A one-step and template-free method to prepare uniform SnO₂ nanospheres with a mesoporous structure was developed for the applications in phosphopeptide enrichment. The as-synthesized mesoporous SnO₂ nanospheres have large surface area and highly active surfaces for the effective binding of phosphopeptides. Compared with the non-porous SnO₂ and commercial TiO₂, mesoporous SnO₂ nanospheres represent superior performance in the specific trapping of phosphopeptides from both standard protein and complex nonfat milk digests for mass spectrometry-based phosphoproteomic analysis. The feasible synthetic approach and the excellent enrichment performance make the mesoporous SnO₂ nanospheres promising in further phosphoproteomic research.

As one of the most common post-translational modifications, protein phosphorylation is of great importance in regulating various biological processes,¹ and powerful sample preparation methods for in-depth exploration of phosphorylation-related biological processes have long been in urgent demand.² Among those methods metal oxide affinity chromatography (MOAC) takes the advantages of the excellent selectivity of various metal oxides, which brings rapid increasing of its applications.³ The basic mechanism of MOAC is

based on the affinity between the phosphate group and metal oxides acting as Lewis acid under acidic conditions. The surface properties of different metal oxide nanomaterials affect their affinity towards phosphopeptides, which often leads to different enrichment performance⁴ in sensitivity,⁵ specificity⁶⁻⁹ or phosphoproteome coverage¹⁰⁻¹². Therefore, both the component and structure of nanomaterials are crucial in designing effective affinity probes.

Due to their large surface area with high surface activity and ready modification, mesoporous nanomaterials are considered promising in various fields¹³⁻¹⁶ and have already attracted increasing attention for the development of effective sample preparation method.^{14, 15-19} With relatively higher Lewis acidity, SnO₂ is considered as an ideal complement for the existing affinity probes and several SnO₂-based nanomaterials were prepared for the improvement of phosphoproteomic analysis.^{4, 5, 20, 21} Reports of other metal oxides demonstrated that mesoporous structures have great potential for efficient phosphopeptide enrichment.^{10, 11, 17} Therefore, mesoporous SnO₂ nanospheres for biological application and their detailed performance are well worth being investigated. Several literatures reported the synthesis of mesoporous SnO₂ spheres as well as their applications in gas sensing, lithium-ion batteries, and photocatalysis.²²⁻²⁷ However, the synthesis was mostly carried out with the assistance of organic additives or templates,^{22, 23, 26-29} which may result in complex steps in synthesis or uncontrollable interferences in phosphopeptide binding and thus limits their applications on practical uses. On the other hand, mesoporous SnO₂ nanospheres with sizes less than 100 nm have been prepared without organic additives, but their surface areas were generally not very high and the application of mesoporous SnO₂ nanospheres in MOAC materials has not been well explored so far.^{24, 25, 30} Hence, it is well worth paying more efforts to develop template-free and simple synthetic methods to gain mesoporous SnO₂ nanospheres with high surface areas and ideal surface properties for large-scale phosphoproteomic analysis.

Herein we reported the facile synthesis of nearly monodisperse mesoporous SnO₂ nanospheres via a one-step, template-free solvothermal method for efficient phosphopeptide enrichment. First, owing to the mesoporous structure, these uniform SnO₂ nanospheres have a large surface area of 109.9 m²/g, which brings more active sites exposed for the effective binding of phosphopeptides. Second, the absence of organic additives, like surfactants, reduces

uncontrollable interferences, which makes the mesopores accessible during the binding step of the phosphopeptide enrichment. Third, the simplicity of this synthesis makes it feasible for biological applications and potential for the nanomaterials commercialization. In the subsequent MS-based phosphoproteomics analysis, excellent performance in both sensitivity and real sample analysis are showed by using these mesoporous SnO₂ nanospheres, indicating their promising potential in phosphoproteomic research.

Mesoporous SnO₂ nanospheres were synthesized by a facile solvothermal treatment of the solution consisting of ethanol, hydrochloride acid and SnCl₄·5H₂O. Figure 1a shows a low-magnification SEM image of the obtained nanospheres after solvothermal reaction at 150 °C for 24 h, which suggests the large-scale formation of nearly monodisperse nanospheres with an average diameter of ~70 nm. The high-magnification SEM image shows that all the nanospheres have a rough surface, indicating that each nanosphere consists of primary nanoparticles (Figure 1b). The TEM image shown in Figure 1c reveals the mesoporous structure of a typical nanosphere consisting of nanoparticles about 5 nm in size. The related selected-area electron diffraction (SAED) pattern shows clearly rings characteristic of rutile SnO₂. The HRTEM image shown in Figure 1d exhibits clear lattice fringes with *d* spacings of 0.34 nm and 0.26 nm, which can be indexed to the (110) and (101) plane of rutile SnO₂, respectively. The X-ray diffraction (XRD) pattern shown in Figure 1e reveals that all the diffraction peaks can be ascribed to SnO₂ crystals with a tetragonal rutile phase (JCPDS No. 41-1445), which is consistent with the SAED result. Detailed analysis of the peak broadening of the (101) reflection using the Scherrer equation indicates an average crystalline size of 5.3 nm, which is in agreement with the TEM result. The N₂ adsorption-desorption isotherm shows a type-IV isotherm with a hysteresis loop in the relative pressure range (*P/P*₀) of 0.8–1.0 (Figure 1f), which

suggests a mesoporous structure. An average pore size around 12 nm was calculated from the desorption branch of the nitrogen sorption isotherm using the BJH (Barrett-Joyner-Halenda) model. The mesoporous SnO₂ nanospheres have a BET (Brunauer-Emmett-Teller) surface area of 109.9 m²/g, which is very high for SnO₂ considering its high density (6.95 g/cm³). This surface area is considerably higher than those of the reported mesoporous SnO₂ nanospheres with similar sizes synthesized without organic additives.^{24, 25, 30}

It was found that hydrochloride acid has binary effects on controlling the hydrolysis process in this ethanol solvent system. A synthesis system comprising 50 μL of concentrated aqueous HCl in 8 mL ethanol is adopted after optimization. Firstly, hydrochloride acid afforded water for the hydrolysis of SnCl₄. When no hydrochloride acid was added, the hydrolysis process of Sn⁴⁺ was greatly inhibited, resulting in a very low output of smaller porous nanospheres (Figure 2a). The hydrolysis process could still happen without hydrochloride acid due to the small amount of water in SnCl₄·5H₂O and ethanol. Secondly, hydrochloride acid acted as a proton donor to control the hydrolysis rate of Sn⁴⁺. Figure 2b shows the products obtained with addition of 50 μL water instead of HCl solution. The yield of products was increased, but the uneven size of products reveals that the hydrolysis rate was not well controlled without the acidity of HCl. If the amount of concentrated hydrochloride acid was increased from 50 μL to 200 μL, the hydrolysis rate was too fast, and irregular aggregates of small nanoparticles were obtained (Figure 2c), indicating that an appropriate amount of hydrochloride acid is the key to keep a moderate hydrolysis rate.

This mesoporous SnO₂ synthetic method has several advantages for their applications in phosphopeptide enrichment: (1) By this facile route, uniform mesoporous SnO₂ nanospheres can be achieved without templates or organic additives, which eliminates interferences and makes the active surface of the material fully accessible to the peptides; (2) With the mesoporous structure and relatively high density, the mesoporous SnO₂ nanospheres provide highly active binding surface as well as the convenient downstream separation by using usual centrifuge; (3) This facile synthesis approach is cost efficient, environmentally friendly, and easy to be scaled up for widespread applications in phosphoproteomic analysis.

As illustrated in Figure 3a, phosphopeptide enrichment from the tryptic protein digests was performed in a batch mode using the as-synthesized mesoporous SnO₂ (mSnO₂) nanospheres as the affinity probe. MALDI-ToF mass spectra show the tryptic digested β-casein (4×10⁻⁷ M) before and after enrichment by mesoporous SnO₂. Three phosphopeptides were detected with the highest signal to noise ratio (S/N) of 4821 in the digests of β-casein (4×10⁻⁷ M) with enrichment by using mesoporous SnO₂ (Figure 3c), which demonstrated the strong affinity of mesoporous SnO₂ towards phosphopeptides. Under the same conditions, both SnO₂ nanoparticles with a smaller surface area of 39.9 m²/g (shown in Figures S1 and S2) and commercial

TiO_2 showed similar results (Figure S3). However, mesoporous SnO_2 revealed much better enrichment efficiency when the concentration of β -casein was lowered to 4×10^{-10} M (Figure 4). Under such low concentration, only one phosphopeptide was detected after enrichment by either non-porous SnO_2 nanoparticles or commercial TiO_2 , while three ones were detected after enrichment by mesoporous SnO_2 . This result indicated a more effective and accurate detection of β -casein under low concentration by mSnO_2 , which was superior to previous reports using non-porous SnO_2 as affinity probes,^{5, 20} highlighting relatively higher sensitivity of mesoporous SnO_2 generated from their highly accessible active surfaces and large binding area. It is interesting that researchers have proved rutile form of titania exhibited better selectivity for the phosphopeptide,³¹ and the same phenomenon has been found for our synthesized rutile SnO_2 . All these features are promising in actual applications considering the high dynamic range of phosphoproteins in biological samples.

To demonstrate their ability to improve phosphoproteomic analysis in complex real samples, these mesoporous nanospheres were further tried to trap phosphopeptides in protein digests from nonfat milk. Before enrichment most of the detected peaks corresponded to nonphosphorylated peptides (Figure S4), while the signals of phosphorylated ones dominated the MS spectrum after treatment by mesoporous SnO_2 , as shown in Figure 5. These mesoporous materials also revealed higher efficiency from the comparison of the MS results gaining from SnO_2 nanoparticles and commercial TiO_2 . Using the same nonfat milk digests, 10 phosphopeptides were detected by SnO_2 nanoparticles or commercial TiO_2 , while 17 phosphopeptides were detected after enrichment by mesoporous SnO_2 . The detailed information of the detected phosphopeptides was listed in Table S1. This result

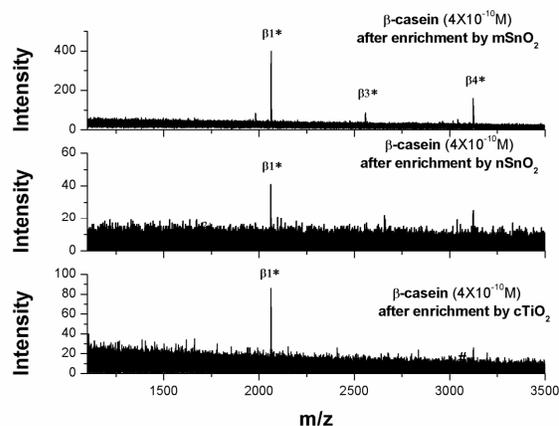

Fig. 4 Phosphopeptide enrichment from β -casein (4×10^{-10} M) by using mSnO_2 , nSnO_2 and cTiO_2 (* phosphopeptides, mSnO_2 : mesoporous SnO_2 , nSnO_2 : non-porous SnO_2 , cTiO_2 : commercial TiO_2)

demonstrated that the large surface area, highly active binding sites and fully accessible surfaces of these SnO_2 spheres are beneficial for binding equilibrium and thus strengthen the enrichment efficiency from complex samples. Meanwhile, the high-quality SnO_2 nanospheres with all the above advantages were obtained from a feasible synthetic method, thus it was practical for the full utilization of their advantages in further phosphoproteomic research on more complex biological systems.

In summary, a feasible synthetic approach for preparation of highly uniform mesoporous SnO_2 nanospheres via a template-free solvothermal method was developed. The absence of templates during synthesis helped to generate accessible binding surface, and the obtained SnO_2 nanospheres have a mesoporous structure and a relatively high density, which offer large surface area together with convenience in centrifugal separation. In addition, the synthesis was cost efficient, environmentally friendly and easy to be amplified for large scale applications. All of the above advantages made the mesoporous SnO_2 nanospheres as promising MOAC affinity probes with high sensitivity in both laboratory and real systems. We believe this work is the starting point of mesoporous SnO_2 in

phosphopeptide enrichment and detection, and more complex biological samples is well-worth exploring in further study, especially in phosphoproteomic study. Furthermore, our work indicates that developing feasible methods for the synthesis of high-quality metal oxides should be considered in the screening of efficient and applicable MOAC affinity probes in target proteomic research.
