Accepted Manuscript

This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

*Accepted Manuscripts* are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this *Accepted Manuscript* with the edited and formatted *Advance Article* as soon as it is available.

You can find more information about *Accepted Manuscripts* in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

4 [Abstract]: This paper reports, for the first time, rapid simultaneous multi-element determination  
5  
6 of Mg, Cr, Ni, Cu and Pb in used lubricating oils after their extraction/preconcentration from  
7  
8 samples using the novel extraction induced by emulsion breaking. The quantification of the metals  
9  
10 of interest in the extracts was performed by ICP-MS using rhodium as internal standard. Firstly, in  
11  
12 order to make it possible to prepare the emulsion, 4 mL of each oil sample was mixed with 1mL of  
13  
14 toluene. Then the diluted oil sample was emulsified with 1mL of Triton X-114 acid solution. Once  
15  
16 the extraction of the metals was completed, the emulsion was broken by centrifugation for 10min  
17  
18 at 6000rpm. After that, the lower aqueous phase, containing the analytes that were extracted from  
19  
20 oil, was collected for the determination by ICP-MS. Several parameters affecting the extraction  
21  
22 efficiency of the procedure were investigated including the nature and concentration of the solvent  
23  
24 used for sample dilution, the type and concentration of the surfactant, the concentration of HNO<sub>3</sub>,  
25  
26 and the other operational conditions (extraction time, collection time and centrifugal speed). The  
27  
28 limits of detection for Mg, Cr, Ni, Cu and Pb were 0.126, 0.058, 0.028, 0.078 and 0.009µg L<sup>-1</sup>,  
29  
30 respectively. The accuracy of the method was checked by application of a recovery test, by an  
31  
32 analysis of standard reference materials (SRM 1084a and 1085b) and by comparison with the  
33  
34 microwave digestion method.

## 1 Introduction

Lubricating oil is one of the most important liquids that are used in almost all vehicles and machines. Lubricating oil plays a dual role of heat transfer and friction reduction which reduces the heat generated in internal combustion engines.<sup>1</sup> The accurate and fast determination of metals in lubricating oils can be used for quality control of oils, engine diagnosis, preventive maintenance and oil wastes assessment.<sup>2</sup> Trace level of metals like Mg, Cr, Ni, Cu and Pb are known to monitor the extent of wearing in engines as metallic particles and organometallic species can be produced during normal operation.<sup>3</sup> Besides, Mg, Cr and Ni are also incorporated into lubricating oils as additives to improve their performance.<sup>4</sup>

Sensitive techniques are required for analysis of used lubricating oils since the capability of monitoring small concentration changes in the key elements is needed.<sup>5</sup> Apart from the existence of a few electroanalytical,<sup>6-8</sup> laser-induced breakdown spectroscopy,<sup>9,10</sup> and XRF<sup>11</sup> methods for the determination of metals in lubricating oils, the majority of analytical methods reported in the literature were based on atomic spectrometric techniques such as FAAS, ET-AAS, DC or ICP-OES, ICP-MS and AFS.<sup>5</sup> Among these, ICP-MS has been recognized as one of the most powerful and widely applied instrumental techniques in analytical chemistry due to the combination of high sensitivity and fast multi-element capabilities.<sup>12</sup> However, the accurate determination of metals in used lubricating oils by plasma-based techniques like ICP-MS is still an analytical challenge, especially because of the nature of the samples, which present very high carbon content, intrinsic heterogeneity and unfavorable physical characteristics such as high viscosity and turbidity. Therefore, designing optimal lubricating oil pretreatment is critical for reliable metal determination in such a matrix.

1  
2  
3  
4 The traditional way to introduce oil samples into ICP is directly diluting with an appropriate  
5  
6 organic solvent.<sup>13-16</sup> This procedure does not minimize the problems associated with the high  
7  
8 organic load, and necessarily requires the use of expensive and unstable organometallic standards  
9  
10 for calibration. Besides, the manipulation of toxic organic solvents makes the procedure very  
11  
12 harmful for the analysts. Alternatively, acid digestions with classical heating, ultrasonic irradiation  
13  
14 or microwaves have been proposed,<sup>17-19</sup> allowing the measurement of metallic ions without  
15  
16 serious interferences due to the total (or almost total) elimination of the organic carbon. However,  
17  
18 these procedures are laborintensive, thus implicating a low sample throughput. Also, the excessive  
19  
20 dilution is imposed to the samples, which impairs the limit of quantification and brings possible  
21  
22 contamination. Emulsification of the sample with detergents and water leading to oil-in-water  
23  
24 emulsion is another alternative.<sup>4, 5, 17, 20</sup> This approach does not require the destruction of the  
25  
26 organic matter or the use of large amounts of organic solvents, and presents relatively high sample  
27  
28 throughput. Using emulsion, the main problem is its instability, which causes phase separation in a  
29  
30 short period of time. Meanwhile, emulsion formation results in sample dilution and degradation of  
31  
32 detection limit. Additionally, a method to determine metals in lubricating oils using pressurized  
33  
34 solvent extraction (PLE) with a semi-automatic extractor ASE 200 by ICP-MS has been developed  
35  
36 in the literature.<sup>21</sup>

37  
38  
39  
40  
41  
42  
43  
44  
45  
46 Only several papers described the direct determination of metals in lubricating oils. Bings<sup>22</sup>  
47  
48 developed a method for the direct determination of Na, Mg, Al, Ti, Cr, Fe, Ni, Co, Cu, Ag and Pb  
49  
50 in used lubricating oils by combining direct laser ablation (LA) of the samples with inductively  
51  
52 coupled plasma time-of-flight mass spectrometry (ICP-TOFMS). Yu et al.<sup>10</sup> proposed a method  
53  
54 based on laser-induced breakdown spectroscopy (LIBS) technique to directly determine metals in  
55  
56  
57  
58  
59  
60

1  
2  
3 lubricating oils. However, these methods were prohibitive for several analytical laboratories  
4  
5 because the high-cost instrumentations needed to be used.  
6  
7

8  
9 Recently, Cassella et al.<sup>23-25</sup> reported a new procedure, based on the extraction induced by  
10  
11 emulsion breaking (EIEB), to extract analytes from oil samples into an aqueous solution. In this  
12  
13 case, the emulsions were prepared by mixing the oil samples with acidic surfactant solutions, and  
14  
15 broken with heating or centrifugation. But, a cleaner aqueous phase was obtained by  
16  
17 centrifugation than heating. After the emulsion breaking, the metals were efficiently transferred  
18  
19 from oil to the aqueous phase. The method was successfully applied in the extraction of various  
20  
21 metals from diesel oil, edible oil, biodiesel and lubricating oil.<sup>23-31</sup> In these works, the  
22  
23 determination of the metals was performed by different analytical techniques (FAAS, ETAAS and  
24  
25 ICP-MS), which proved the versatility of the methodology.  
26  
27  
28  
29  
30

31  
32 The main goal of this study was to propose a novel method for the simultaneous  
33  
34 determination of Mg, Cr, Ni, Cu and Pb in used lubricating oils by ICP-MS after a simple  
35  
36 extraction/preconcentration procedure based on EIEB. In this work, all the samples were diluted  
37  
38 with an organic solvent before the formation of emulsions and the amount of nitric acid and  
39  
40 surfactant was reduced, when compared to our previous work on edible vegetable oils.<sup>31</sup> In  
41  
42 addition, the emulsions were broken by centrifugation at 6000rpm for 10min which was shorter  
43  
44 than that reported by Caldas et al.<sup>27</sup> As a result, the total pretreatment time was reduced, which had  
45  
46 vital significance especially if a great number of samples are to be measured.  
47

### 52 **2.1 Apparatus**

53  
54  
55  
56 The determination of the analytes was performed using a Perkin-Elmer (Concord, Canada)  
57  
58  
59  
60

1  
2  
3  
4 inductively coupled plasma mass spectrometer, model Elan DRC-e, operated under the conditions  
5  
6 listed in Table 1. The determination of Mg, Cr, Ni, Cu and Pb was performed by measuring the  
7  
8 isotopes  $^{25}\text{Mg}$ ,  $^{53}\text{Cr}$ ,  $^{60}\text{Ni}$ ,  $^{63}\text{Cu}$  and  $^{208}\text{Pb}$  respectively, while rhodium ( $^{103}\text{Rh}$ ) was employed as  
9  
10 internal standard. The emulsion breaking was induced by centrifugation using an Eppendorf  
11  
12 (Hamburg, Germany) 5804 centrifuge. The evaluation of the extraction time was performed by  
13  
14 shaking (80 rpm) the emulsions with a roller mixer, model SRT-202, supplied by Kylin-Bell  
15  
16 (Haimen, China). The total digestion of used lubricating oil samples was performed with an Anton  
17  
18 Paar (Graz, Austria) microwave oven, model Multiwave 3000, equipped with PFA vessels.  
19

Ultrapure water employed for the preparation of all aqueous solutions was obtained in a Milli-Q  
Element A10 water purification System (Millipore, Bedford, MA, USA). All solvents employed in  
the test of the influence of the solvent (ethyl benzene, toluene and hexane) were HPLC-grade  
(Tjshield, Tianjin, China).

A multi-elemental aqueous stock solution of 10 mg L<sup>-1</sup> containing 29 elements (Al, As, Ba,  
Be, Bi, Ca, Cd, Co, Cr, Cs, Cu, Fe, Ga, In, K, Li, Mg, Mn, Ni, Pb, Rb, Se, Na, Ag, Sr, Tl, V, U, Zn)

1  
2  
3 dissolved in 5% HNO<sub>3</sub> was supplied by Perkin-Elmer (Shelton, USA). Aqueous stock solution of  
4  
5  
6 rhodium (10 mg L<sup>-1</sup>) was also supplied by Perkin-Elmer (Shelton, USA). The aqueous standard  
7  
8  
9 solutions used in the experiments were prepared by dilution of the stock solutions with 1% v/v  
10  
11 HNO<sub>3</sub>. The nitric acid was of MOS grade (Sinopharm Chemical Reagent, Shanghai, China).  
12

13  
14 Certified reference materials, SRM 1084a and 1085b (Wear-Metals in Lubricating Oil) were  
15  
16 from the National Institute of Standards Technology (NIST, Gaithersburg, MD, USA). Oil-based  
17  
18 stock solutions of magnesium, chromium, nickel, copper and lead of 1000 µg g<sup>-1</sup> were supplied by  
19  
20 Conostan (Houston, TX, USA). The oil standard solutions used to spike the samples in the  
21  
22 recovery test were prepared by suitable dilution of the stock solutions with HPLC-grade hexane.  
23  
24

25  
26 The acid solutions of Triton X-114 and Triton X-100 (Acros Organics, New Jersey, USA),  
27  
28 used for emulsification of lubricating oils, were prepared by dissolving suitable masses of each  
29  
30 surfactant in exactly 100 mL of HNO<sub>3</sub> solution. The concentrations of Triton X-114, Triton X-100  
31  
32 and HNO<sub>3</sub> were established according to the value desired for each experiment.  
33  
34

35  
36 Total ten used lubricating oil samples were collected from gas stations located in the city of  
37  
38 Hangzhou, China, and no information regarding the type of oils or their time of use could be  
39  
40 obtained. They were stored in a low-density polyethylene flask and kept in a light-free place at  
41  
42 ambient temperature.  
43  
44

### 45 46 **2.3 Extraction/preconcentration procedure**

47  
48 The extraction of metals from used lubricating oils was performed by using EIEB procedure. The  
49  
50 EIEB procedure was involved in three main steps:  
51  
52

53  
54 (1) Dilution: 4 mL of each oil sample (approximately 3.45 g) was mixed with 1 mL of toluene,  
55

56  
57 in order to decrease the viscosity and allow a convenient mixing with the emulsifying  
58  
59  
60

1  
2  
3 aqueous solution.  
4

5  
6 (2) Emulsification: 1 mL of solution containing the acidic Triton X-114 was added to the  
7  
8 capped plastic tube of 15 mL capacity, which contained 5 mL of diluted oil sample, and  
9  
10 then was mixed vigorously in order to obtain stable water-in-oil emulsion. Afterwards,  
11  
12 the emulsion was transferred to a roller mixer, agitated for 25 min in order to improve the  
13  
14 extraction of the analytes.  
15  
16

17  
18 (3) Emulsion breaking: The tube was transferred to the centrifuge, centrifuged at 6000 rpm to  
19  
20 reach the phase separation, and also the emulsion breaking time was recorded during this  
21  
22 step. At the end of the emulsion breaking, two well-separated phases were observed, as  
23  
24 shown in Fig. 1: (A) an upper phase containing the diluted oil and the surfactant and (B) a  
25  
26 lower phase, containing the aqueous acid solution with the extracted metals. Then, the  
27  
28 lower aqueous phase was collected (approximately 0.8 mL) with the aid of a micropipette  
29  
30 and used to measure the metals of interest by ICP-MS. The calibration strategy was based  
31  
32 on the internal standardization approach, using Rh as the internal standard to minimize  
33  
34 possible interferences due to the injection of complexes matrices (residual concentrations  
35  
36 of the surfactant). When necessary, a defined volume of the aqueous phase was taken and  
37  
38 diluted with ultrapure water in order to adjust the concentration of the metals to the linear  
39  
40 portion of the analytical curves. The blank was prepared in the same way of the sample,  
41  
42 but without adding lubricating oil.  
43

56  
57  
58  
59  
60

**Fig. 1** Emulsion (1) before and (2) after breaking by centrifugation at 6000rpm. (A) Used lubricating oil phase and (B) aqueous phase. The phase separation process took 10 min.

#### 2.4 Microwave digestion of the samples

The microwave digestion of the oil samples was performed by acid dissolution in a closed-vessel microwave oven. For this purpose, approximately 0.250 g of oil was digested with 5 mL of concentrated  $\text{HNO}_3$ . The microwave heating program consisted of five steps: 2 min at 250 W, 2 min at 0 W, 6 min at 250 W, 10 min at 600 W and 10 min at 800 W. The final volume was completed to 25 mL with ultrapure water. The metals were also measured by ICP-MS using Rh as the internal standard.

### 3 Results and discussion

The optimization of the proposed methodology was studied by investigating the effect of some parameters on the extraction efficiency and the time spent to complete the procedure: (A) type and concentration of the solvent used to dilute the oils, (B) the concentrations of Triton X-114 and Triton X-100 used for emulsification (C) the concentration of  $\text{HNO}_3$  used for extraction and (D)

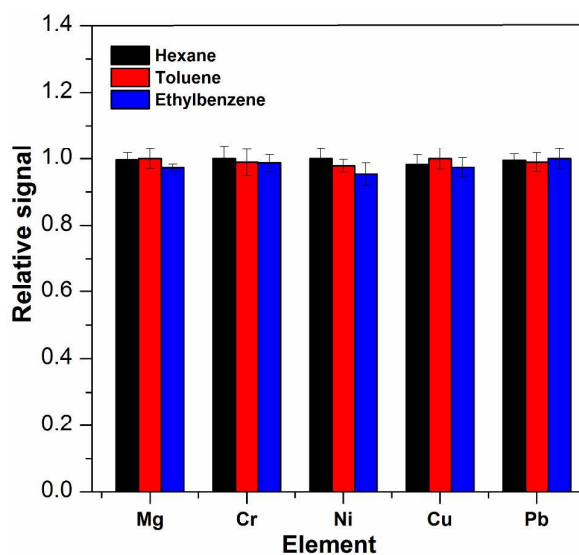

1  
2  
3  
4 the operational extraction conditions. In the experiments, relative signals were used to evaluate the  
5  
6 results because of the different magnitude of the signals obtained for each metal. Relative signals  
7  
8 are defined as the ratio between each analytical signal and the highest analytical signal obtained in  
9  
10 the set.  
11

### 12 13 14 **3.1 Effect of the type and concentration of the solvent**

15  
16 The first parameter studied in the optimization of the proposed procedure was the influence of the  
17  
18 type and concentration of the solvent. The formation of a convenient emulsion has fundamental  
19  
20 importance for the success of the procedure, because a proper dispersion of water droplets through  
21  
22 the oil samples enhances the extraction efficiency due to the increase of the interfacial area  
23  
24 between oils and extractant aqueous solutions. However, the mixture of the samples with the acid  
25  
26 solutions of Triton X-114 or X-100 was impaired by the characteristic of high viscosity of used  
27  
28 lubricating oils, which made it practically impossible to prepare the emulsions. In order to  
29  
30 overcome this drawback, an organic solvent was introduced to reduce the viscosity of the oil and  
31  
32 to facilitate the interaction between oil and the non-ionic surfactant, resulting in good formation of  
33  
34 emulsion. Three solvents were carried out where used lubricating oils were highly soluble: toluene,  
35  
36 ethylbenzene and hexane. The volumetric proportion of solvent was kept constant at 20% v/v and  
37  
38 the extraction efficiency was evaluated. And no significant difference of the signals was noted for  
39  
40 all analytes by using any of the three solvents (Fig. 2). Nevertheless, when the sample was diluted  
41  
42 with toluene, the separation of an aqueous phase with lowest turbidity was observed. It indicated  
43  
44 that the transference of organic material to this phase was minimized with toluene. So, toluene  
45  
46 was chosen as solvent for the method.  
47  
48  
49  
50  
51  
52  
53  
54

55  
56 Meanwhile, the effect of the concentration of toluene was performed in the range of 10-50%  
57  
58  
59  
60

v/v. There was a significant decrease among the signals obtained with the increase proportion of toluene, which could be explained by the increased dilution factor. However, when the proportion of toluene was between 35 and 50% v/v, a practical problem appeared that the emulsion breaking was very difficult. In this case, residual amounts of emulsified oil remained in the interface between the two phases and it was extremely inconvenient to collect the lower aqueous phase. In order to avoid excessive dilution of the samples and make the collection of the aqueous phase easier, a proportion of 20% v/v was chosen for the method.

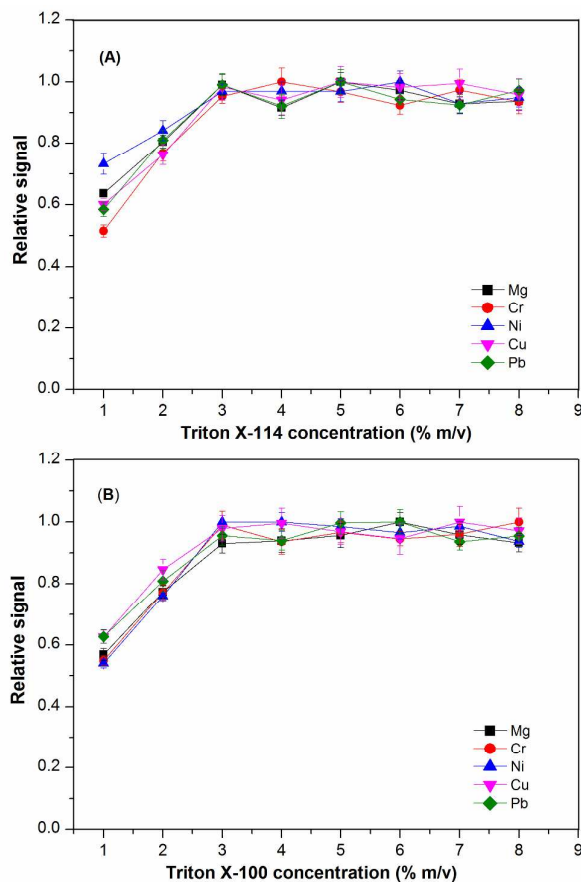

**Fig. 2** Effect of the solvent type to decrease the viscosity of used lubricating oil on the extraction of metals by the proposed procedure. The solvents concentrations were 20% v/v.

### 3.2 Effect of the surfactant type and concentration

Surfactants are able to improve the characteristics of many chemical reactions and the performance of certain analytical methods. The surfactant (Triton X-114 or X-100) plays an important role in this proposed method, since it decreases the surface tension between aqueous and oil phases, lowering the energy required for emulsification. The experiment was carried out by changing the concentration of Triton X-114 or X-100 in the range of 1–8% m/v. The concentration

1  
2  
3  
4 of HNO<sub>3</sub> was fixed at 15% v/v, the sample was diluted with toluene (20% toluene + 80% sample)  
5  
6 before emulsification and the emulsion breaking was performed by centrifugation at 6000 rpm.  
7  
8  
9 Fig. 3 shows the results obtained in the experiment.

10  
11 In the range of 1–3% m/v, the increase of the concentration of the surfactants enhanced the  
12 extraction efficiency which was denoted by the increase of the analytical signals for all analytes.  
13  
14 But there is no remarkable variation in the magnitude of the signals in the range of 3–8% m/v. And  
15  
16 an efficient extraction of the metals can be reached independently of the type of surfactants, since  
17  
18 the curves with similar profiles were verified when Triton X-114 and X-100 were employed for  
19  
20 the emulsification. The effect of the surfactant concentration was also examined in terms of the  
21  
22 time required for the emulsion breaking. It is important to remark that the use of higher  
23  
24 concentrations of surfactants resulted in the formation of more stable emulsions, which took  
25  
26 longer time to be broken. And the emulsions prepared from Triton X-114 were broken at a reduced  
27  
28 time than Triton X-100, which indicated that Triton X-114 was more suitable for the EIEB  
29  
30 procedure. Therefore, Triton X-114 concentration of 3% m/v was selected for further experiments  
31  
32 to achieve the highest extraction efficiency and form emulsions easy to break.

**Fig. 3** Effect of the concentration of the surfactants on the extraction of metals by the proposed method. (A) Triton X-114 (B) Triton X-100. Toluene concentration was 20% v/v, HNO<sub>3</sub> concentration was 15% v/v.

### 3.3 Effect of the nitric acid concentration

Nitric acid is responsible for the extraction of metals in used lubricating oils, where they can be present in free form, in metallic particles, in oxide species or as part of organic structures. When the acid is used, the organic matrix is not destroyed; only element extraction is carried-out.<sup>32</sup> In order to investigate the effect of this variable, the concentration of HNO<sub>3</sub> in the extract solution was changed in the range of 1-30% v/v, always maintaining the Triton X-114 concentration at 3% w/v, and the emulsion breaking was carried out by centrifugation at 6000 rpm. Fig. 4 showed the variation of the analytical signals with the variation of the concentration of HNO<sub>3</sub>.

The analysis of the results showed that the concentration of HNO<sub>3</sub> presented noticeable effect

on the extraction of Cr, Ni and Cu. For Mg and Pb, the extraction efficiency was practically unaltered along the whole range evaluated, while for Cr, Ni and Cu, there was a clear increase of the extraction efficiency with the increase of the HNO<sub>3</sub> concentration until 15% v/v. For concentrations higher than 15% v/v, the signals remained almost constant. This fact could indicate that the particles of Cr, Ni and Cu were more difficult to dissolve than the particles of Mg and Pb. Herein, the HNO<sub>3</sub> concentration of 15% v/v was chosen for the method to ensure maximum extraction of all analytes only at one condition.

The emulsions breaking time was also influenced by the concentration of HNO<sub>3</sub>. But they were always very low, varying from 7 to 13 min in the range of 1-30% v/v. In the experiment using 15% v/v of HNO<sub>3</sub>, the time needed to break the emulsions was 10min, which was considered satisfactory because it did not affect the total time taken to complete the procedure.

**Fig. 4** Effect of the HNO<sub>3</sub> concentration on the extraction of metals by the EIEB procedure. Toluene concentration was 20% v/v and Triton X-114 concentration was 3% m/v.

### 3.4 Effect of the operational extraction conditions

In this study, some practical aspects, related to the operational conditions, were also evaluated. In this context, three parameters were tested: (i) extraction time; (ii) collection time and (iii)

1  
2  
3 centrifugal speed.  
4  
5

6 The extraction time is considered as the time elapsed between the formation and breaking of  
7  
8 the emulsions. In this experiment, emulsions were prepared and agitated on a roller mixer for  
9  
10 increasing time in the range of 0–60 min to evaluate the importance of the contact time between  
11  
12 the same lubricating oil and extractant solution. As it can be seen in Fig. 5, no influence of this  
13  
14 parameter was observed on the signals of Mg and Pb. But for Cr, Ni and Cu, the increase of the  
15  
16 extraction time increased the extraction efficiency, which was denoted by the increase of the  
17  
18 analytical signals, and the maximum extraction could only be achieved when the emulsions were  
19  
20 agitated for at least 20 min. These results could further indicate that the transference of Cr, Ni and  
21  
22 Cu to the acidic aqueous phase was more difficult than Mg and Pb in used lubricating oil. In order  
23  
24 to ensure the maximum extraction of all analytes, an extraction time of 25 min was established for  
25  
26 the method.  
27  
28  
29  
30  
31  
32

33 The collection time is the time passed from the end of the emulsion breaking until the  
34  
35 collection of the aqueous phase. The importance of collection time grows if a greater number of  
36  
37 emulsions are broken simultaneously. In order to test this effect, the collection time was varied  
38  
39 from 2 (the minimum time for the separation of the phases with the micropipette) to 100 min. The  
40  
41 variation of the signals was negligible, evidencing that all analytes remained in the solution even if  
42  
43 the separated oil and aqueous phase were maintained in contact as long as 100 min.  
44  
45  
46  
47  
48

49 In order to evaluate the effect of the centrifugal speed on the extraction efficiency, this  
50  
51 variable was varied in the range of 2000-10000 rpm and no remarkable differences among the  
52  
53 analytical signals was verified. This fact evidences that the extraction efficiency did not depend on  
54  
55 the centrifugal speed employed for the emulsion breaking. However, the centrifugal speed  
56  
57  
58  
59  
60

presented noticeable effect on the emulsion breaking time, which was strongly decreased with the increase of centrifugal speed in the range of 2000-6000 rpm. At centrifugal speed higher than 6000 rpm, the time of the emulsion breaking (10 min) remained almost constant. Therefore, a centrifugation speed of 6000 rpm and a centrifugation time of 10 min were selected for the method.

**Fig. 5** Effect of the extraction time on the extraction of metals by the proposed procedure. Toluene = 20% v/v, Triton X-114 = 3% m/v, HNO<sub>3</sub> = 15% v/v.

### 3.5 Analytical features of the proposed methodology

The limits of detection and quantification for Mg, Cr, Ni, Cu and Pb determination in used lubricating oils were derived from the calibration curves based on online internal standard method with 20 μg L<sup>-1</sup> Rh as an internal standard, which were constructed with aqueous standard solutions prepared in 1% v/v HNO<sub>3</sub> medium. The instrumental limits of detection (3s criterion) and quantification (10s criterion) were estimated from eleven measurements of 1% v/v HNO<sub>3</sub> solution. The limits of detection and quantification of the methodology were estimated from the analysis of the blank solution obtained in the EIEB procedure. The repeatability (within-run) of the methodology was estimated in the determination of analytes in the sample ULO<sub>1</sub>. Reproducibility

(between-run) was tested by analyzing independent aliquots of same sample ULO<sub>1</sub> in three consecutive days. These data are presented in Table 2.

**Table 2** Analytical features of the proposed methodology

Parameters	Metals				
	Mg	Cr	Ni	Cu	Pb
Instrumental LOD ( $\mu\text{g L}^{-1}$ )	0.089	0.032	0.012	0.057	0.005
Instrumental LOQ ( $\mu\text{g L}^{-1}$ )	0.297	0.107	0.041	0.190	0.017
Methodological LOD ( $\mu\text{g L}^{-1}$ )	0.126	0.058	0.028	0.078	0.009
Methodological LOQ ( $\mu\text{g L}^{-1}$ )	0.420	0.194	0.093	0.262	0.031
Repeatability (%) (n=3, sample ULO <sub>1</sub> )	2.99	4.01	1.87	2.98	2.55
Reproducibility (%) (n=3, sample ULO <sub>1</sub> )	5.03	6.23	6.76	5.44	4.95

### 3.6 Validation and application of the proposed methodology

Three different strategies were carried out to assess the efficiency and accuracy of the method. In the first case, the accuracy of the EIEB and microwave digestion procedure was calculated from six aliquots of the certified lubricating oil SRM 1084a and 1084b, each measured three times. Table 3 presents satisfactory recoveries for the EIEB (90–108%) and microwave digestion (93–106%) procedure. Secondly, the results obtained by the developed method were compared with those obtained when the samples were analyzed using microwave digestion. As it can be seen in Table 4, there was no statistical difference between the results of them when the Student-t test (95% confidence level) was applied. Lastly, the recovery test was performed by the analysis of real samples spiked with known amounts of analytes in the form of organometallic standards (Conostan standards). The results are given in Table 5a and b, recovery percentages ranging from 86% to 110% were observed in the determination of Mg, Cr, Ni, Cu and Pb, showing that these metals were quantitatively extracted by EIEB procedure and confirming that no matrix interferences were present in the measurement of metals by ICP-MS.

The developed methodology was applied in the determination of Mg, Cr, Ni, Cu and Pb in

ten samples of used lubricating oils (Table 4). The magnesium values were lower than those reported by Paradelo et al.,<sup>21</sup> but higher than the literature values by Zmozinski et al.<sup>17</sup> The chromium and nickel contents were in agreement with those reported in the literatures.<sup>13,16,20,23</sup> The copper levels were higher than those found by Yawar,<sup>16</sup> but lower than those reported by Paradelo et al. and Caldas et al.<sup>21,27</sup> Our lead levels were lower than those found in the literatures,<sup>13,21,22</sup> indicating less wearing in engines.

#### 4 Conclusions

In this work, the extraction induced by emulsion breaking procedure coupled to ICP-MS was proposed for the determination of Mg, Cr, Ni, Cu and Pb in used lubricating oils. The results obtained were in excellent agreement with the certified values of standard reference materials (SRM 1084a and 1085b), proving the accuracy of the developed procedure. Several advantages over existing methods were observed by the application of the proposed method: (A) the

1  
2  
3 transference of the analytes to the water extract eliminated spectral interferences due to carbon  
4  
5  
6 compounds and avoided injector clogging which could result in sensitivity loss and precision  
7  
8 degradation; (B) inorganic standards could be used for calibration because the determination was  
9  
10 always performed in simple aqueous phase instead of complex organic matrix; (C) a  
11  
12 preconcentration factor of four was achieved, once all metals present in 4 mL of oil sample were  
13  
14 transferred to 1 mL of acidic extractant solution, which improved the limits of detection and  
15  
16 quantification; and (D) the whole procedure only employed 15% v/v HNO<sub>3</sub> solution for the  
17  
18 extraction, avoiding the use of large amounts of concentrated acid.  
19  
20  
21  
22  
23

24 One of the main points of the proposed method was the use of toluene for the dilution of used  
25  
26 lubricating oils, which decreased the viscosity of the samples and permitted their emulsification.  
27  
28 In this case, a volumetric percentage of 20% of toluene was enough to give stable emulsions.  
29  
30

31 The developed methodology was successfully applied in the analysis of real samples of used  
32  
33 lubricating oil. The obtained results were in agreement with those obtained by the microwave  
34  
35 digestion method. Meanwhile, recovery percentages in the range of 86–110% were observed when  
36  
37 the metals of interest were added to the samples as organometallic standards.  
38
