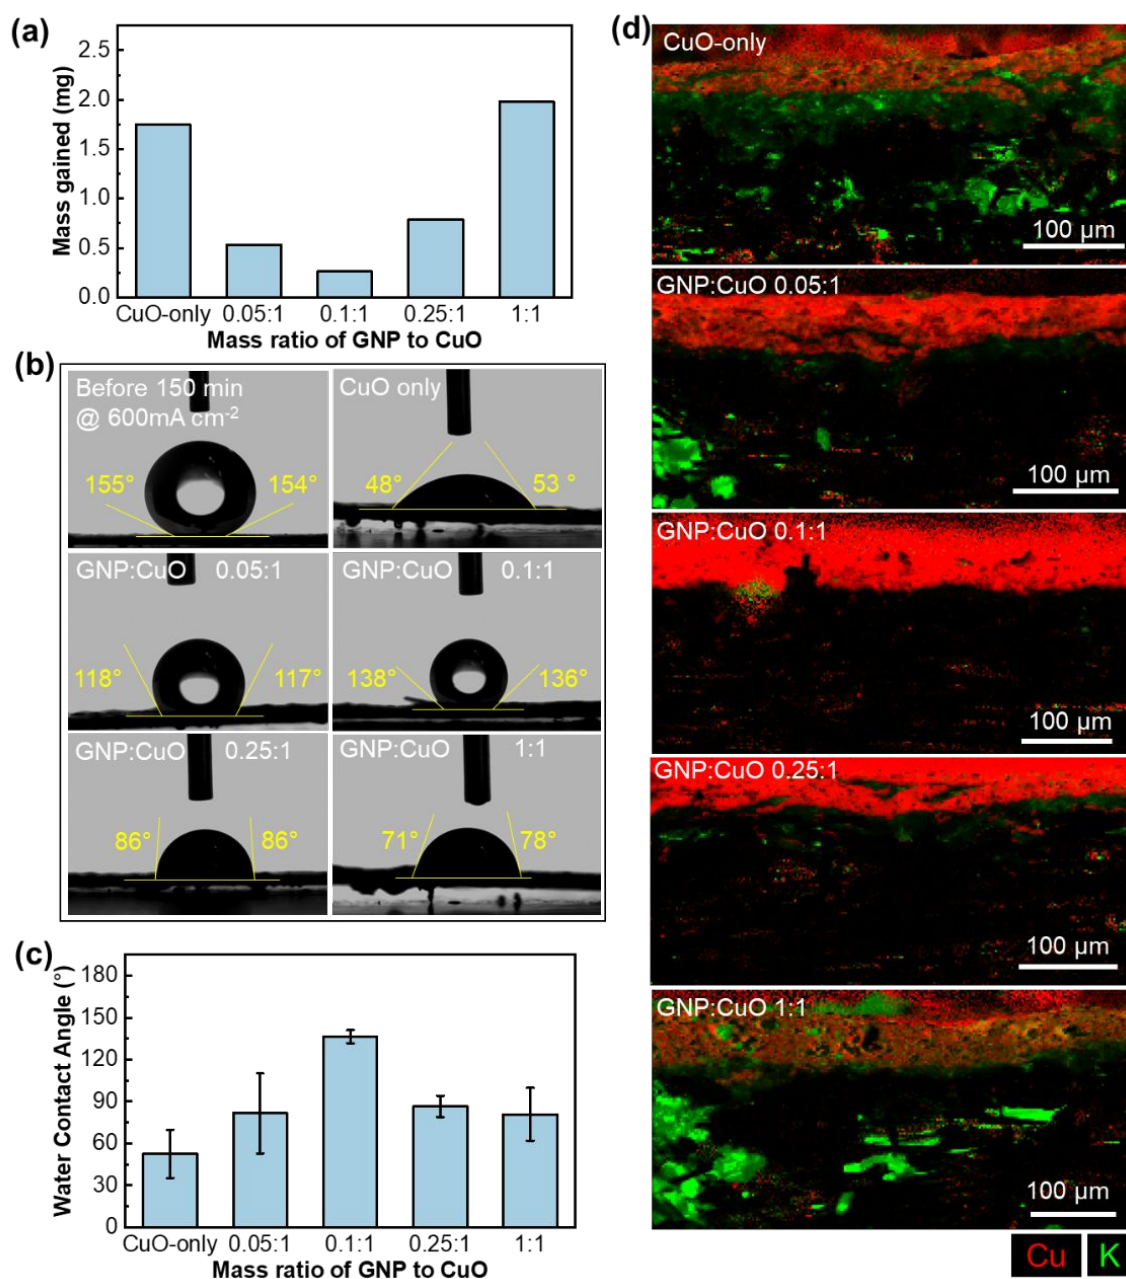

Figure 3. GDE characterisation after a reaction time of 150 minutes at 600 mA cm⁻² (pH 2) to assess flooding. (a) Mass gain of the used GDEs after a 150-minute reaction compared to that of the as-prepared GDEs. (b) Water contact angles (WCAs) of as-prepared CuO-only GDEs and CuO-only and GNP–CuO GDEs after a reaction time of 150 minutes. (c) Average WCAs of CuO-only and GNP–CuO GDEs after a reaction time of 150 minutes; the error bars represent standard deviations from at least three independent regions. (d) Quantitative mapping of Cu and K across the cross-section of the used GDEs after a reaction time of 150 minutes.

ARTICLE

The quantitative mapping of Cu and K across the cross-section of the used GDEs after 150 minutes at 600 mA cm⁻² reveals the degree of flooding (Figure 3d; the back-scattered electron images and EDX acquisition areas are presented in Figure S18), consistent with the mass gain data, and reflects the concentration distribution of each element. In the concentration maps for the CuO-only and GNP:CuO 1:1 samples, K penetrates completely through the entire mass of the GDE. In some regions, large salt deposits are visible within the GDL. In the GNP:CuO 0.05:1 sample, similar salt blocks are present, but they are more localised compared to the widespread K distribution observed in the CuO-only and GNP:CuO 1:1 samples (where K extends from the CL through the MPL to the GDL). In the GNP:CuO 0.25:1 sample, no significant K presence was detected in the GDL; however, the electrolyte has noticeably penetrated through the CL and reached the MPL. The least-flooded GDE is GNP:CuO 0.1:1, where K is confined to the CL, with a negligible presence in both the MPL and GDL. Count intensity maps acquired from two additional regions of the used GDEs show a similar trend (Figures S19–S23). Notably, Cu was also detected in the cross-sections, possibly due to dynamic catalyst relocation via a dissolution–re-deposition process³⁷.

Considering the results thus far, the flooding resistance of the GDE is improved by the addition of GNP, with the optimal resistance observed at a GNP:CuO mass ratio of 0.1:1. However, increasing the GNP content beyond this ratio results in reduced flooding resistance. To elucidate this trend, it is necessary to examine both the structure of the CL and the CO₂ diffusion process for various amounts of GNP added to a fixed CuO loading of 0.2 mg cm⁻² on the GDE. A custom-made cell for evaluating CO₂ permeation through the GDE is illustrated in Figure 4a, consisting of an H-cell with two compartments, where the GDE sample is placed between them using two rubber gaskets to create gas- and liquid-tight seals. In the compartment exposing the rear side of the GDE, CO₂ gas is

introduced in a flow-by configuration. In the opposite compartment exposing the CL, a fixed volume of water is added, followed by the insertion of a dissolved CO₂ probe. This design closely mimics the flow-by mode of a typical flow cell and enables the measurement of CO₂ diffusing through the GDE and dissolving in the liquid phase. The CL thickness was determined from the chemical contrast observed in the BSE-SEM images of the GDE cross-section, with the bright layer corresponding to the CuO-containing CL (Figure S24).

The concentration of dissolved CO₂ in the liquid compartment of the cell increases over time, rising from the ambient level of approximately 400 ppm to a saturation plateau of around 1600 ppm, close to the solubility limit of 33 mmol L⁻¹ (Figure 4b). With the addition of approximately 5 wt% GNP to the CuO catalyst (with the CuO loading fixed at 0.2 mg cm⁻² for all samples), the time required to reach 1500 ppm of dissolved CO₂ is reduced from 39 minutes to a mere 16 minutes (Figure 4c). An increase in the CL thickness from 18 to 33 μm can be noted (Figures 4d and 4e), suggesting that the inclusion of GNP leads to a more porous, less dense structure. Upon increasing the GNP:CuO mass ratio to 0.1:1 (approximately 9%), the time required to reach 1500 ppm of dissolved CO₂ rises to 22 minutes. This increase can be attributed to a thicker CL (rising from 33 to 48 μm), thereby creating a longer diffusion path for CO₂. Within this low-GNP mass range (up to 9 wt%), it is likely that the 2D structure of GNP forms a scaffolded, house-of-cards-like architecture. This structure introduces additional voids within the CL, promoting more effective CO₂ diffusion than a densely packed CuO-only layer, as evidenced by the top-view BSE-SEM images of the GDE (Figure S25).

Increasing the GNP content to 20 wt% (GNP:CuO 0.25:1) results in reduced CO₂ permeation, with the time to reach 1500 ppm increasing to 26 minutes. Interestingly, the CL thickness decreases slightly to 39 μm, suggesting a densification of the CL. At the highest GNP loading of 50 wt% (GNP:CuO 1:1), the CL thickness remains almost unchanged (42 μm, but within the

error bar). However, the time required to reach 1500 ppm increases further to 32 minutes, indicating a continued loss of CO₂ permeability. This progressive densification at higher GNP loadings is likely due to the excessive amount of 2D GNP sheets. While a low GNP:CuO ratio can create a loosely packed, scaffold-like architecture with additional voids and enhance CO₂

diffusion, a higher ratio leads to the stacking and aggregation of the GNP sheets. The porous, percolated network obtained with a GNP ratio lower than 9 wt% is replaced by a more compact, less permeable structure that hinders effective CO₂ mass transport through the GDE.

DOI: 10.1039/D6TA00347H

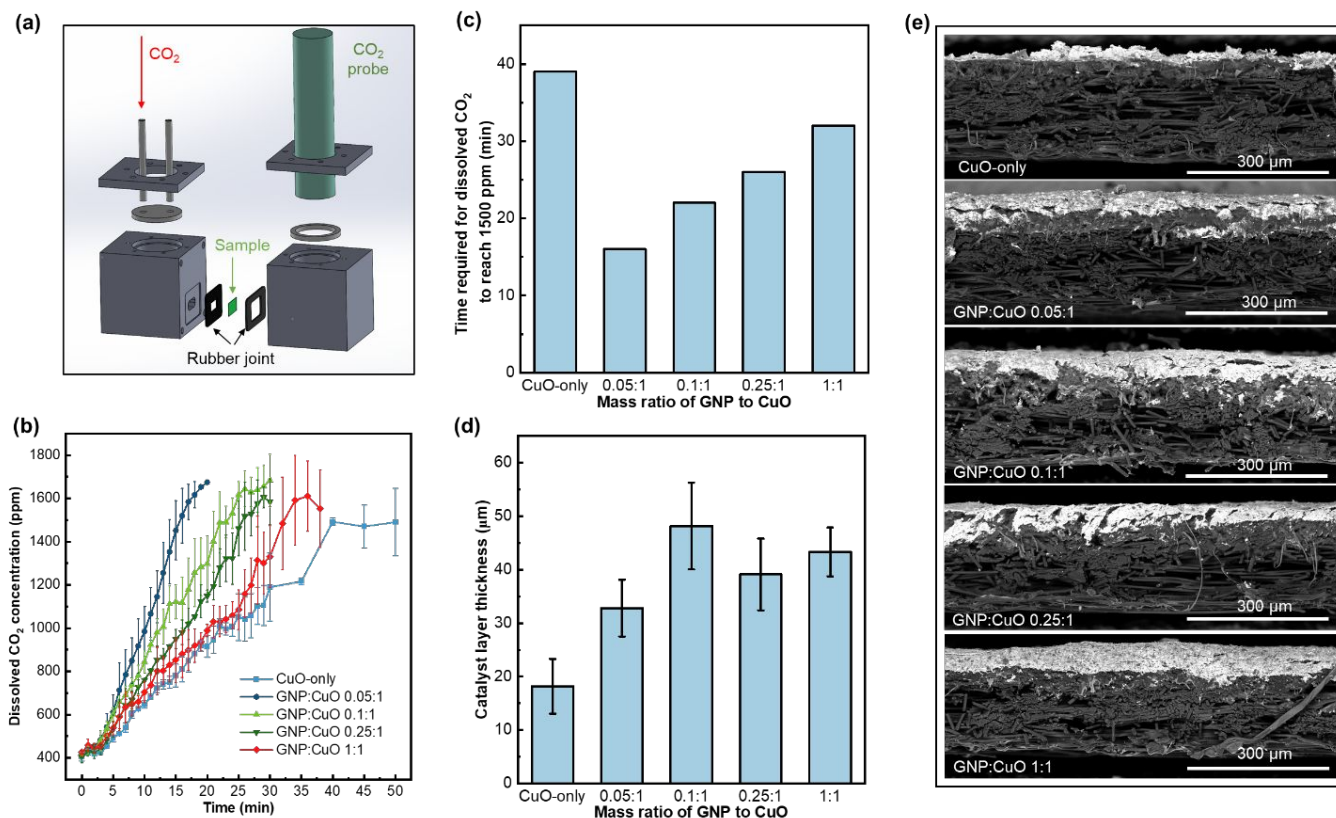

Figure 4. Balancing CO₂ transport and flooding accommodation in CuO-only and GNP–CuO GDEs. (a) Design of the custom-made cell for measuring the CO₂ diffusion time. (b) Measurement of dissolved CO₂ transport across the GDEs in a flow-by configuration. (c) Time required for dissolved CO₂ to reach 1500 ppm. (d) Average catalyst layer (CL) thickness determined from backscattered electron (BSE)–SEM images; the error bars represent standard deviations from at least six independent regions. (e) Representative BSE–SEM images highlighting the chemical contrast for determining the CL thickness.

Considering these observations, the longest lifetime, achieved with a GNP:CuO ratio of 0.1:1, was attributed to a thick CL exhibiting a house-of-cards structure. A thick CL with a high void fraction provides more space to accommodate catholyte seepage while still ensuring the sufficient diffusion of CO₂ throughout the layer. Simply increasing the thickness of the CL (from 18 to 27 μm) by raising the catalyst loading (from 0.2 to 0.34 mg cm⁻²) can increase the GDE lifetime (Figure S26); however, an excessive loading (1.3 mg cm⁻² and a corresponding CL thickness of 56 μm) leads to higher selectivity towards the

HER and a reduced resistance to flooding (Figure S27). By incorporating a scaffold phase (2D structure), a comparable thickness of 48 μm (compared to 56 μm obtained with a CuO loading of 1.3 mg cm⁻²) can be achieved with a minimal catalyst loading of only 0.2 mg cm⁻² and a scaffold phase loading of 0.02 mg cm⁻².

Regulation of Reaction Interfaces by GDE Microstructure

In a GDE, the equilibrium at the gas–liquid interface (where the CO₂ reduction reaction occurs) is governed by the gas-phase

pressure, liquid-phase pressure, and capillary pressure, which is determined by the pore size and surface wettability^{11,24,38,61}. In the hydrophobic components of the GDE, such as the MPL and the GDL, flooding is resisted by the capillary pressure: only when the differential between the liquid- and gas-phase pressure across the electrode exceeds the capillary pressure threshold can the electrolyte invade the pores. Small pores in hydrophobic materials create a higher capillary pressure, thus providing greater resistance to flooding. For the CL, it should have sufficient wettability to enable proton supply to the reaction sites and provide sinks for liquid products. The CL also needs to maintain adequate CO₂ diffusion within its structure to ensure sufficient reactant availability. The CL must not become completely flooded to avoid shifting the gas–liquid interface towards the MPL side and limiting CO₂ access to the catalyst.

Ideal wetting is achieved by coating the catalyst particles with a thin layer of a hydrophobic binder; this covers the catalyst surface with an electrolyte film for supplying protons, providing sinks for liquid products, and enabling ionic buffering, while the remaining voids ensure CO₂ diffusion. Similar to the MPL, small pores can be beneficial for the CL by increasing the capillary threshold when the CL is partially hydrophobic. However, pore volume is also important for accommodating liquid seepage, and increasing pore volume solely by increasing catalyst loading may lead to large gradients between different selectivity zones³⁶. Therefore, creating a house-of-cards structure through GNP incorporation enables higher pore volume while extending the mixed interface between the catalyst, electrolyte, and CO₂ throughout the CL.

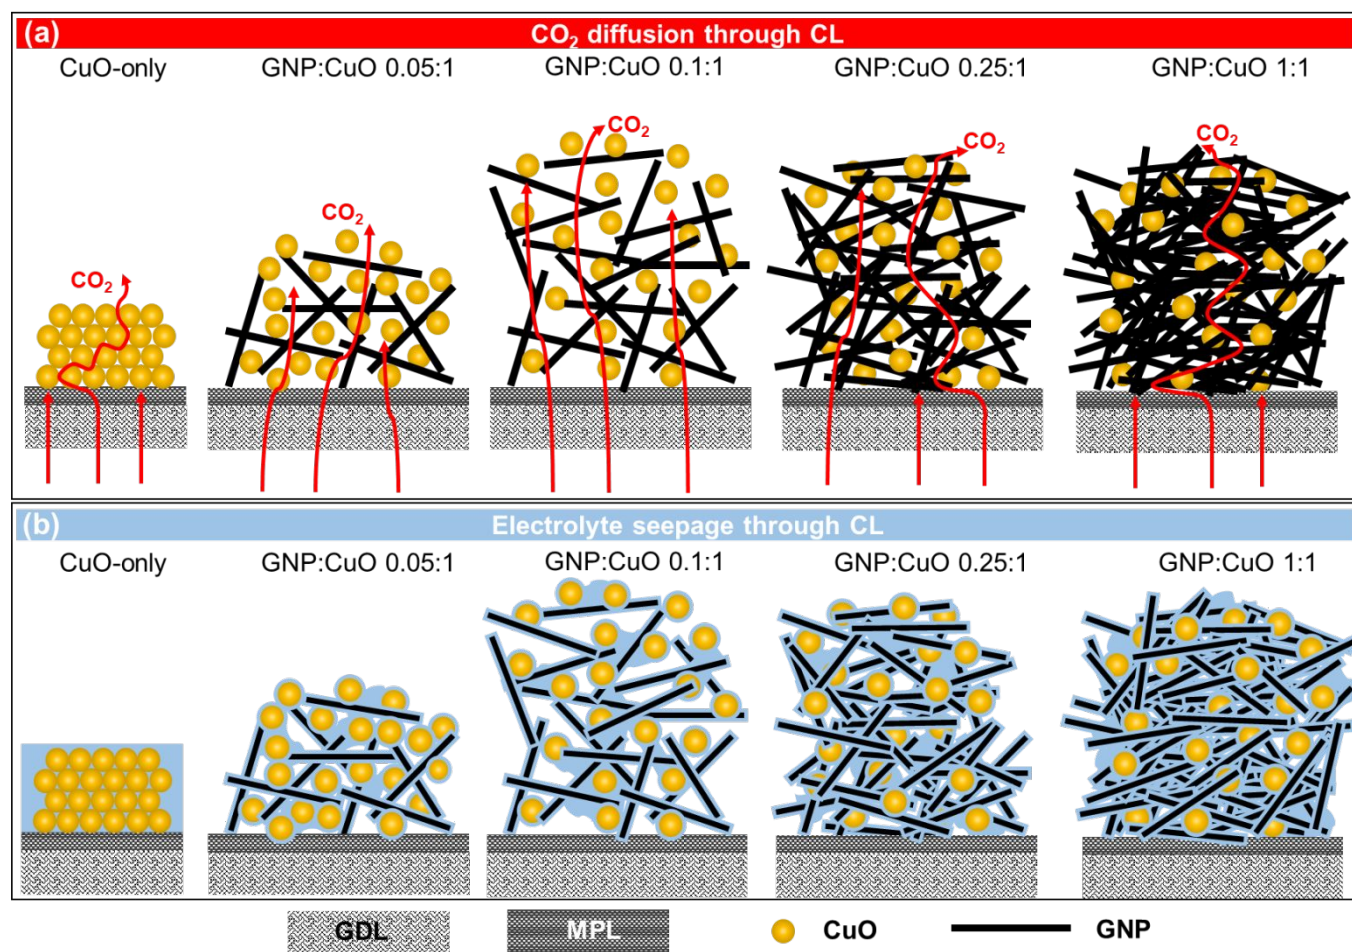

Figure 5. Schematic (not drawn to scale) of the CL cross-section for the CuO-only GDE and GNP–CuO GDEs at various GNP-to-CuO mass ratios, based on a constant CuO catalyst loading across all samples; the differences in the CL thickness reflect observations from SEM cross-sectional imaging. (b) Depiction of wetting behaviour within the CLs, highlighting the free volume available to accommodate electrolyte seepage.

ARTICLE

Resistance to flooding can be further enhanced via the microstructuring of the CL architecture, by tuning the pore properties to facilitate CO₂ transport and accommodate liquid seepage. For a dense and thin CL composed of only CuO (0.2 mg cm⁻²), the CL is likely to become fully flooded when electrowetting occurs, as the capillary force draws liquid into the small pores. Provided that CO₂ access to catalytic sites remains sufficient, increasing the catalyst loading (CuO-only, 0.34 mg cm⁻²) can act as a physical barrier to flooding since the additional material may reduce the pore connectivity and increase the total pore volume, slowing down electrolyte intrusion. However, for excessively high catalyst loadings (CuO-only, 1.3 mg cm⁻²), an extensively thick barrier results in a reduced buffering capacity³⁶, which leads to the accumulation of OH⁻ ions at the gas–liquid interface (now located closer to the MPL) and severe flooding. Furthermore, while reduced pore connectivity hinders liquid intrusion, it also limits CO₂ access, as reflected by the increased FE for H₂. The incorporation of an inert, 2D phase at an appropriate mass ratio can modify the pore connectivity and pore volume of the CL, thereby altering the tortuosity and liquid distribution within the CL, as illustrated in Figure 5. Upon the addition of 5 wt% GNP (GNP:CuO mass ratio = 0.05:1), the CL thickness doubles, while the time required to reach a saturated CO₂ concentration is reduced by half. This suggests that the addition of GNP modifies the pore structure of the CL, likely reducing tortuosity and allowing CO₂ to diffuse more rapidly through a thicker CL. These results support the formation of a house-of-cards architecture introduced by the GNP, which improves the pore connectivity and increases the pore volume. Upon increasing the GNP content to 9 wt% (GNP:CuO ratio = 0.1:1), the time required for CO₂ to diffuse through the entire GDE increases, most likely due to the longer diffusion path associated with the thicker CL. We concluded that the house-of-cards structure is preserved at these two GNP percentages, as the CL thickness increases with the GNP:CuO ratio. With a thicker CL maintaining this

architecture, the CO₂ diffusion time becomes longer because of the increased travel distance, though an increased void volume is available to accommodate electrolyte seepage. The GNP:CuO mass ratio of 0.1:1 represents an optimal balance between CO₂ diffusion and liquid intrusion, enabling a maximal GDE lifetime. Further increases in the GNP content (GNP:CuO ratios of 0.25:1 and 1:1) lead to longer diffusion times, even though the CL thickness remains unchanged. This suggests an increase in tortuosity, forcing CO₂ to travel across a more convoluted path within the CL. The addition of material with no accompanying increase in the CL thickness indicates the densification of the CL. Specifically, excessive GNP partially disrupts the anisotropic arrangement as in the house-of-cards structure, resulting in a more isotropic, in-plane ordering. This arrangement increases the CL tortuosity and may block pores, hindering CO₂ access. Moreover, densification reduces the volume of void space available to accommodate electrolyte seepage, which explains the observation of a reduced GDE lifetime at GNP contents above 9 wt%.

Methods

Synthesis of CuO catalysts & preparation of GDEs

The Cu-based catalysts were synthesised using a similar protocol as previously reported¹⁹. Briefly, 1.3 g of Cu(NO₃)₂·3H₂O (Sigma-Aldrich) was dissolved in 100 mL of Milli-Q water, after which 30 mL of 0.15 M NH₄OH prepared from ammonium hydroxide (28% NH₃, Alfa Aesar), was added. Subsequently, 10 mL of 1.0 M NaOH (Reactolab SA) was introduced dropwise at 2 mL min⁻¹ under continuous magnetic stirring to induce Cu(OH)₂ precipitation. The mixture was stirred for 30 min, and the resulting precipitate was collected by centrifugation, filtered, and washed sequentially with deionised water and ethanol. The washed solid was freeze-dried for 72 h and calcined in air at 300 °C for 1 h to obtain CuO catalysts.

Catalyst inks were prepared by dispersing 4 mg of the as-synthesised CuO (for CuO-only inks) or 4 mg of the CuO/GNP composite powder in 1 mL isopropanol. To this dispersion, 16 μL of a 5 wt% PTFE suspension (diluted from a 65 wt% stock (Fuel Cell Store)) was introduced. The ink was spray-coated onto as-received gas diffusion electrodes (YLS-30T, Suzhou Sinero Technology Co.) to reach theoretical CuO loading of 4 mg per 10 cm^2 . After solvent evaporation, the coated GDEs were calcined in air at $300\text{ }^\circ\text{C}$ for 30 min to melt the PTFE and achieve a uniform, conformal coating over the catalyst layer.

Electrochemical characterizations & products quantification

Electrochemical tests were conducted using a potentiostat (Metrohm Autolab PGSTAT302N). Gaseous products were quantified in real time via an online gas chromatograph (SRI Instruments 8610C) equipped with both a thermal conductivity detector and a flame ionisation detector. Upon completion of chronopotentiostatic runs, the electrolyte was collected for analysis of liquid products by 1H nuclear magnetic resonance (1H NMR; Bruker 400 MHz AVIII HD) spectroscopy.

Electrolysis was performed in a single-pass flow cell setup identical to that described in previous work (ref xx), featuring a cation-exchange membrane (Nafion 115, Ion Power) separating cathode and anode compartments. The electrode area exposed to electrolyte was 0.5 cm^2 . A leakless Ag/AgCl reference electrode (Metrohm) and a platinum plate counter electrode were used. The catholyte consisted of 3 M KCl (Sigma-Aldrich), with pH adjusted to 2 via addition of 3 M H_3PO_4 (diluted from 85%, Sigma-Aldrich). The anolyte was a 3 M KHCO_3 solution (Thermo Scientific).

Material characterizations

Scanning electron microscopy (SEM) and energy-dispersive X-ray (EDX) elemental mapping were performed on a FE-SEM (ThermoFisher Teneo). Bright-field and high-resolution transmission electron microscopy (HR-TEM) images were acquired on a ThermoFisher Tecnai Osiris operated at 200 kV. Elemental compositions were quantified by inductively coupled plasma-optical emission spectrometry (ICP-OES; Agilent 5110). Operando Raman spectroscopy was conducted in a custom semi-flow cell under continuous CO_2 gas flow. The catholyte

comprised 3 M KCl, acidified to pH 2 with 3 M H_3PO_4 , while the anolyte consisted of 3 M KHCO_3 . Both electrolytes remained static during measurement. A Leica $63\times$ immersion objective was used for signal collection, with excitation from a 632 nm laser. Water contact angles were measured using a Krüss EasyDrop Drop Shape Analyser. CO_2 permeation measurements were performed using a dissolved- CO_2 probe (BGT Technology, Beijing).

Conclusion

In summary, this study confirmed the formation of C_{2+} products in the CO_2RR under acidic conditions, driven by a high local alkalinity at the catalyst surface. However, this also induced the flooding of the GDE, despite the acidic bulk electrolyte. Introducing a loosely packed CL with a high void fraction and partial wettability, termed the “house-of-cards” structure, showed promise in mitigating flooding. This structure was obtained by incorporating GNPs – a 2D, nonreactive material – into the catalyst ink, followed by spray-coating onto the GDE. For a GNP content below 9 wt%, a house-of-cards structure was successfully formed, as evidenced by an increased CL thickness and a reduced CO_2 diffusion time through the layer. At a GNP mass fraction of 9% (GNP:CuO mass ratio = 0.1:1), the GDE lifetime reached 10 hours at a current density of 600 mA cm^{-2} , attributed to an optimal CL structure that balanced CO_2 transport with the void volume to accommodate electrolyte seepage. Higher GNP fractions induced CL densification, reducing the void volume and CO_2 diffusion and shortening the GDE lifetime. This microstructural design of the CL complements ongoing research efforts on the microporous and gas diffusion layers, offering a viable approach to enhancing the flooding resistance of GDEs.
