Accepted Manuscript

This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

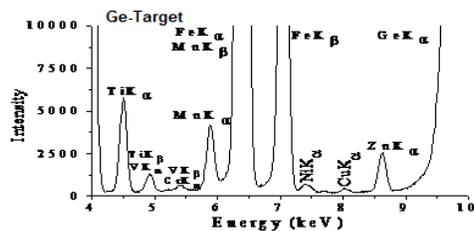

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this *Accepted Manuscript* with the edited and formatted *Advance Article* as soon as it is available.

You can find more information about *Accepted Manuscripts* in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

Novelty of the work: The use of these techniques can improve the development of ED-XRF results evaluation procedures that really is in a new phase.

Abstract

In this study, the X-ray intensities obtained from 76 soil samples were converted to concentration by means of the Epsilon software program applying the fundamental parameters method (FP). Various National Institute of Standards and Technology (NIST) standard reference materials (SRMs) were used to evaluate the accuracy of the analysis. The discussion was restricted to the analysis of only ten elements. The results have indicated that the soil samples contain V(10-93), Mn(313-7227), Co(3-18), Ni(47-281), Cu(1-32), Zn(20-86), As(30-236), Sr(131-592), Ba(78-7329), Rb(25-149) and Pb(17-67) between minimum and maximum values in a range of mg/kg. Partial Least Squares (PLS) and Principle Component Regression (PCR) models were used to predict the elemental concentrations. Cross-validation (CV) was used to calculate the Estimated Mean Square Predictive Error (*EMSPE*) values and to determine the optimal number of PLS and PCR components. Predicted concentrations were based on *EMSPE* values, utilizing 1 PLS and PCR components for V, Co, Cu, Zn, 3 PLS and PCR components for Mn, Ni, Pb, 5 PLS and 8 PCR components for As and Ba, 7 PLS and 10 PCR components for Rb and 3 PLS and 4 PCR components for Sr with minimum *EMSPE* values. It was observed that prediction errors and increasing factor numbers were depend on the reference material concentration intervals as much as the number of SRM's. On the other hand, when PLS and PCR models were compared among themselves, it was seen that PLS model had a strong relation with FP method as compared to PCR model with less prediction errors and component numbers.

Key Words: *ED-XRF; fundamental parameters method; multivariate calibration procedures; partial least square regression; principle component regression; method validation; trace element.*

53 Introduction

54 During the last decade, energy-dispersive X-ray fluorescence (ED-XRF) spectrometry has
55 been experiencing a revival. Improvements in electronics, detector and X-ray tube technology
56 combined with an ever increasing computer power has led to various new versatile, compact
57 and reasonably cheap ED-XRF instruments. The nature of applications requires a fast
58 processing of the gathered data. As such, a direct conversion of the obtained spectra into
59 constituent concentrations without user interaction would be an ideal situation. However, the
60 current data processing methods only partially fulfill this goal. The main drawbacks of ED-
61 XRF are the spectral interference of element characteristic lines due to the limited resolution
62 of the solid-state detector and the presence of matrix effects that make a straightforward
63 conversion of peak intensities into element concentrations difficult.¹

64 The fundamental parameters method is based on mathematical expressions first
65 derived by Sherman and by Shiraiwa and Fujino.^{2,3} The application of the fundamental
66 parameters method requires certain conditions to be satisfied, e.g. homogeneous and flat
67 samples. However, the major drawback is that the complete procedure and in particular the
68 spectrum processing remains difficult to automate. The fundamental parameters method is
69 especially interesting because it allows the semi-quantitative analysis of completely unknown
70 samples. Unfortunately, the approach suffers from uncertainties in mass absorption
71 coefficients and fluorescence yields of the individual elements. The implementation of expert
72 systems to enable automation has been considered.⁴

73 Apart from fundamental parameters method a large variety of multivariate methods
74 are used in combination with XRF results. Orthogonal multivariate regression models are
75 those most employed for quantitative analysis, as well as principle components regression
76 (PCR) and partial least square regression (PLS).⁵ PLS combines spectral and analytical
77 information of a number of samples to build predictive models by establishing a direct
78 correlation between spectra of samples and properties of interest (generally concentration

1
2
3 79 values) of the species contained in them. All these implementations have opened the
4
5
6 80 possibility of usage of XRF as a rapid and low cost technique to obtain basic information of
7
8 81 total concentration of metals in the assessment of potentially polluted soils and sediments.⁶
9
10 82 Compared with the classical method, PLS and PCR embody both the spectrum evaluation and
11
12 83 the quantitative analysis. The analysis merely consists of a multiplication of matrices and does
13
14
15 84 not require much computer power and time. PLS and PCR methods end by pointing out the
16
17 85 major drawback when applied to XRF, i.e. the need for a large number of calibration samples.
18
19 86 A good agreement between calculated and experimental results is critical for a successful
20
21
22 87 implementation of the PLS and PCR methods.¹
23

24
25 88 PCR method has a significant drawback with respect to ED-XRF. The PCR is the
26
27 89 standard formulation for which the PCs defining score matrix are in accordance with the size
28
29 90 of their corresponding eigen values alone and not on their predictive value. This procedure
30
31 91 neglects low variance components that may have predictive value. The PCs solely describe
32
33 92 the largest variance components of the spectral data, X , and it is not necessarily true that this
34
35 93 is the most informative variance to model the concentration data, y . This is particularly the
36
37 94 case for ED-XRF. Suppose PCR is used for the quantitative analysis of Pb in soil samples. It
38
39 95 is obvious that the Pb signals are only responsible for a small part of the total variation in the
40
41 96 ED-XRF spectra. Other elements such as Si, Fe, Ca and K contribute much more to the total
42
43 97 variation in X and though it is captured by the first PCs, it is of secondary importance to
44
45 98 describe the Pb concentration. Yet, PCR will primarily use the first PCs to model the Pb
46
47 99 concentration. Therefore, several authors suggest retaining, in the final PCR model, only
48
49 100 those PCs that show a good correlation with the y -variable.^{7,8,9} Another solution is to derive
50
51 101 the eigenvectors in such a way that the more predictive information is placed in the first PCs.
52

53
54
55 102 In 1995 only two publications on the use of PLS for XRF analysis were reported.
56
57
58 103 Wang et al.¹⁰ applied the PLS method for the analysis of Nickel alloy samples employing
59
60

1
2
3 104 WD-XRF. The first application of PLS to ED-XRF was reported by Swerts et al.¹¹ who used
4
5 105 the combined method for the analysis of Sulfur-Graphite mixtures. After 1995, Urbanski and
6
7
8 106 Kowalska applied the PLS method to various low-resolution ED-XRF analyses.¹²
9

10
11 This study aims to provide an alternative validation method for the quantitative
12
13 108 analysis of ED-XRF results. The first part of this work focuses on the fundamental parameters
14
15 109 calibration procedure to calculate the concentrations of heavy metals in soil samples and then
16
17 110 principles of PLS and PCR and their tailoring for ED-XRF results will be discussed, followed
18
19
20 111 by application of the methods.
21

22 112

23 24 113 **PCR and PLS regression models**

25 26 27 114 **1. Methodology**

28
29 115 The matrix \mathbf{X} is used exclusively to contain the ED-XRF intensity data. For example \mathbf{X} ($n \times$
30
31 116 p) is a matrix containing n samples each of which consist of p elements. Usually, n is the
32
33 117 number of objects or samples for which the spectrum is recorded. Likewise, \mathbf{Y} is used
34
35 118 exclusively to contain the element concentrations. \mathbf{Y} ($n \times m$) is a matrix containing the
36
37 119 concentrations for each m element in n samples.
38
39

40
41 120 The idea in principle component analysis (PCA) is to construct successive linear
42
43 121 combinations so that each one accounts for as much of the total variation as possible subject
44
45 122 to the constraint that it is orthogonal to the linear combinations already extracted.¹³ After PCA
46
47 123 is carried out, the original data contained in \mathbf{X} and described by p variables is represented by
48
49 124 score matrix, if one is satisfied with the rank m approximation. By doing so, the number of
50
51 125 variables is also reduced from p to m without a significant loss of information. The PCR
52
53 126 method uses the linear combinations or PCs (Principle Components) of \mathbf{X} , derived using
54
55 127 PCA, to model the relationship between \mathbf{X} and p . The derivation of the PCs is independent on
56
57 128 p and therefore different y -variables are all modeled by means of the same subset of PCs. In
58
59
60

1
2
3 129 an improved approach, only those PCs are used that show a good correlation with the p -
4
5 130 variable of interest but often, and especially in ED-XRF, this is not sufficient. In contrast to
6
7
8 131 PCR, the subspace retained in PLS is constructed with reference to the vector of observations.
9
10 132 Moreover, the PLS method is not restricted to one variable and several dependent variables
11
12
13 133 can be modeled simultaneously.

14 134

17 135 2. Validating the regression models

19
20 136 Validating the models essentially concerns the selection of the optimal number of PLS and
21
22 137 PCR components. In addition, the validation method provides a value for the prediction error
23
24 138 enabling the assessment of the predictive capacity of the model. The determination of the
25
26
27 139 optimum number of PLS and PCR components is mainly done by calculation of the Estimated
28
29 140 Mean Square Predictive Error (*EMSPE*) with cross-validation (CV)¹⁴;

30 141

$$32 \quad EMSPE = \sqrt{\frac{\sum_{i=1}^n \left(y_i - \hat{y}_i \right)^2}{n}} \quad (1)$$

33 144

34
35
36
37
38
39 145 in which n denotes the number of observations, y is the given (or ‘true’) value of the analyte
40
41 146 of interest and \hat{y} is the value predicted by the PLS and PCR model. Given a certain data set,
42
43 147 the *EMSPE* values are calculated for different numbers of components included in the PLS
44
45
46 148 and PCR model. Normally the *EMSPE* reduces with increasing number of PLS components
47
48
49 149 until a minimum or constant value is reached and the corresponding number of components is
50
51 150 regarded as optimal. The predicted error is composed of two contributions, the remaining
52
53
54 151 interference error and the estimation error. The former is the systematic error due to
55
56
57 152 unmodeled interference in the spectral data and the latter is caused by random measurement
58
59
60 153 noise of various kinds or of systematic error not relevant for the modeled analyte y . The

1
2
3 154 interference error decreases with an increased modeling of the systematic variance by
4
5 155 including more PLS or PCR components. However, at the same time the statistical uncertainty
6
7
8 156 error increases. Including too few PLS or PCR components results in under fitting and one
9
10 157 risks that important phenomena are not modeled. Including too many components results in
11
12
13 158 over fitting and this is equivalent to the modeling of noise.

14
15
16 159

17 160 **Materials and methods**

18 19 20 161 **1. Sample preparation and analytical method**

21
22 162 The powder certified reference materials with 0.63 μm particle diameters were pressed into
23
24 163 thin pellets of 40 mm diameter. It was required a substrate material, thus 0.46 g of wax (high
25
26 164 purity cellulose binder with 20 μm particle diameters) was pressed with a compression of 5
27
28 165 kN and then the mixture (0.48g of specimen and 0.09g of wax) was pressed together with
29
30 166 substrate material with a compression of 10 kN. Samples for EDXRF analysis are usually
31
32 167 prepared as powder pellets with the use of a binder.

33
34 168 The measurement parameters were set up using the Epsilon 5 EDXRF (PANalytical, Almelo,
35
36 169 the Netherlands) system's in-built software. Samples were irradiated by X-rays **from** a Gd
37
38 170 tube under vacuum, equipped with a liquid nitrogen cooled PAN-32 Ge X-ray detector having
39
40 171 a Be window thickness of 8 μm . The maximum power, typical current and voltage of the
41
42 172 instrument were 600 W, 24 mA and 100 kV, respectively. The instrument has a 3D
43
44 173 (Cartesian) optical geometry in which the primary beam from the X-ray tube first irradiates a
45
46 174 polarizing target before striking the sample placed at 90°. The sample spectrum is recorded by
47
48 175 a detector placed at 90° to the sample in a third plane, thus eliminating the effect of scattered
49
50 176 X-ray tube radiation by polarization and considerably reducing spectral background level.¹⁵
51
52
53 177 The schematic set-up is as given in Figure 1. This method is a nondestructive which requires
54
55
56 178 little sample preparation and gives reliable results within almost analysis time. The Epsilon 5
57
58
59
60

1
2
3 179 EDXRF spectrometer has been used significantly for the analyses of macro, micro and trace
4
5 180 elements in environmental samples such as soil, rock, coal, oil, plastics, moss and sediment.¹⁶
6
7
8 181 The detection limits of several kinds of XRF apparatus are not good enough for trace
9
10 182 elements, but the environmental concentrations of trace elements are much higher than the
11
12 183 trace values. Spectral interferences between peaks can affect detection limits and accuracy for
13
14
15 184 XRF analysis.

16
17
18 **FIGURE-1**
19

20 186
21
22 187 The system's software (Epsilon 5 software) automatically analyzed the sample
23
24 188 spectrum and determined the net intensities of element peaks as soon as the measurement was
25
26 189 completed. When elements overlap one another, accuracy is essential for the trace element
27
28 190 analysis. Representative spectra are illustrated in Figure 2.

29 191
30
31 192 **FIGURE-2**
32

33 193
34 194 Lower Limits of Dedection (LLDs) were calculated using 3 times the square root of
35
36 195 the background (count rates obtained by deconvolution) as shown in the following equation:
37

38 196
39
40 197
41
42 198
$$\frac{N_p}{\sqrt{N_b}} \geq 3 \quad (2)$$

43

2. System calibration using FP method

Pellets (solid) of 40 mm diameter with 1.2g Standard Reference Materials (SRM) with different elemental contents (for geological materials) were measured to calibrate the spectrometer. The SRMs and their elemental context are shown in Table 3. Determination of the concentrations of the other elements, coefficients (intercept and slope) was calculated by using regression statistic based on concentration and intensity values for each element. Linear calibration curves for all elements were accomplished. After determination of coefficients, concentrations of unknown elements in the samples could be calculated using linear equation related to their intensity values. Regression equation was given as below;

$$y = D(\text{slope})x + E(\text{intercept}) \quad (3)$$

where y and x represent from concentration of element and intensity of analysts line, respectively. Calibration parameters such as intercept, slope, R^2 , estimated standard uncertainties of the method, and 95% confidence levels for coefficients were calculated using regression statistics as given in our previous paper by Cevik et al.¹

TABLE-3

3. Computation procedure

All calculations were performed using Matlab R2011b [The Math Works Inc, Natick, USA and the Chemometrics Toolbox (Eigenvector Research, USA)]. This application is first to test the suitability of the PLS and PCR methods for quantitative ED-XRF analysis using fundamental parameters method validation. This particular example concerns the analysis of 76 soil samples. The results of the analysis were used to evaluate the calibration procedure. For this purpose, PLS and PCR calibration procedures by using the concentration and

1
2
3 235 intensity values were performed. In order to symbolize of the sample matrix, an independent
4
5 236 variable matrix $\mathbf{X}(76 \times 38)$ was built using dominant intensity values of 38 elements (Al, Si, S,
6
7
8 237 Cl, K, Ca, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Ga, As, Br, Rb, Sr, Y, Zr, Nb, In, Sn, Sb, Cs,
9
10 238 Ba, La, Ce, Pr, Nd, Sn, Yb, Hf, Ta, W ve Pb) in the soil matrix. On the other hand, dependent
11
12 239 variable matrix $\mathbf{Y}(76 \times 1)$ was created with $n=76$ and $m=1$ values (n is the number of samples,
13
14
15 240 m is represent from concentrations for each m element in n samples). The results predicted by
16
17 241 PLS and PCR model were then used for the comparison of the measured ED-XRF results.
18
19 242 Since this application was primarily used to verify of classical quantitative fundamental
20
21 243 parameters method using multivariate PLS and PCR calibration procedures, the discussion
22
23
24 244 was restricted to the analysis of only V, Mn, Co, Ni, Cu, Zn, As, Sr, Ba, Rb and Pb.
25
26
27 245

28 29 246 **Results and discussion**

30
31 247 When the optimum component number is identified, the PLS and PCR models are used to
32
33 248 determine (predict) the concentration of the elements. This prediction is also performed for an
34
35 249 increasing number of PLS and PCR components included in the model and the Estimated
36
37 250 Mean Square Predictive Error (*EMSPE*) is calculated and plotted together with the validation
38
39 251 curves. The true predicted error can be calculated and compared with the predicted error
40
41 252 ascertained via the validation techniques. *EMSPE* curves are observed starting at 1 PLS and
42
43 253 PCR components. The *EMSPE* curve has a minimum at 1 or 3 PLS and PCR components
44
45 254 while the *EMSPE* curve keeps going down even further until 5 or 8 PLS and PCR
46
47 255 components. Based on this observation, a model including 1 or 3 PLS components; is
48
49 256 probably the most parsimonious choice. As seen from the plot, it is clear that *EMSPE* curve
50
51 257 gives too optimistic predicted errors for all numbers of PLS and PCR components for 76 soil
52
53 258 samples. The *EMSPE* curves with PLS and PCR components were given for V, Mn, As, Sr,
54
55 259 Ba and Pb in Figure 3.

FIGURE-3

As concentration values were calculated depending on the SRMs and according to FP model of examples, PLS and PCR models have been limited at the certain intervals because they depend on the high correlation set among the different concentrations. In Figure 4, graph showing each element stating the number of components and the concentration results that plotted with FP models are shown.

FIGURE-4

According to results, for the elements (except As Rb, Ba and Sr) concentration predictions were done with PLS and PCR models using only either 1 or 3 components. In an application that was used the results of 76 samples, 1 and 3 components numbers were marvelous. PLS and PCR models for V, Co, Cu and Zn could predict a strong correlation with only one component. As it is stated above, SRMs number used in the application of calibration and reference intervals had an important role among the parameters that was applied in algorithm. The number of reference materials used for V, Co and Zn were 17, 12, and 19, respectively. The number of reference materials used for these elements were appropriate for getting a calibration curve and it could be concluded that the reason why prediction errors were a little bit high as compared to others could be attributed to the concentration intervals of SRM. As it is seen in R^2 values, PLS model has shown a more strong correlation than PCR model among most of the elements (R^2 values are given on Table 4).

TABLE-4

1
2
3 284 For Ni and Pb, PLS and PCR models have proved the coherence with a low predicted
4
5 285 error using 3 components. The numbers of SRMs for both elements were 17. As many
6
7
8 286 number of reference materials will keep the limited concentration interval wide, models
9
10 287 predicted low error with a few component. On the other hand, according to application of Mn
11
12 288 with 3 components, it was predicted the concentration with a 100 % coherence for each of the
13
14
15 289 models without any error. The numbers of reference materials used in calibration were 18 and
16
17 290 it showed that SRMs have the same characteristics in which 100 % coherence was used.

18
19
20 291 While PLS regression for Sr was applied with 3 and 4 components, PCR regression
21
22 292 was used with 4 components. PLS regression was showed to be a meaningful correlation with
23
24 293 3 components. On the other hand, PLS regression with 4 components showed a stronger
25
26 294 correlation than PCR model using 4 components. During the calibration process, although the
27
28 295 numbers of reference materials were 7, these correlations were quite strong. This situation
29
30 296 showed that reference material compositions were rather different.

31
32
33
34 297 New concentration values were predicted using 7 components in PLS regression for
35
36 298 Rb and 10 components in PCR regression. Because the sample numbers used for 7 and 10 are
37
38 299 high, component numbers are acceptable. Uncertainties were decreased with increasing
39
40 300 components numbers. If we consider the best of components numbers and low error, it could
41
42 301 also be attributed to the SRM numbers and concentration intervals used during the process of
43
44 302 calibration.

45
46
47
48 303 For Ba, 9 SRMs were used during the calibration process and PLS with 5 components
49
50 304 and PCR with 8 components were done with a little predicted error. PLS regression was tested
51
52 305 with 5 and 6 components and 6 components showed less error in correlation. However; as 5
53
54 306 components clarified the issue sufficiently, components with 6 factors were not showed in the
55
56 307 graphics.

1
2
3 308 PLS and PCR models were applied using 5 and 8 components for As, respectively. As
4
5 309 SRMs and concentration intervals used in EDXRF calibration gave rise to a set of limitations
6
7
8 310 and if lots of reference materials was used, reliable concentration intervals would increase on
9
10 311 calibration. Reference materials concentration intervals were important as much as the
11
12 312 number of reference material. For this reason, the calibration that was set carefully with same
13
14
15 313 characteristic SRMs give result in less error.
16

17 314

19 315 **Conclusion**

20
21
22 316 The most general evaluation that was gotten from the application; PLS and PCR models that
23
24 317 were developed over the results of calibrated ED-XRF spectrometer used classical
25
26 318 quantitative fundamental parameters method (FP). The method has successfully proved for
27
28 319 many trace elements of interest. As it was seen from the results, decreasing number of
29
30 320 reference materials has increased the most appropriate component numbers including the
31
32 321 information belongs to samples (As, Rb, Sr and Ba). It was observed that prediction errors
33
34 322 and increasing factor numbers were depend on the reference material concentration intervals
35
36 323 as much as the number of SRM's. In this way, correctness of elemental analysis results that
37
38 324 was carried out for ST-EDXRF spectrometer was validated by means of setting of PCR and
39
40 325 PLS regression models simulation. On the other hand, when PLS and PCR models were
41
42 326 compared among themselves, it was seen that PLS model had a strong relation with FP
43
44 327 method as compared to PCR model with less prediction errors and component numbers.
45
46
47
48
