This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Vapochromism associated with the changes in the molecular arrangement of organic crystals

Shinji Yamada,* Ayaka Katsuki, Yuka Nojiri and Yoko Tokugawa

Exposure of the yellow anhydrate crystals of 4'-alkoxy-4-azachalcones to water vapor gave red hydrate crystals. On the other hand, dehydration of the hydrate phase by heating recovered the anhydrate yellow phase. A comparison of the crystal structures of the anhydrate and hydrate crystals confirmed that the molecular arrangement is significantly changed during the hydration-dehydration processes: the changes in the orientation mode from head-to-tail to head-to-head, and the displacement of chloride ions and water molecules are involved in the crystal transformations. PXRD studies clarified the reversibility of the crystal transformations occurring in the hydration-dehydration processes.

Introduction

Compounds showing reversible color changes in the solid-state in response to vapor molecules have received considerable attention due to their potential utility as sensing materials. Among the various vapochromic materials reported to date, MOFs and metal complexes have been extensively explored as they can uptake vapor molecules due to their porosity and coordination properties. On the other hand, although a number of organic crystals are known to show vapor-induced crystalline transformations, only a few vapochromic organic crystals have been reported. The origins of the vapochromism in organic crystals have been shown to conformational and structural changes in the molecules, leading to a CT interaction and changes in the electronic properties.

In the course of our studies on crystal engineering using cation-π interactions, we have reported that 4'-methoxy-4-azachalcone hydrochloride forms crystals with a head-to-tail columnar motif stabilized by cation-π interactions. Continuing our research program, we found a new polymorphic red hydrate phase (1a·HCl·H₂O) that has a significantly different crystal structure from that of the yellow anhydrate phase described above. In this communication, we report the vapochromism associated with the remarkable changes in the molecular arrangement of organic crystals during in the hydration and dehydration processes (Fig. 1).

Experimental section

Crystallization

Crystallization of 4'-methoxy- (1a) and 4'-ethoxy-4-azachalcone (1b) from MeOH in the presence of 1.2 equiv of HCl produced yellow single crystals of 1a·HCl and 1b·HCl. On the other hand, crystallization from MeOH and H₂O produced red hydrate crystals 1a·HCl·H₂O and 1b·HCl·H₂O (Scheme 1). The yellow and red crystals are shown in Fig. 2. The hydrate...
crystals contained 1.0 equiv of water molecules, which was confirmed by thermogravimetric analysis.

**Crystallographic details**

All measurements were made on a Rigaku R-AXIS RAPID II diffractometer using graphite monochromated Cu-Kα radiation. The data were collected at a temperature of -150 ± 1°C to a maximum 2θ value of 136.5°. The structures were solved by direct methods and expanded using SHELXS697 program and refined by full-matrix least-squares refinement on F^2 using SHELX-97. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms of all CH and NH were refined using the riding model. On the other hand, hydrogen atoms of water molecules were located by the difference Fourier synthesis and refined isotropically. Figures were generated using the program Mercury.¹³

Crystal data for 1a·HCl·H₂O: C₁₂H₆NO₃Cl; red block, monoclinic, space group P2₁/n; a = 5.19126(15), b = 33.4280(10), c = 9.2170(3) Å; β = 112.0213(14)°; V = 1482.77(8) Å³; Z = 4; ρcalcd = 1.316 g cm⁻³; 2θmax = 136.5°; T = 298(1) K; 23293 reflections collected, 2669 independent, 191 parameters; µ = 2.344 mm⁻¹; R1 = 0.0500 [I > 2.0σ(I)], wR2 = 0.1510 (all data); CCDC deposition number 1006003.

Crystal data for 1b·HCl: C₁₂H₆NO₃ClO; yellow prism, monoclinic, space group P2₁/c; a = 7.1274(2), b = 12.8781(3), c = 15.9263(5) Å; β = 103.450(2)°; V = 1424.95(6) Å³; Z = 4; ρcalcd = 1.351 g cm⁻³; 2θmax = 136.5°; T = 123(2) K; 15692 reflections collected, 2621 independent, 182 parameters; µ = 2.379 mm⁻¹; R1 = 0.0371 [I > 2.0σ(I)], wR2 = 0.1004 (all data); CCDC deposition number 1006004.

Crystal data for 1b·HCl·H₂O: C₁₂H₆NO₃ClO; red plates, triclinic, space group P-1; a = 4.88516(18), b = 8.6653(3), c = 18.6176(7) Å; α = 86.980(3), β = 85.549(3), γ = 80.147(2)°; V = 773.52(5) Å³; Z = 2; ρcalcd = 1.321 g cm⁻³; 2θmax = 136.5°; T = 123(2) K; 8223 reflections collected, 2764 independent, 198 parameters; µ = 2.344 mm⁻¹; R1 = 0.0549 [I > 2.0σ(I)], wR2 = 0.1249 (all data); CCDC deposition number 1006005.

**Thermal analysis**

TG/DTA measurements of the crystals of 1a·HCl, 1b·HCl, 1a·HCl·H₂O and 1b·HCl·H₂O were carried out using Bruker TG-DTA 2000SA instrument to examine the thermal stability of the crystals and to determine the wt% of the water remaining in the crystals. DSC measurements were carried out using Bruker DSC3100SA. In the experiments, the samples were examined in a sealed pan under nitrogen atmosphere.

**Results and Discussion**

**Crystal structures of 1a·HCl, 1a·HCl·H₂O, 1b·HCl and 1b·HCl·H₂O.**

X-ray crystallographic analyses of 1a·HCl, 1b·HCl, 1a·HCl·H₂O and 1b·HCl·H₂O were then performed. The crystal structure of 1a·HCl, which is as previously reported,¹¹ is shown in Fig. 3a and 3b. The molecules and chloride anions associated through the N-H···Cl⁻ and C-H···Cl⁻ hydrogen bonds to form a 2D sheet. The molecules were arranged in a head-to-tail manner and formed columns through cation-π interactions.

The crystal structure of 1a·HCl·H₂O, in which 1 equiv of water molecules was involved, is shown in Fig. 3c and 3d. A comparison of the X-ray structures with those of 1a·HCl shows that the water molecule displaced the chloride anion to form H-bonds with the substrate molecule and chloride ion via C(2)-H···O(1) and O(1)-H···Cl(2) hydrogen bonds. The chloride anion and the molecules associated through the N(1′)-H···Cl(2) and C(5′)-H···Cl(2) hydrogen bonds to form a 2D sheet involving a synthon with an R₂⁺(10) ring motif.¹⁴ The molecules were arranged in a head-to-head and face-to-face fashion to form columns as shown in Fig. 3d. The pyridinium and benzene rings reside above and below the double bond moiety. The distances between the centroids of the double bond and those of the pyridinium and aren rings are 3.659 Å and 3.572 Å, respectively, suggesting that the columns are stabilized by cation-π and π-π interactions.¹⁵ The water molecules and the chloride anions linked together through an O-H···Cl hydrogen bond to form a 1D zigzag chain motif. This chain, linked with the columns through N(1)-H···Cl(1) and C(2)-H···O(1) hydrogen bonds, assists in the formation of the head-to-head column motif. The D···A distances of O(2)-H···Cl(1), O(3)-H···Cl(1), N(1)-H···Cl(1) and C(2)-H···O(1) are 3.169(3), 3.175(3), 3.024(2) and 3.380(4) Å, respectively. The crystal structures of 1b·HCl and 1b·HCl·H₂O are shown in Fig. 4. Their structural features with respect to orientation modes and H-bond networks are very close to those of the crystal structures of 1a·HCl and 1a·HCl·H₂O, respectively.
Fig. 3 Crystal structures of 1a·HCl and 1a·HCl·H₂O: (a) top view and (b) side view of 1a·HCl, and (c) top view and (d) side view of 1a·HCl·H₂O. Selected H-bond distances (Å) for 1a·HCl: Cl1···C2 = 3.552, Cl1···C5' = 3.500, Cl1···N1" = 2.977. Selected H-bond distances (Å) for 1a·HCl·H₂O: Cl1···N1 = 3.024, Cl1···O2 = 3.175, Cl1···O3 = 3.170, O1···C2 = 3.380, O1···C7 = 3.556, O1···C10 = 3.481.

Fig. 4 Crystal structures of 1b·HCl and 1b·HCl·H₂O: (a) top view and (b) side view of 1b·HCl, and (c) top view and (d) side view of 1b·HCl·H₂O. Selected H-bond distances (Å) for 1b·HCl: Cl1···C2 = 3.604, Cl1···C5' = 3.471, Cl1···N1" = 2.999. Selected H-bond distances (Å) for 1b·HCl·H₂O: Cl1···N1 = 3.064, Cl1···O2 = 3.203, Cl1···O3 = 3.180, O1···C2 = 3.429, O1···C7 = 3.515, O1···C10 = 3.502.
Powder XRD patterns

To elucidate changes in the molecular arrangement of 1a·HCl occurring in during the dehydration-hydration processes, we performed PXRD experiments. When the hydrate crystals of 1a·HCl·H₂O were heated at 80°C for 5h under reduced pressure, the color of the powder turned from red to yellow. Thermogravimetric analysis of the resultant yellow powder confirmed the completion of dehydration. Fig. 5b shows the PXRD pattern of the dehydrated powder, which is in agreement with the simulation pattern of 1a·HCl (Fig. 5a). When this anhydrous powder was kept in a desiccator with saturated water vapor for 7 days, new peaks appeared (Fig. 5c). After exposure for 10 days, the crystals turned red once more, and the PXRD pattern was in close agreement with the simulation pattern of the hydrate, showing that the anhydrous 1a·HCl was rehydrated to produce 1a·HCl·H₂O (Figs. 5d and 5e). Thermogravimetric analysis of the resultant red powder confirmed the completion of hydration (ESI).† These observations show the reversibility of the crystal transformation taking place during in the hydration and dehydration processes, and which involves changes from a head-to-tail to a head-to-head orientation and a displacement of the chloride anions and water molecules.

Although a similar phenomenon was also observed for 1b·HCl and 1b·HCl·H₂O, the hydration of the dehydrate 1b·HCl was much faster than that of 1a·HCl and gave the hydrate 1b·HCl·H₂O even in open air (ESI).† Fig. 6 clearly shows the rapid change in the color of the crystals. The red 1b·HCl·H₂O crystals shown in Fig. 6a were dehydrated by heating at 80 °C for 5h to give yellow crystals (Fig. 6b). When these were left in open air for 5 min, the surface of the crystals turned red (Fig. 6c). After 18h, the color was restored to that before dehydration (Fig. 6d).

DSC experiments

Differential scanning calorimetry (DSC) measurements for the hydrate 1a·HCl·H₂O were performed, and endotherm and exotherm peaks were observed at around 88.9 °C and 103.4 °C, respectively (Fig. 7). The endotherm corresponds to a loss of 1 equiv of water molecules, which was confirmed by thermogravimetric analysis. As the dehydrate phase upon heating was in agreement with the anhydrous phase of 1a·HCl, as elucidated by the PXRD experiments described above, the exothermic transition could be attributed to the reorientation of the molecules from a head-to-head to a head-to-tail orientation stabilized by cation-π interactions. Similar endotherm and exotherm peaks were also observed in the DSC experiments for 1b·HCl·H₂O.
property. It has been reported that, in the opsin protein, the key role in the absorption wavelength. The distance between a counter anion and an iminium moiety plays during the hydration process.

The position of the chloride ion was also significantly changed during the hydration process. The interplanar angle between two six-membered rings changed from 5.27 to 12.59 degree and the red shift. Furthermore, the position of the chloride anion is unclear, the changes in the orientation mode of the molecules remarkably red shift induced by the hydration process is still a problem. Although the reason for the present case, little conformation changes occur during the hydration-dehydration processes. To the best of our knowledge, there is no example of vapochromism involving such a remarkable changes in the crystal transformation. Although the mechanism underlying the significant red shift upon hydration is still unclear, the changes in the orientation mode and H-bond network as well as in the location of the counter ion toward the pyridinium ring are speculated to be responsible for the remarkable color change.
