Accepted Manuscript

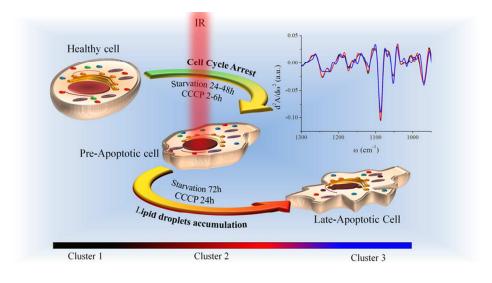

This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about *Accepted Manuscripts* in the **Information for Authors**.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard <u>Terms & Conditions</u> and the <u>Ethical guidelines</u> still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

Infrared microspectroscopy and flow cytometry were used to study apoptosis in starved and CCCP-treated U937 monocyte cells. 40x20mm~(600~x~600~DPI)

Apoptotic pathways of U937 leukemic monocytes investigated by infrared microspectroscopy and flow cytometry

Giovanni Birarda^{a,b}, Diana E. Bedolla^a, Elisa Mitri^{c,d}, Sabrina Pacor^c, Gianluca Grenci^{d,e} and Lisa Vaccari^a

5 Received (in XXX, XXX) Xth XXXXXXXXX 20XX, Accepted Xth XXXXXXXX 20XX DOI: 10.1039/b000000x

Apoptosis is a strictly regulated cell death mechanism that plays a pivotal role for the normal evolution of multicellular organisms. Its misregulation has been associated to many diseases, making its early and reliable detection a key point for modern cellular biology. In this paper, we propose the use of infrared microspectroscopy (IRMS) as a label-free methodology for the detection of apoptotic-related 10 biochemical processes induced on U937 leukemic monocytes by serum starvation and CCCP-exposure. The spectroscopic results are in agreement with parallel Flow Cytometry (FC) experiments, were plasma membrane integrity and mitochondrial activity were assessed. Spectroscopic outcomes complement FC data and allow drawing a more complete picture of the apoptotic pathways. In particular, we established that the two apoptosis-inducing treatments, cell starvation and CCCP treatment, affect the cell cycle in a different way, with the former, cell death is preceded by a cell cycle arrest, whereas the latter causes an increased cell cycle progression. Spectral data 15 demonstrate that for both conditions apoptosis proceeds through the accumulation of lipid droplets within cells. Moreover, we were able to establish a spectral marker for DNA condensation/fragmentation: the enhancement of the PhI band component centred at ~1206 cm⁻¹ which is more sensitive than the relative intensity of PhII band, to which phospholipids and carbohydrates also contribute significantly. In conclusion, we demonstrate that the intrinsic multi-parametric nature of IRMS and its application on cells under physiological conditions can be well exploited for the investigation of apoptotic pathways.

Introduction

Apoptosis is a naturally occurring event through which a cell ends its life by Programmed Cell Death (PCD). From the discovery of the phenomenon, first described as PCD in 1964 by 25 Lockshin¹ and later in 1972 as apoptosis by Kerr², many questions have found an answer but some remain still open.

It has been established that apoptosis is the natural route followed for eliminating cells that are aged, redundant, damaged or infected. It is a fundamental process for the control of the 30 embryonic development and for the maintenance of the tissue homeostasis, so it is vital for the normal evolution of an organism³. It is therefore not surprising that the shortcoming of this cellular function is implicated in a myriad of diseases⁴. For example, increased apoptosis has been 35 neurodegenerative diseases⁵, ischemic damage⁶, and to autoimmune diseases⁷ while, when reduced or suppressed, leads to uncontrolled cell proliferation, associated to cancer⁸ and some viral infections⁹. The development of new drugs for modulating cellular apoptosis can open encouraging perspectives in the 40 treatment of many diseases, and therefore apoptosis related research has increased substantially since the early 1990s.

The apoptotic process is characterised by a series of common morphological features10, such as cell shrinkage, chromatin condensation and segregation at the nuclear membrane, plasma 45 membrane blebbing and finally cellular breakdown into apoptotic bodies (APs). APs are small cellular fragments, delimited by plasma membranes expressing phosphatidylserine residues,

where the potentially toxic or immunogenic cellular content of dying cells is encapsulated. The ultimate fate of APs is to be 50 engulfed and destroyed by macrophages. The AP content (cytosol, condensed chromatin and cellular organelles) may induce an inflammatory response, and this happens as a consequence of necrotic cell death, where the cell is dismembered in an uncontrolled way¹¹.

Morphological changes associated to PCD are related to the biochemical events occurring within cells. Even if signalling pathways may differ from each other depending on the triggering stimuli, two major apoptotic routes have been identified: extrinsic and intrinsic¹². The extrinsic pathway begins outside the cell: it 60 can be initiated by different stimuli that involve the triggering of death receptors of the Tumour Necrosis Factor (TNF) superfamily. In the intrinsic way, stress-inducing intracellular stimuli injure the cell, which in turn can commit PCD. However, both extrinsic and intrinsic pathways involve the activation of 65 cysteine-aspartate-specific proteases, known as caspases, which initiate the proteolytic cascade and execute the cleavage of both DNA, into oligonucleosomal fragments, and specific proteins, which guarantee the integrity of cytoplasm and organelles ¹³⁻¹⁵.

Microscopy techniques, such as light and electron microscopy, 70 have been largely employed for the qualitative determination of apoptosis 16,17. However, they are not useful for a quantitative analysis of the phenomenon. Flow cytometry (FC) can better accomplish this task. Morphological changes, fragmentation and loss, plasma membrane modification and 75 mitochondrial dysfunction can all be monitored by FC¹⁸. Moreover, to monitor the sequence of events in apoptosis, to

distinguish between apoptosis and necrosis, to complement apoptosis-related information with cell cycle phase distribution or marker expression are all goals achievable by running multicolour FC experiments¹⁹. However, the multi-parametric 5 advantage offered by FC always implies the use of dyes and often of permeabilizing agents and fixatives that can tune the cellular response and bias the results. Moreover, only circulating or detached cells, which have the ability to flow in the system, can be analysed.

10 To avoid any possible interference due to fixation processes or probe molecules, label-free techniques, like impedance sensing (IS) or infrared microspectroscopy (IRMS) could be a valid option. Electric cell-substrate impedance sensing (ECIS) is a technique that correlates the electrode impedance variations to 15 changes in shape, motion and, in general, to all those events that involve a cytoskeleton rearrangement in cells ²⁰. This method has been demonstrated to be particularly suitable for the study of biological processes like cell's cycle and cell's apoptosis²¹⁻²³. Although very useful, the data obtained are mainly related to 20 physical proprieties (e.g. shape, cell coverage, etc.) and do not provide any chemical information on the system. IRMS on the contrary, is intrinsically a multi-parametric and label-free analytical tool, which can provide a quick and comprehensive overview of the chemical changes happening within the sample. 25 Specifically, it highlights differences in the cellular biochemistry, in terms of composition and structure of the fundamental cell constituents, without the need of any staining. However, the strong absorbance features of water in the Mid IR regime²⁴ and the difficulties in handling IR-transparent materials have limited 30 up to now the possibility of working under physiological conditions. The use of microfabrication techniques for the production of Visible-Infrared (Vis-IR) transparent devices has recently opened an innovative way for overcoming the current constraints when measuring live cells with this analytical tool. In 35 this decade, our team and others ²⁵⁻²⁹ developed a new generation of microdevices that allow assessing at cellular level the effects of fixatives and dehydration^{30, 31}, determining cell cycle stages^{32,} ³³, and accomplishing several other tasks ²⁶.

In this paper, we propose IRMS as a tool for investigating the 40 biological events involved in PCD of U937 leukemic monocytes. We report on the biochemical changes revealed by IRMS of U937 cell line driven to apoptosis by serum deprivation and mitochondrial membrane depolarization induced by CCCP (Carbonyl Cyanide m-Chloro Phenylhydrazone). The spectral 45 shape of unperturbed U937 was compared with that of cells subjected to serum deprivation for 24, 48 and 72 hours and stimulated with CCCP for 2, 6 and 24 hours. The same samples were also tested for membrane damage and mitochondrial dysfunction by FC. A comparison between the IRMS and FC 50 results was done in order to highlight the uniqueness and complementarity of these two techniques.

Experimental

Cell-based assays

The cell line U937 (American Type Culture Collection, 55 Rockville, Md.) was used for the experiments. It is a leukemic monocyte cell line in-vitro established that displays many

characteristics of human monocytes³⁴. Control cells were cultured in RPMI 1640 medium supplemented with 10% Fetal Bovine Serum (FBS), 2 mM L-glutamine and penicillin (100U/mL)/ 60 streptomycin (100U/mL). Cells were maintained in incubator at 37°C with 5% of CO₂ and the cell passage was routinely done every three days.

Apoptosis induction by serum starvation. U937 control cells were cultured 500.000 cells/mL in multi-well plates in complete 65 medium supplemented with 10 % FBS for 24, 48 and 72 hours without medium exchange (Ctrl_24, Ctrl_48 and Ctrl_72 hereafter). Starved cells were grown in the same conditions without the addition of FBS to RPMI medium (Star_24, Star_48 and Star 72 hereafter).

70 Apoptosis induction by CCCP (Carbonyl Cyanide m-Chloro Phenylhydrazone). U937 cells were cultured 500.000 cells/mL in multi-well plates in complete medium supplemented with 10% FBS and let grow for 24 hours. Then, they were treated with CCCP 50 µM for 2, 6 and 24 hours (CCCP_2h, CCCP_6h and 75 CCCP 24h hereafter).

Flow cytometry determination of cellular apoptosis. Control and treated cells were incubated for 15 minutes with the fluorescent dye DiOC₆ (3,3'-dihexyloxacarbocyanine iodide) at 100nM final concentration. Then, cells were removed from culture medium, 80 washed in PBS twice and marked with Propidium Iodide (PI, 10µg/mL final concentration). Double stained cells were immediately run by FC. All cytometry analysis were performed on 10000 events/sample acquired by FC500 Beckman-Coulter Instrumentation and data were submitted to FCS Express Version 85 3, at Life Sciences Department of University of Trieste.

Device microfabrication

All the devices were manufactured in LILIT clean rooms, (Laboratory for Interdisciplinary LIThography of IOM-CNR Trieste, Italy)³⁵. CaF₂ static devices were employed for the IRMS 90 analysis of control and starved cells, as well as for testing the effects of CCCP at 2, 6 and 24 hours. More details on the device design and fabrication are given elsewhere³⁶. biocompatibility of the devices was verified by contact cytotoxicity tests as described elsewhere 30.

95 IRMS experiments

All spectroscopic experiments were carried out at the infrared beamline SISSI (Synchrotron Infrared Source for Spectroscopic and Imaging) at Elettra - Sincrotrone Trieste, Italy ³⁷.

Sample preparation was minimal, in order to minimize stress 100 level suffered by the cells. Once removed from the incubator, both control and treated cells were washed twice by centrifugation (400g, 1 min) and re-suspended in NaCl 0.9% sterile physiologic solution or complete medium for testing the effects of starvation and CCCP-incubation respectively. 1 µL of 105 cells' suspension was dropped into the Vis-IR transparent device and the chip was assembled.

FTIR transmission spectra were acquired using a Bruker Hyperion 3000 Vis-IR microscope equipped with a mid-band HgCdTe detector having a 100 µm sensitive element, coupled 110 with a Bruker Vertex 70 interferometer. Both interferometer and microscope were purged with nitrogen in order to reduce the spectral contributions from the environmental water vapour and carbon dioxide. Spectra were collected in transmission mode

using 15X Schwarzschild condenser and objective and setting the apertures to 20x20 µm in order to collect groups of two to three cells. For each spectrum, collected from 900 to 4000 cm⁻¹ in double side, forward/backward acquisition mode with a scanner 5 velocity of 40 KHz, 256 scans were averaged with a spectral resolution of 4 cm⁻¹. The Fourier transform was carried out with Mertz phase correction, Blackman-Harris-3 terms apodization function. For each condition 50 to 80 cell groups were collected. An air background was collected with the same acquisition 10 parameters while a buffer spectrum was acquired near to each measured cell group.

Data pre-processing, post-processing and analysis. Raw cell and buffer spectra were corrected for carbon dioxide and water vapour and baseline corrected in the 3730-950 cm⁻¹ spectral 15 region (rubberband method, 32 baseline points) using the OPUS 6.5 routines (Bruker Optics GmbH). An offset correction was then applied. In order to disclose the cellular spectral details hidden by the prominent water features, the buffer spectrum was subtracted from the cell one. The subtraction procedure was 20 carried out using an in-house developed Matlab script. For further details see 30. Subtracted live cell spectra do not exhibit appreciable distortions of the spectral feature ascribable to Resonant Mie scattering 38, thanks to the similarity between the refractive indexes of air and cellular components $^{39, \, 40}$ and water. 25 Therefore, spectra were analysed without any further manipulation.

Spectral features driving the discrimination between control and treated cells were highlighted by Hierarchical Cluster Analysis, HCA, performed in R environment, using HyperSpec⁴¹ 30 and stats packages. HCA was performed on vector normalized second derivatives of subtracted spectra (9 smoothing point, Savitsky-Golay algorithm), based on Euclidean distances and Ward's algorithm. Both vector normalization and clustering algorithm were applied in the 3000-2800&1760-950 cm⁻¹ spectral 35 region. Given that second derivatives of raw and water-subtracted spectra do not exhibit variations in peak positions²⁸, subtracted spectra were preferred in order to avoid any possible artefact in clustering due the degradation of the cellular medium in time, related to the accumulation of catabolites produced by 40 monocytes⁴². Absorbance profiles related to each cluster were also obtained by averaging the belonging spectra in the 3050-950 cm⁻¹ spectral region, in order to highlight relative differences in concentration of the most fundamental cell constituents.

The area integral of the following bands have been calculated 45 with OPUS 6.5: methylene asymmetric stretching, 2945-2900 cm⁻¹ ¹ (CH₂); methyl asymmetric stretching, 2980-2945 cm⁻¹ (CH₃); spectral region 3000-2835 cm⁻¹ (Lipids); Amide II, 1590-1483 (AmII); Phosphate I, 1270-1186 cm⁻¹ (PhI); Phosphate II, 1146-1004 cm⁻¹ (PhII); spectral region 1760-950 cm⁻¹. The integral ₅₀ area 3000-2835 plus the 1760-950 cm⁻¹ has been considered indicative of the total cell biomass⁴³ (Cell).

Results

Flow cytometric signatures of apoptotic cells

The apoptotic pathways induced by both serum starvation and 55 CCCP-exposure on U937 leukemic monocytes were followed by FC. Specifically, the integrity of the plasma membrane was

Table 1 Apoptosis assessment by two-colour FC analysis. Control and treated U937 leukemic monocytes were stained with PI and DiOC₆ dyes. The percentage of viable (PI-, DiOC6+), early apoptotic (PI-, DiOC6<), 60 late apoptotic (PI>, DiOC6<) and necrotic (PI+, DiOC6-) cells is reported. Standard errors of the mean have been calculated on triplicate

probed by the exclusion of propidium iodide (PI) while 65 alterations in the mitochondrial transmembrane potential ($\Delta \Psi_{\rm m}$) were measured by using the dye 3,3'-dihexyloxacarbocyanide iodide (DiOC6)Cell shrinkage typical in early apoptotic events was assessed by measuring the forward scattering (FSC) while nuclear fragmentation that characterizes late apoptosis resulted in 70 a reduced side scattering (SSC).

Results for all tested conditions are summarized in Table 1.

FC data shows that U937 leukemic monocytes are quite resistant to Growth Factor (GF) withdrawal by serum deprivation. Differences from the control can be noticed for 0% FBS only 75 after 72 hours. At day three of starvation, a population of smaller and less granulose cells appears (FSC- and SSC-). These cells have a reduced mitochondrial membrane potential (DiOC6 <): some of them retain plasma membrane integrity (early apoptotic cells), while others do not (late apoptotic ones). Conversely,

80 CCCP induces mitochondrial dysfunction and cellular shrinkage within the first 2 hours of incubation. Most of the cells persist in the early apoptotic status for several hours while a partial or complete loss of plasma membrane integrity can be seen only after 24 hours of incubation.

85 IRMS signatures of apoptosis induced by serum starvation

Using HCA, three major classes of spectral similarity, CL1, CL2 and CL3, were identified and are shown in the Fig. 1a. The table in panel 1b shows the distribution of each subset of cells within the clusters. Due to high spectral variability of non-synchronized 90 cells and unavoidable bias on the choice of sampled areas, distribution must not be considered quantitative, but roughly representative of cellular progression toward apoptotic status. Control cells, grown in complete medium supplemented with 10% FBS, are entirely described by CL1 and CL2 clusters at each 95 experimental time point. The effects of serum withdrawal are indeed discernable within the first 24 hours of treatment, since Star24 and Star48 cells are still represented by CL1 and CL2, but the CL1 population becomes prevalent. Finally, CL3 describes univocally and almost entirely U937 monocytes grown without 100 FBS for 72h. By comparison with FC data, it is possible to reasonably conclude that CL1 and CL2 clusters represent spectral profiles of viable cells, whilst CL3 of apoptotic ones.

Figures 1 c, d and e display the centroids of each class in the spectral regions of major variability: 3025-2800 cm⁻¹, 1800-1480

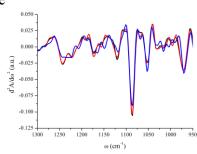

Fig. 1 IRMS assessment of U937 apoptosis induced by serum starvation.

(a) Dendrogram showing the results of HCA analysis on second derivative spectra of serum-starved U937 monocyte-derived cells as described in the Experimental section. (b) Distribution of Ctrl24, Ctrl48, Ctrl72, Star24, Star48 and Star72 cells among CL1, CL2 and CL3 clusters. (c-e) CL1, CL2 and CL3 cluster centroids in the spectral regions 3025-2800 cm⁻¹, 1800-1480 cm⁻¹and 1300-950 cm⁻¹ respectively.

10 cm⁻¹ and 1300-950 cm⁻¹. In Table 2, the relative intensity of the considered spectral bands of average absorbance spectra associated to each cluster (AbsCL1 to AbsCL3 hereafter) are reported.

The position of the most intense bands in the 3025-2800 cm⁻¹ 15 is quite well preserved in all clusters (see Fig. 1c): methyl and methylene asymmetric and symmetric stretching bands are at 2961 cm⁻¹, 2873 cm⁻¹, 2923 cm⁻¹, 2852 cm⁻¹ respectively. The position of stretching band of the methine groups is also preserved (2897 cm⁻¹), while the C-H stretching of vinyl 20 moieties, centred at 3012 cm⁻¹ for CL1 and CL2, splits into two components at 3007 and 3020 cm⁻¹ in CL3. The methylene to methyl asymmetric stretching ratio is markedly higher for AbsCL3 with respect to AbsCL2 and even more with respect to AbsCL1. The relative content of lipids with respect to the overall 25 cellular biomass follows the same trend. Moreover, the carbonyl ester band of phospholipids is centred at 1745 cm⁻¹ for all three cluster centroids, but, from the inspection of Fig. 2d, it is possible to deduce that its relative contribution to the spectral shape is more relevant for CL3 apoptotic cells.

Striking differences among the centroids' cluster profiles can be appreciated in the 1300-950 cm⁻¹ region, where there are the stretching bands of PO2 moieties of the phosphodiester bonds of nucleic acids and phospholipids as well as several bands related to carbohydrates. Two major contributions to PhI band of CL1 and CL2 can be seen in Fig. 1d, centred at ~1220 and ~1241 cm⁻¹, and arising respectively from the B-helical form of DNA&RNA and from the A-helical form of double stranded RNA, as well as DNA-RNA hybrid helices^{44, 45}. On the contrary, PhI band for CL3 cluster is almost completely de-structured, while a shoulder 40 centred at 1206 cm⁻¹ becomes prominent. Similarly to PhI, PhII band shares common spectral features among CL1 and CL2 clusters. It results from the superimposition of three major contributions, centred at 1114, 1086 and 1054 cm⁻¹, and other minor contributions at 1068, 1030 and 1016 cm⁻¹. The same 45 second derivative minima characterize leukemic monocytes belonging to CL3 clusters, but the band shape clearly highlights that the relative intensity of the components at 1114 and 1053 cm changes with respect to the spectral profiles of viable monocytes. The relative intensities of both PhI and PhII band 50 with respect to cellular proteins were considered, using the area of the Amide II band, which is less affected than Amide I by uncertainties due to water subtraction. As can be seen from Table 2, the PhI/AmII ratio is comparable between AbsCL1 and AbsCL2, while it slightly but significantly decreases for AbsCL3. 55 Conversely, the PhII/AmII ratio exhibits a higher variability within all three clusters.

The spectral region between PhI and PhII band is also distinctive for CL3. From the cluster centroids in Fig 1d it is possible to deduce that the intensity of the non-hydrogen bonded

stretching mode of C-OH groups at 1172 cm⁻¹ decreases⁴⁶, while the hydrogen bonded component at 1164 cm⁻¹ and the band centred at 1150 cm⁻¹, still related to the C-O stretching of protein residues or glycol-materials⁴⁷, increases.

The spectral region 1720-1480 cm⁻¹ is dominated by the protein bands Amide I (1710-1590 cm⁻¹) and Amide II (1590-1484 cm⁻¹). All clusters are characterized by three major

Table 2 Relative intensities of several diagnostic spectral bands obtained as described in the Experimental section. Results of both starvation and CCCP experiments are reported. Analysis of variance (ANOVA) has been done by setting the significance level at 0.05. Differences among two 5 clusters (Δ) significant for p-value smaller than 0.05 are labelled as Δ^* , if not significant as Δ^{\dagger} .

components of the Amide I, centred at 1680, 1657 and 1640 cm⁻¹ (see Fig. 1e). For CL3, an extra component at 1620 cm⁻¹ is 10 discernible. The Amide II band shows the same components for all the families, centred at 1548 and 1515 cm⁻¹, accounting for the α -helix contribution⁴⁸ and tyrosine amino acid⁴⁹, respectively.

IRMS signatures of apoptosis induced by CCCP

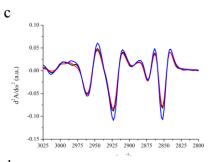

HCA of untreated U937 monocytes (Ctrl and Ctrl24) and of U937 15 monocytes incubated with 100nM final CCCP concentration for 2 hours (CCCP_2), 6 hours (CCCP_6) and 24 hours (CCCP_24), grouped the data into three major classes of spectral similarity, CL1 to CL3, as shown in Fig. 2a. The table in Fig. 2b panel shows the distribution of each dataset within the clusters, while 20 Figs. 2c to 2e display the centroids of each class in different spectral ranges. Ctrl and Ctrl24 cells are entirely grouped in CL1 and CL2 clusters. After 2 and 6 hours of CCCP incubation, CL2 becomes gradually less populated while the remaining cells' subsets distribute prevalently between CL1 and CL3. Upon 24 25 hours of CCCP exposure, none of the cells is represented by CL1 and CL2, while the entire population belongs to CL3. The global trend deduced by HCA analysis is that CCCP-exposed U937 monocytes preserve most of the characteristics of viable control cells for short and medium-term exposure to CCCP (2 and 6 30 hours). After 24 hours of exposure, the entire cell population is described by CL3. In parallel, FC reveals that almost the entire cell population is in an early apoptotic status within few minutes after incubation with the protonophore CCCP.

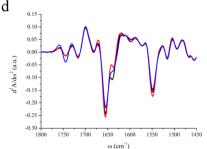

As can be seen from Fig. 2c, C-H stretching vibrations of 35 methyl, methylene, methine and vinyl moieties have the same positions detected for the starvation experiment and there are no relevant band shifts on the CCCP treated samples. The relative content of lipids with respect to the total cellular content as well as the methylene to methyl stretching ratio are higher for AbsCL3 40 and lower for AbsCL1 and AbsCL2. From Fig 2d, it is possible to deduce that the peak height of the carbonyl ester band of

59 60 phospholipids, centred at ~1745 cm⁻¹ is comparable for AbsCL1 and AbsCL2 while it is higher for AbsCL3.

The PhI band of CL1 and CL2 clearly shows the usual components centred at 1240 and 1220 cm⁻¹, while the shoulder at 5 1206 cm⁻¹ is barely visible (see Fig. 2e). The latter became more pronounced for CL3. PhII band is again composed by three major contributions, centred at 1114, 1086 and 1054 cm⁻¹, and minor contributions at 1068, 1103 and 1016 cm⁻¹. Differently from what was highlighted for cluster CL3 in starvation experiments, there 10 are no major variations in the relative weight of the three major components. The PhI/AmII ratio has a minimum for AbsCL2 and it is the highest for AbsCL3, while the PhII/AmII ratio has a minimum for AbsCL2 and the highest for AbsCL1 (see Table 2).

Amide I and Amide II bands have the same components 15 already identified for the starvation experiments, and major changes have not been detected among the three clusters.

Discussion

Apoptosis is a key event in the control of healthy monocyte population, which during inflammation processes can undergo 20 dramatic variations⁵⁰, as well as in pathological conditions of transformed cells. Therefore, the understanding of the sequence of events in monocyte PCD is fundamental in order to develop new strategies to enhance/inhibit the immune response and to control neoplastic proliferation. To this effect, U937 monocyte-25 derived cell line has been chosen for the purpose of this study, which aims to complement the outcomes of label-free IRMS on live cells with the ones of a probe-based technique, FC.

IRMS experiments on live monocytes have been made possible thanks to the use of biocompatible microfabricated 30 devices. They have a height of 8.5 microns, that permits to avoid the saturation of the water bending band and, consequently, to disclose the Amide I profile by subtracting the water contribution as described elsewhere³⁰. U937 cells have an average diameter of 8-10 µm and therefore they fit within the devices without 35 suffering any deformation stress that could alter the cellular response as already demonstrated by the authors⁵¹.

FC data revealed that U937 leukemic monocytes were quite resistant to GF withdrawal by serum deprivation⁵². No appreciable differences were noticed after 24-48 hours of 40 starvation in both cell size and granularity from FSC vs SSC scattering plots as well as in plasma membrane integrity and mitochondrial activity. Only at day three of starvation, the percentage of both early and late apoptotic cells increased with respect to the control grown with 10% FBS. IRMS results agree 45 perfectly with FC: after 72 hours of starvation, the cell population showed peculiar cellular features, as the ones of cluster CL3.

The mechanism by which growth factors removal may lead to apoptosis is both GF- and cell-dependent, but all possible apoptotic pathways are characterized by a decrease of basic 50 cellular functions, such as metabolic rate^{53, 54}. This reduction activates endonucleases via cytochrome c (cyt c) release, determining chromatin condensation and fragmentation, and ending with cell death⁵⁵. Specifically, Caspase Activated DNase (CAD) cleaves DNA at the linker space between nucleosomes, 55 originating DNA internucleosomal fragments that are roughly multiple of 180 base pairs (bp)^{13, 56}. DNA condensation and fragmentation during apoptosis, responsible for the nuclear

morphological changes associated with PCD, is a phenomenon that has been extensively investigated and still under study. Three 60 distinct stages of apoptotic DNA condensation have been recently discovered⁵⁷. At stage 1, ring condensation, chromatin condenses as a continuous ring at the interior surface of the nuclear envelope without fragmentation. For the completion of stage 2, necklace condensation, DNase activity is needed: the chromatin ring 65 appears discontinuous and the nucleus shrinks. In stage 3, nuclear collapse/disassembly, the nuclear content splits into individual

The relative decrease of the integral intensities of both PhI and PhII bands of Star72 cells reveals that CADs are active upon 72h 70 of GF withdrawal and that most of the starved cells are likely undergoing stages 1 and 2 of apoptotic DNA condensation. Some of them possibly have a nuclear envelope (NE) almost intact, while others discontinuous, but still present. Spectroscopic evidences of the nuclear condensation were reported also by other ₇₅ authors^{58, 59}. In particular, Gasparri and Muzio demonstrated that the PhII/AmideII ratio is inversely correlated to apoptotic index, as confirmed also in our experiments. However, very few information is available on the conformational rearrangements undergone by DNA during PCD. Therefore, the structural 80 changes of nucleic acids, which can be deduced from the destructuration of the PhI band of Star72, are probably related to the degradation of higher-order DNA but they are hardly accountable in a punctual manner. Whether the spectral components of Star72 PhI band other than those at 1240 cm⁻¹ and 1220 cm⁻¹ should be 85 attributed to a partial transition from B to A-like DNA structures or to the stacking of nucleosomal DNA fragments is impossible to establish at the actual state of knowledge. Particularly interesting is the prominence of the band shoulder centred at 1206 cm⁻¹. Whether this component could be assigned to asymmetric 90 stretching of PO₂ group and possibly to Z-DNA⁴⁵, to Amide III band⁴⁷ or to C-O and C-O-C vibrations of polysaccharides⁶⁰ is hard to tell, but for sure it became prominent in apoptotic cells.

The modulation of PhII band shape during apoptosis also matches with the cleavage of cellular nucleic acids during PCD, 95 as reported also by Gasparri and Muzio⁵⁸. Furthermore it might highlight the alteration of the carbohydrate metabolism, reflected also by the spectral shape variation in the 1190-1140 cm⁻¹ energy range. The ensemble of the biochemical processes responsible for synthesis, lysis and transformation of carbohydrates in living 100 cells is quite complex as well as the triggering of the different pathways. This complexity and the numerous contributions determining the spectral shape between 1300 and 900 cm⁻¹ (mainly phosphate head of phospholipids, phosphate backbone of nucleic acids and C-O stretching vibrations of mono-, oligo- and 105 poly-saccharides) make difficult any attempt to describe the spectral changes observed. However, they can be associated to the sharp decline in glucose metabolism consequent to GF withdrawal: the surface expression of glucose receptors is lost after GF deprivation and the remaining intermediates of 110 glycolysis are consumed. When glucose flux is reduced below the level needed for maintaining $\Delta \Psi_{\rm m}$, cyt c is released resulting in the activation of initiator caspases and PCD commitment.

Once activated, initiator caspases in turn activate execution caspase enzymes, responsible for the deliberate disassembly of the cell into apoptotic bodies during PCD. Caspases are protease

enzymes that promotes the cleavage of several different proteins; their direct action and the cascade of events promoted permits the ordered dismantling of the dying cell, that requires major modification of the cellular cytoskeleton⁶¹. These events may be 5 responsible for the structural variations of proteins detected in Star72, as reported also by other authors⁵⁸.

However, the more striking spectral features of Star72 apoptotic cells are the increased relative intensities of C-H stretching modes of both methyl and methylene moieties, the 10 higher value of the methylene to methyl ratio and the prominence of the phosphodiester band of phospholipids. The extent of these variations is not fully justified by the formation and accumulation of APs, characteristic of the ultimate stages of apoptosis. Indeed, plasma membrane bulges outward as a consequence of the 15 cleavage of several cytoskeleton components⁶¹ but blebbing involves mostly pre-existing membrane components. Moreover, several evidences demonstrate that in Star72 stage 3 of nuclear DNA condensation has not been accomplished yet: i-optical images of the monocytes within the devices showed round shaped 20 cells, characterized by black spots of condensed material but not by membrane blebbing; ii- PhI and PhII bands are clearly detectable for Star72 U937 monocytes.

It is nowadays established that the fluidity of the plasma membrane increases during apoptosis^{62, 63}. An increased lipid 25 mobility could justify the detected vinyl C-H shift but the variation of the methylene to methyl ratio would be expected to be directed in the opposite way: long chains fatty acids possess better association properties with respect to shorter ones, determining more rigid membranes ⁶⁴. Moreover, the increased 30 relative content of lipids with respect to the cellular content suggests the concurrence of other events. Despite the decrease in both level and activities of the enzymes involved in lipogenesis in apoptotic cells, accumulation of lipid droplets have been established in several primary cells and cell lines⁶⁵. The 35 mechanism responsible for this phenomenon is still unclear, probably related to *de novo* synthesis of neutral lipids as a result of inhibition of mitochondrial fatty acid β-oxidation. Lipid droplets are dynamic cellular organelles made by a central core of neutral lipids, mostly tryacylglycerides (TAG) and cholesterol 40 esters, and an external shell of phospholipid monolayer⁶⁶. Their chemical nature perfectly fits with our spectroscopic results, that overall support the hypothesis that apoptosis proceeds through lipid droplets accumulation. Indeed, a higher CH2/CH3 ratio has been determined by ¹H magnetic resonance of intact apoptotic 45 Jurkat T-cells, a leukemic monocyte cell line, and these evidences were directly linked to accumulation of TAGs⁶⁷.

FC results did not point out dramatic differences between Star24 and Star48 with respect to the relative controls, while IRMS analysis revealed that the cellular variability decreased 50 within the first 24 hours of starvation. The absence of GF is known to induce cell cycle arrest and, generally speaking, apoptotic stimuli often arrest growth before inducing cell death⁶⁸. Cell survival, progression and death share common pathways that make these events tightly interconnected ⁶⁹. Specific checkpoints 55 are present at all stages of the cell cycle and at their boundaries, which allow cells to enter the next proliferating stage once fully and properly accomplished the previous one. In case of any adverse event, whether the cellular damage produced can be

repaired, progression to the cell cycle resumes while, if not, PCD 60 events cascade starts. It is known that the withdrawal of specific growth factors can prevent the expression of genes needed for DNA synthesis and duplication and it is therefore reasonable to think CL1 having most of the characteristics of low-metabolic, quiescent G0 cell cycle phase^{32, 33, 70}.

The understanding of the experimental results obtained for apoptosis induction by CCCP-exposure requires in-depth analysis on the mechanism of action the chemical compound. Carbonyl cyanide m-chlorophenyl hydrazone is a lipid-soluble weak acid that acts as an ionophore: it makes the mitochondrial inner 70 membrane permeable to solutes with molecular weight below 1.5 KDa, due to the opening of the so called Mitochondrial Permeability Transition (MPT) pores. The opening of these mitochondrial megachannels leads to the quick dissipation of $\Delta \Psi_{m}$, to mitochondria swelling and outer membrane integrity 75 damage. These events end with the release of several proteins normally confined within the intermembrane space into the cytoplasm. Among them, cyt c has been recognized to play a pivotal role in apoptosis. CCCP is also an uncoupling agent, which uncouples the respiratory chain from the phosphorylation 80 system (ATP production), acting at this level as an apoptotic agent. FC data clearly reveals that CCCP induce the immediate loss of the mitochondrial inner plasma membrane potential. However, it is well established that the mitochondrial membrane depolarization can be a reversible process and there are several 85 studies that report that the caspase activation induced by CCCP can take place several hours or even days after the cell exposure to the drug 71. This holds true, for example, for the leukemic monocyte cell line Jurkat-neo, where exposure to CCCP 25µM induced immediate mitochondrial collapse but caspase 3 90 activation only 24 hours later. Therefore, even if DiOC6 probe is often used as a diagnostic tool of early apoptosis, it should be exclusively referred to $\Delta\Psi_m$ impairment, without implications on the cellular viability as suggested also by other authors.

From this perspective, functional data from FC and 95 biochemical ones from IRMS can be complemented and summarized as follows. U937 monocytes respond almost immediately to CCCP insult by losing the $\Delta\Psi_m$. However, the mitochondrial permeability transition (MPT) is a necessary event for apoptosis commitment but not sufficient. Actually, cells 100 survive for several hours in this status characterized by an affected steady-state mitochondrial activity, implementing adaptation mechanism. One of these mechanisms presumably implies the levelling and accumulation of U937 monocytes into the cellular phase identified by CL1. Some cells, more 105 susceptible to the dissipation of $\Delta \Psi_{\rm m}$ (those belonging to CL2, possibly corresponding to cycling cells into S and G2/M phases) in part evolve from CL2 toward not-viable condition, described by CL3, and in part accumulate in CL1 within the first incubation hours, a time shorter than the U937 cell cycle, that is almost of 24 110 hours. From the spectral examination of CL3 cluster centroid, the prominence of the PhI band shoulder centred at 1206 cm⁻¹ emerges, and we identify it as characteristic of apoptotic Star_72 cells. However, PhI band of CL3 of CCCP exposed monocytes is much more structured than the one of CL3 of starved cells. These 115 evidences reveal that nucleosome fragmentation is minimal in CCCP exposed cells, also after 24 hours treatment. Indeed,

optical images (not shown here), acquired before IRMS data collection at all-time points, showed cellular morphologies quite unperturbed, without the presence of dark cellular spots diagnostic of chromatin condensation and fragmentation, as 5 revealed for Star72.

Moreover, we did not observe a significant decrement of relative intensity of neither PhI nor PhII bands with respect to cellular proteins for the cells exposed to CCCP for 24 hours, differently from what observed for Star72 cells. In case DNA 10 fragmentation started, its effect on both PhI and PhII band intensity is not clearly detectable and maybe hidden by the contributions of carbohydrates and phospholipids to these bands. In particular, with respect to the lipidome profile, CCCP exposed cells are characterized by methylene to methyl ratio higher than 15 the ones of viable cells and it is related to increased lipid content with respect to the total cell biomass, especially of phospholipids as can be deduced by the prominence of the carbonyl stretching band centred at 1745 cm⁻¹ in CL3. It seems reasonable to attribute this trend to the early and progressive accumulation of 20 mobile TAGs in the form of cytoplasmic lipid droplets after U937 exposure to CCCP, as a consequence of the increased intracellular content of reactive oxygen species and related inhibition of fatty acid oxidation due to the loss of $\Delta \Psi_m^{-71}$. This phenomenon goes along with an increment of plasma membrane 25 fluidity as highlighted by the more pronounced contribution of the vinyl stretching band centred at 3013 cm⁻¹ in CL3 centroid.

Given that lipid droplets accumulation precedes chromosomal DNA fragmentation, it is reasonable to look at CL3 as a spectral family of cells that are suffering an irreversible apoptotic event 30 that follows the ultimate loss of plasma membrane potential and precede extensive DNA fragmentation.

Conclusion

The results presented in this paper allow highlighting the diagnostic capabilities of IRMS for the detection of cellular 35 apoptosis, and its sensitivity not only to late and ultimate steps of PCD, but also to early-reversible stages. There are no direct infrared biomarkers of cellular functionality, but IRMS is able to indirectly reveal the biochemical perturbations that result from cell metabolic impairment. Cell cycle arrest and accelerated 40 cellular progression, consequent to adaptation mechanism during U937 serum withdrawal and CCCP exposure, as well as carbohydrate metabolism alterations are active cellular processes that have been revealed through IRMS. Moreover, it was possible to determine that cell death induced by both GF withdrawal and 45 CCCP exposure proceeds through the accumulation of lipid droplets, an event that can be related to mitochondrial dysfunction and cytc release. Finally, we revealed that structural changes of nuclear DNA can be detected before evident extensive DNA fragmentation by the decrease of both PhI and PhII bands 50 and thanks to the prominence of the 1206 cm⁻¹ band component that characterizes irreversible apoptotic U937 events.

The biological meaning of the latter spectral feature is hardly accountable at the actual state of knowledge, since most of the efforts have been directed in the assessment of the degree of 55 DNA fragmentation during apoptosis more than on structural rearrangements undergone by nuclear DNA and histone proteins. However, our results offer a new perspective on the IRMS

signatures of apoptosis and its progression, and we can envision that the complement of IRMS with other approaches could 60 eventually provide a global understanding on a variety of cellular processes.
