This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Regulative peroxidase activity of DNA-linked hemin by graphene oxide for fluorescence DNA sensing†††

Quanbo Wang, Nan Xu, Jianping Lei and Huangxian Ju*

The inhibition effect of graphene oxide toward the peroxidase activity of DNA-linked hemin was identified and conveniently utilized to design a homogenous fluorescence strategy for DNA sensing with high sensitivity.

As an active cofactor for a variety of natural enzymes such as horseradish peroxidase and catalase, Fe(III)-protoporphyrin IX (hemin) has attracted extensive research interest in mimicking catalysis for numerous applications.1 In particular, the regulation of its catalytic activity is very important for obtaining tunable detection signal and achieving high analytical sensitivity. For example, after hemin binds with guanine quadruplex to form DNAzyme, the peroxidase activity of hemin can be greatly enhanced compared with free hemin.2 The DNAzyme is frequently used as signal amplifying labels to develop optical or electronic biosensors for DNA/RNA, proteins, and metal ions.3 To more efficiently utilize the catalysis function of hemin, it is urgent to seek an effective way to reversibly regulate the catalytic activity of hemin.

Recently, graphene has been identified as a useful carrier to load hemin or other porphyrins for enhancing the catalytic properties of hemin.4 The hemin/graphene hybrid can be prepared by the direct assembly of hemin on graphene with π-π interaction.4a Interestingly, graphene oxide (GO) cannot improve the catalytic activity of hemin due to its damaged structure.4d Through the chemical reduction of GO, the enhancement properties of graphene can be recovered.5 However, the low water-solubility of graphene or reduced GO and the irreversible assembly of hemin limit its application in bioanalysis.

DNA-linked hemin can provide a feasible way to control the attachment/detachment of hemin on GO surface according to the different affinity of GO toward single-stranded DNA (ssDNA) and double-stranded DNA (dsDNA).6 Furthermore, hemin can catalyze non-fluorescent substrate to form fluorescent product in the presence of hydrogen peroxide (H₂O₂),7 which thus provides a possibility to amplify the detection signal in a “one target to multiple signal molecules” manner. This work designed a hemin labeled DNA probe (Table S1), and demonstrated the regulative peroxidase activity of DNA-linked hemin by GO. The tunable catalysis activity could be conveniently utilized to develop a simple homogenous fluorescence strategy for highly sensitive detection of DNA.

The hemin labeled DNA probe was synthesized via amide reaction in aqueous solution, and was characterized with mass spectroscopy (Fig. S1) and high-performance liquid chromatography (Fig. S2). As shown in Scheme 1A, the probe could be absorbed on GO surface due to its flexible structure and the π-π interaction between GO and the exposed nucleotide bases of ssDNA, which brought hemin to GO surface and inhibited its catalytic property. The observed inhibiting effect of GO was reversible, and it could be relieved by hybridizing the probe with complementary DNA target to detach the formed dsDNA and thus the linked hemin from GO surface. Based on this discrimination, a homogenous fluorescence DNA sensing strategy with high sensitivity was conveniently developed (Scheme 1B).

To verify the feasibility of the proposed method, tyramine was used as a non-fluorescent substrate, which could be catalytically oxidized into a fluorescent dimeric phenol product via the peroxidase activity of the probe in the presence of H₂O₂ (Scheme S1A). Compared with the weak fluorescence (FL) signal catalyzed by free hemin (Fig. 1A, curve a), the fluorescent signal catalyzed by the probe was 7.3 times higher (Fig. 1A, curve b). This phenomenon
could be attributed to the facts that hemin possesses weak solubility in aqueous solution, which led to its self-aggregation and lowered the peroxidase activity, while the grafting of hemin with ssDNA improved its solubility and thus excluded the aggregation to produce high peroxidase activity. Further, when the probe was absorbed onto GO surface, the catalytic fluorescent signal was significantly suppressed with a decrease of 88.5% (Fig. 1A, curve c). The signal inhibition could be attributed to two reasons as follows: GO possessed strong quenching effect on the fluorescence of the catalyzed product, and the peroxidase activity of hemin was inhibited after it was absorbed on GO. To clarify this phenomena, control experiment was carried out by adding GO in product of the catalytic reaction. In this case, the decrease of fluorescence intensity was attributed to only the fluorescent quenching effect of GO, which showed a signal decrease 11.5% (Fig. 1A, curve d). Therefore, the inhibition of peroxidase activity of hemin by GO in this system was mainly responsible for the decrease of fluorescent signal. The inhibition effect could be attributed to the decreasing diffusion rate of the probe after absorbed on GO, the steric hindrance effect of GO and the possible interaction of GO with the oxidation intermediate. The latter could be concluded by the effect of GO concentration on its inhibiting efficiency. With the increasing GO concentration, the inhibiting efficiency increased and reached a plateau at 0.75 µg mL⁻¹ (Fig. 1B), indicating that the peroxidase activity of DNA-linked hemin could be regulated by changing GO concentration.

![Fig. 1](image1.png)

**Fig. 1** (A) Fluorescent spectra of oxidation product of tyramine catalyzed by 10 nM hemin (a), probe (b), probe/GO (c) for 10 min, and probe for 10 min following by mixing with 0.75 µg mL⁻¹ GO (d). (B) Effect of GO concentration on its inhibiting efficiency. The catalytic reaction is carried out in 50 mM Tris-HCl (pH 7.4, containing 300 mM NaCl) with 0.7 mM tyramine and 2 mM H₂O₂.

To clarify the inhibition efficiency of GO toward the peroxidase activity of the probe, the 2,7'-dichlorodihydrofluorescein diacetate (H₂DCFDA) as non-fluorescent substrate was involved in this system. This compound could be catalytically oxidized into fluorescent 2,7'-dichlorofluorescein in the presence of H₂O₂ (Scheme S1B). Although the catalytic fluorescent signal was also inhibited by GO, the inhibiting efficiency of 57.1% was lower than the case of tyramine even at 20 times higher GO concentration of 15 µg mL⁻¹ (Fig. S3). The different inhibition effects of GO could be explained as shown in Scheme S2. After GO absorbed the hemin labelled ssDNA probe through π-π interaction between ssDNA and GO, hemin would be brought to the hydrophobic π-conjugated carbon structures in the center of GO. Compared with tyramine, H₂DCFDA has a larger π-conjugated structure with more hydrophobic property, which allowed easier access to hemin absorbed on GO surface. Thus GO exhibited a more remarkable inhibition effect for tyramine than H₂DCFDA.

The inhibiting efficiency for tyramine depended on pH of the reaction buffer. Although the inhibiting efficiency increased with the decreasing pH from 9.0 to 6.5 (Fig. 2A), the probe showed the highest catalytic fluorescent signal at pH 7.4 (Fig. S4). Thus pH 7.4 was chosen as optimal value for next experiments. The inhibiting efficiency on catalytic fluorescent signal also depended on salt concentration of the buffer. As shown in Fig. 2B, with the increasing NaCl concentration, the inhibiting efficiency increased and reached a maximum at 300 mM. More concentration of Cl⁻ led to the axial coordination between Fe³⁺ and Cl⁻, thus slightly lowered the peroxidase activity of hemin. Both low pH and high NaCl concentration were favour of minimizing the electrostatic repulsion between the negatively charged probe and GO, thus resulted in the closer contact between labeled hemin and GO as well as intense peroxidase activity inhibition by GO. High concentrations of tyramine and H₂O₂ slightly decreased the inhibiting efficiency due to the limited amount of probe/GO and the maximum efficiency was achieved at 0.7 mM tyramine and 2 mM H₂O₂ (Fig. 2C and 2D).

![Fig. 2](image2.png)

**Fig. 2** Effects of (A) pH, (B) NaCl, (C) tyramine and (D) H₂O₂ concentration on inhibiting efficiency of GO toward fluorescent signal of oxidation product catalyzed by the probe. The concentration of probe and GO is 10 nM and 0.75 µg mL⁻¹, respectively.

The catalytic property of the hemin labeled ssDNA probe was further investigated by recording fluorescence kinetic curves. After adding tyramine and H₂O₂ to initiate the catalytic reaction, the fluorescent signal of the oxidation product catalyzed by probe or probe/target duplex increased obviously and reached a plateau at 10 minutes (Fig. 3A, curves a and b), indicating the hybridization with target would barely affect the peroxidase activity of the probe. When GO was introduced to interact with the probe, the fluorescent signal catalyzed by probe/GO was greatly suppressed (Fig. 3A, curve c). However, when the probe was firstly hybridized with target DNA from 10 to 40 nM and then added GO, the fluorescent signal catalyzed by the probe enhanced gradually (Fig. 3A, curves d, e and f). This change could be attributed to the weaker affinity of GO to dsDNA than ssDNA due to the rigid duplex structure and the shield of phosphate backbone on the nucleotide bases, thus weakened the interaction between hemin labelled dsDNA and GO, and the inhibition effect of GO.

The interaction between the probe or probe/target duplex and GO was demonstrated by gel electrophoresis. As shown in Fig. S5, the probe displayed only one band in the gel (lane a). After interaction with GO, the probe/GO did not show obvious band (lane b) because the probe was absorbed by GO to form the probe/GO, which could hardly penetrate into the gel due to the large steric hindrance of GO. However, when the probe was firstly hybridized with target and then mixed with GO, the probe/target duplex exhibited a slow-moving band (lane c), suggesting the hybridization of target with probe led to the detachment of the probe from GO.

The different inhibition effects of GO toward peroxidase activity of ssDNA- and dsDNA-linked hemin offered a opportunity to design a novel homogeneous fluorescence DNA sensing strategy. GO was usually used as fluorescent quencher in conventional fluorescence...
