This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
The role of oxygen vacancies and their location on the magnetic properties of Ce$_{1-x}$Cu$_x$O$_{2-\delta}$ nanorods

Ceria (CeO$_2$) is a promising dilute magnetic semiconductor. Several works report that the intrinsic and extrinsic structural defects are responsible for room temperature ferromagnetism in undoped and transition metal doped CeO$_2$ nanostructures; however the nature of the necessary kind of defect to promote and stabilize the ferromagnetism in such system is still a matter of debate. In the work presented here, nanorods from the system Ce$_{1-x}$Cu$_x$O$_{2-\delta}$ with $x = 0, 0.01, 0.03, 0.05$ and $0.10$, with the higher stable \{111\} surface exposed were synthesized by a microwave-assisted hydrothermal method. A very careful structure characterization confirms that the Cu in the samples assumes a majority 2$^+$ oxidation state, occupying the Ce$^{4+}$/Ce$^{3+}$ sites with no secondary phases up to $x = 0.05$. The inclusion of the Cu$^{2+}$ in the CeO$_2$ structure leads to the introduction of oxygen vacancies in a density proportional to the Cu$^{2+}$ content. It is supposed that the spatial distribution of the oxygen vacancies follows the Cu$^{2+}$ distribution by means of the formation of a defect complex consisting of Cu$^{2+}$ ion and an oxygen vacancy. Superconducting quantum interference device magnetometry demonstrated a diamagnetic behavior for the undoped sample and a typical paramagnetic Curie–Weiss behavior with antiferromagnetic interactions between the Cu$^{2+}$ ions for the single phase doped samples. We suggest that the presence of oxygen vacancies is not a sufficient condition to mediate ferromagnetism in the CeO$_2$ system; only oxygen vacancies in the surface of nanostructures would lead to such long range magnetic order.

1. INTRODUCTION

Ceria (CeO$_2$) nanostructures have attracted the interest of many researchers in the past decade due to their great potential for applications in catalysis, electrochromic devices, gas sensors, ultraviolet radiation detectors, environmental-friendly pigments, gamma radiation dosimetry, etc.$^1$ Concerning its magnetic properties, some experimental results have observed room temperature ferromagnetism (RTFM) for transition metal doped$^2$ and undoped$^3$ systems. These results launch the CeO$_2$ systems to the class of materials known as dilute magnetic oxides (DMOs) with potential application in the development of spintronic devices. Moreover, due to its cubic structure and cell parameter close to the Si, the CeO$_2$ systems have also the desirable advantage of easy integration to the conventional electronic devices.$^4$

For DMOs the main theoretical models that take into account the observed RTFM for the different oxide matrices are the $d^0$ magnetism for undoped systems,$^5$ the Bound Magnetic Polaron (BMP) theory,$^6$ and the carrier-mediated mechanism,$^7$ the two latter for the transition metal (TM) doped systems. It is important to mention also a sub-category of BMP theory named F-center exchange (FCE).$^8$ In all these models the defect concentration plays an important role. In the $d^0$ magnetism the defects by themselves are responsible for the RTFM by means of a spin polarized density of states around the Fermi level, whereas in the BMP theory the defects are responsible for the ferromagnetic coupling between the magnetic ions used to dope the oxide matrix, and in the carrier-mediated mechanism the free charge carriers introduced in the system by donor or acceptor-like defects are the responsible ones for the ferromagnetic coupling. In this context, the origin of the observed RTFM for doped and undoped oxides and its relation with specific group of defects is still a matter of debate.$^9,15$

Nanostructured CeO$_2$ samples are normally a nonstoichiometric compound of the type CeO$_{2-\delta}$, due to the losses of oxygen in the regions near the surfaces with the environment. As a consequence of the introduced oxygen vacancies (V$_O$), a reduction of the Ce$^{4+}$ ions to Ce$^{3+}$ occurs in these regions, leading to a lattice expansion for CeO$_{2-\delta}$ nanoparticles.$^{16,17}$ Sundaresan et al.$^{13}$ suggested that all metal oxides in nanoparticulate form would exhibit room-temperature ferromagnetism due to the exchange interactions between unpaired electron spins arising from oxygen vacancies at the nanoparticles surface. After Sundaresan, a variety of experimental and theoretical papers reported the observation of RTFM in doped and undoped nanostructured CeO$_2$ samples and also correlated it to oxygen vacancies.$^{18,20}$ On the other hand, Liu et al.$^{21}$ showed that oxygen vacancies do not mediate the ferromagnetism in undoped CeO$_2$ nanostructures, but instead, cerium vacancies would be the
responsible for the observed RTFM. Fernandes et al.\textsuperscript{9} observed a considerable decrease of the magnetization saturation with the storage time (age). These authors associated this behavior to an oxidation process (loss of oxygen vacancies) and concluded that part of observed ferromagnetic behavior could be directly associated to this kind of defect. However, after a long period of storage time, a low effective remnant magnetization was observed and, like Liu et al.,\textsuperscript{22} attributed this fraction of the observed RTFM to Ce vacancies. All the last cited references\textsuperscript{9,18-23} argue that the most important defects associated to the RTFM would be located at the surface of the grains or nanoparticles, following Sundaresan et al.\textsuperscript{3}

In the present work, nanorods from the system Ce\textsubscript{1−x}Cu\textsubscript{x}O\textsubscript{2−δ} with $x = 0, 0.01, 0.03, 0.05$ and $0.10$, with the higher stable {111} surface exposed (growth direction [211]) were synthesized by a microwave-assisted hydrothermal method. This synthesis method combines the advantages of both hydrothermal and microwave-irradiation techniques such as very short reaction time, production of small particles with a narrow size distribution and high purity.\textsuperscript{24} Nanostructured Cu-doped CeO\textsubscript{2} (Ce\textsubscript{1−x}Cu\textsubscript{x}O\textsubscript{2−δ}) materials are of large interest because of their high catalytic activity. Several reports on the literature have proven that the Ce\textsubscript{1−x}Cu\textsubscript{x}O\textsubscript{2−δ} system is efficient catalyst for the selective CO oxidation,\textsuperscript{25} the hydrogen combustion reaction,\textsuperscript{26} and for the water-gas shift (WGS) reaction,\textsuperscript{27} just to cite a few examples. In the context of the dilute magnetic semiconductors, the Cu doping has the advantage that metallic dopant, as well as all possible dopant-based secondary phases, are nonferromagnetic.\textsuperscript{28} Therefore, if any ferromagnetism is observed in a Cu-based system, it would undoubtedly be an intrinsic property of the material. Moreover, the most stable oxidation state of Cu is $+2$,\textsuperscript{29} for this reason, the introduction of Cu in the CeO\textsubscript{2} matrix in a substitutional character of the Ce ions (Ce\textsuperscript{4+}) leads, by a charge-compensation process,\textsuperscript{30} to the introduction of oxygen vacancies into the system in double proportion of the Ce\textsuperscript{2+} concentration ($\delta = 2x$).\textsuperscript{31} The doping of CeO\textsubscript{2} matrix with nonferromagnetic elements was reported for different groups.\textsuperscript{19,32} Here, the conclusions are also controversial, while most of them associated the ferromagnetic properties to oxygen vacancies, Chen et al.\textsuperscript{32} attributed the observed ferromagnetism to lattice distortions caused by the smaller size of the dopant. In the special case of Cu doping there is few reports on the literature concerning its magnetic properties. Slusser et al.\textsuperscript{33} reported paramagnetism (PM) in undoped and RTFM in Cu doped CeO\textsubscript{2}. Seehra et al.\textsuperscript{34} observed a small RTFM component superimposed in a main PM component for both undoped and Cu-doped CeO\textsubscript{2} nanoparticles, for the undoped CeO\textsubscript{2} samples the observed RTFM was attributed to Fe impurities. However, for Cu-doped samples they observed a correlation between the PM and the RTFM components and the Cu content and the observed magnetic properties were argued to be an intrinsic effect due to Cu doping. Based on the Slusser and Seehra reports, Li et al.\textsuperscript{35} performed first-principles calculations within density-functional theory (DFT) to study the origin of the magnetism in Cu-doped CeO\textsubscript{2}. In their report they conclude that the Cu doping by itself could not account for the observed RTFM. However, they found that a strong ferromagnetic coupling can be achieved between the defect complexes Cu\textsuperscript{4+} + V\textsubscript{O}. In another article, Fernandes et al.\textsuperscript{36} reported the loss of magnetization under doping the CeO\textsubscript{2} matrix with transition metals. The observed magnetic behavior was analyzed under the scope of the F-center exchange (FCE) interaction model.\textsuperscript{8} They argued that the dopant elements change the spatial-charge density distribution impairing the formation of magnetic moments along the volume of the sample. In the context of the aforementioned research, the main goal of our work was to elucidate the ambiguous situation concerning the influence of oxygen vacancies and the Cu doping on the magnetic properties of nanostructured CeO\textsubscript{2} systems.

2. EXPERIMENTAL

In a typical procedure to obtain Ce\textsubscript{1−x}Cu\textsubscript{x}O\textsubscript{2−δ} ($x = 0.01, 0.03, 0.05$ and $0.10$) nanostructures, $0.02$ mol of precursors, cerium chloride (CeCl\textsubscript{3}·7H\textsubscript{2}O) and copper chloride (CuCl\textsubscript{2}·2H\textsubscript{2}O), were dissolved in $50$ mL of distilled water. Then, $50$ mL of $10$ mol.\textsuperscript{−1} NaOH was added rapidly under vigorous stirring. The mixed solution was placed in a $110$ mL Teflon autoclave reaching $90\%$ of its volume, which was sealed and placed in a microwave hydrothermal system, applying $2.45$ GHz of microwave radiation at a maximum power of $800$ W. The as-prepared solution was subjected to the microwave hydrothermal synthesis temperature of $140$ °C for $10$ min at a heating rate of $140$ °C-min\textsuperscript{−1} and then air-cooled at room temperature. The as-obtained precipitate powder was washed several times with distilled water and isopropyl alcohol and then dried at $60$ °C for $24$h.

The powders were characterized structurally in an X-ray diffractometer (Rigaku, Rotaflex RU200B) with CuK\textsubscript{α} radiation ($50$ kV, $100$ mA, $\lambda = 1.5405$ Å), using a $0–20$ configuration and a graphite monochromator. The scanning range was between $20$ and $80°$ ($20$), with a step size of $0.02°$ and a step time of $5.0$ s. A Rietveld analysis was performed using the program GSAS.\textsuperscript{37} The size and morphology of the samples were determined by transmission electron microscopy (TEM) using a JEOL JEM 2010 URP, operating at $200$ keV. Raman spectroscopy was carried out at room temperature in a Jobin-Yvon-4000 micro-Raman system in the backscattering geometry, using the $488$ nm line of an Ar\textsuperscript{+} laser for excitation. We used an optical lens with $100X$ magnification, which supplies an average laser spot size of $1$ μm. X-ray absorption near edge spectroscopy (XANES) and extended X-ray absorption fine structure (EXAFS) measurements at Ce $L_{\text{III}}$-edge of Ce\textsubscript{1−x}Cu\textsubscript{x}O\textsubscript{2−δ} samples were collected in transmission mode as a function of the temperature using a Si(111) channel-cut monochromator at the LNLS (National Synchrotron Light Laboratory) facility. XANES spectra at Cu $K$-edge were also acquired. The extraction and fit of EXAFS spectra were performed using the Multi-Platform Applications for X-Ray absorption (MAX) software package\textsuperscript{38} and theoretical spectra were calculated using FEFF9 code.\textsuperscript{39} The magnetic measurements were performed in a Quantum Design superconducting quantum interference device (SQUID) system.

3. RESULTS AND DISCUSSION

3.1. Electron Microscopy and Elemental Analyses. Figure 1 presents representatives TEM and HRTEM images of the Ce\textsubscript{0.95}Cu\textsubscript{0.05}O\textsubscript{2−δ} nanoparticles. The samples are composed mainly of nanorods with an average diameter of $10$ nm and a length of $70$ nm (Figure 1(a)). The HRTEM image (Figure 1(b) and (c)) and their respective Fast Fourier Transform (FFT) (Figure 1(d)) confirm the single-crystal nature of the Ce\textsubscript{1−x}Cu\textsubscript{x}O\textsubscript{2−δ} nanostructured samples. The HRTEM results revealed that the growth direction of the nanorods is along the [211] direction. In spite of the few reports on the synthesis of nanorods with the same growth orientation in literature,\textsuperscript{36,41} the growth along the [211] direction has proven to be feasible from the theoretical point of view\textsuperscript{35} and is explained by an oriented attachment (OA) process followed by Ostwald ripening of ceria nanocrystals of truncated octahedral shape enclosed by eight {111} and six {200} planes.\textsuperscript{52} By this process the CeO\textsubscript{2} nanocrystals, which acts as seeds of the nanorods, may attach by the alignment through the [211] direction leaving exposed the [111] surfaces, or by aligning through the [110] direction with [200] surfaces exposed. Since the CeO\textsubscript{2} [111] surface is the most stable,\textsuperscript{43} the former would be more energetically favorable. These results
are in accordance with a previous report, where CeO$_2$ nanorods were obtained by the same synthesis route. Also, one might say that the introduction of Cu (limited between 1 and 10% Cu in this paper) in CeO$_2$ matrix does not affect the morphology of the nanoparticles.

(c) Expanded view of selected region in (b) and (d) Fast Fourier Transform (FFT) of selected region, zone axis [110]. (e) Length and (f) diameter size distribution histograms. The dashed line in panel (e) and (f) is the log-normal fit.

3.2. X-Ray Diffraction. Figure 2 shows the X-ray diffraction (XRD) patterns for Ce$_{1-x}$Cu$_x$O$_2$−$_\delta$ nanostructured samples. The typical fluorite CeO$_2$ structure (ICSD n° 156250) is observed in all samples. CuO peaks were detected only in the sample with 10% of Cu content (Ce$_{0.90}$Cu$_{0.10}$O$_2$−$_\delta$). No copper or other foreign peaks were observed for the other samples within the XRD detection limit. Table 1 presents the lattice parameter (a) and the oxygen occupancy factor ($O_{oc}$) calculated from the Rietveld refinement for the whole set of samples. The lattice parameter of our nanostructured undoped CeO$_2$ sample is slightly bigger than that for bulk CeO$_2$, 5.411 Å (JCPDS 43-1002). The surface-to-volume fraction is large at nanoscale, facilitating the oxygen loss from CeO$_2$ matrix to an inert gas environment. As mentioned before, these introduced oxygen vacancies, lead to the reduction of the oxidation states of the Ce ions (Ce$^{4+}$ into Ce$^{3+}$), which induces an increase in the lattice parameter due to the decrease in electrostatic forces and due to the bigger ionic radii of Ce$^{3+}$ (ionic radii = 1.283 Å), as compared to the Ce$^{4+}$ (ionic radii = 1.11 Å). The lattice parameters for the Cu-doped samples neither vary with Cu content nor show significant difference as compared to the undoped one. As pointed out by McBride et al., the resulting lattice constant under doping is not determined solely by the ionic radius. Coulomb effects, oxygen vacancies, and changes in the force constants introduced by doping may also play important roles. In fact, our results are in good agreement with that one obtained by Wang et al., which observed very small variations in cell dimension as a consequence of doping ceria with Cu. The small expansion of the Ce$_{1-x}$Cu$_x$O$_2$−$_\delta$ cell volume was attributed to the O vacancies in the oxide lattice. Wang et al. also argue that due to the relatively small size of Cu$^{2+}$ with respect to Ce$^{4+}$, the Cu cations do not fit well in the dodecahedral standard positions for the Ce cations in the ceria lattice and tend to adopt a nearly planar, four-coordinated first shell. In others words, the introduction of O vacancies did not lift the unexpected eight-coordination of the Cu cations and led to small expansion in the cell dimensions. The expected decrease in oxygen occupancy with increasing copper content is shown on Table 1. The increase of the Ce$^{3+}$ content with copper doping was also further confirmed by analysis of the local structure.

3.3. Raman Scattering Spectroscopy. Figure 3 shows Raman spectra of the samples. Dioxides with a fluorite structure have only one allowed Raman mode, which has a F$_{2g}$ symmetry and can be viewed as a symmetric breathing mode of the oxygen atoms around each cation. Since only the oxygen atoms move, the mode...
frequency should be nearly independent of the cation mass. In bulk CeO$_2$ this frequency is 465 cm$^{-1}$. Here we observed two main features centered at 460 and 600 cm$^{-1}$. The former is assigned to the fluorite $F_{2g}$ mode, confirming the XRD results. The broad band from 550 to 650 cm$^{-1}$ can be deconvoluted into two main bands, one at 550 cm$^{-1}$ and other at 600 cm$^{-1}$. The 550 cm$^{-1}$ band is assigned to oxygen vacancies introduced into the ceria in order to maintain charge neutrality when Ce$^{4+}$ ions are replaced with Cu$^{2+}$ ions. Besides, the 600 cm$^{-1}$ band is ascribed to the intrinsic oxygen vacancies due to the presence of Ce$^{3+}$ ions in the ceria matrix, which can be observed in the Raman spectrum for the undoped sample (CeO$_{2.0}$). As the copper content increases, the $F_{2g}$ mode slightly shifts to higher frequencies (not shown) and become broader and asymmetric at the low-frequency side, while the mode around 600 cm$^{-1}$ becomes more intense. Since the lattice parameter remains constant with increasing copper content, one can assume that this behavior is due to the increase of oxygen vacancies related to the Cu incorporation to the CeO$_{2.8}$ matrix. For the sample with 10% of Cu content (Ce$_{0.90}$Cu$_{0.10}$O$_{2.8}$), the modes at around 300 and 630 cm$^{-1}$ can be attributed to the CuO segregated phase, corroborating XRD results presented before.

![Figure 3. Raman spectra of the Ce$_{1.0}$Cu$_{0.0}$O$_{2.8}$ nanorods. The inset shows the part of the spectra corresponding to modes associated to oxygen vacancies. The spectra were normalized by the integrated area of the $F_{2g}$ mode. For clarity, the curves are displaced along the vertical axis.](image)

3.4. X-ray Absorption. Figure 4 presents the XANES spectra at Ce $L_{III}$-edge for Ce$_{1.0}$Cu$_{0.0}$O$_{2.8}$ samples and the spectrum of a CeO$_2$ standard reference with Ce$^{4+}$. These spectra result from the configuration interaction due to mixing of Ce 4f and O 2p valence orbitals associated with the crystal-field splitting of the Ce 5d final state. At the pre-edge region the peak denoted as A is associated to a forbidden dipole transitions from the bottom of the conduction band. Peak labeled as C corresponds to a transition to the final state of 2p4f$^15d^1\nu$ (electron excited from 2p to 5d, with empty 4f; $\nu$ denotes a hole in the valence band) of Ce$^{3+}$, whereas peaks D$_1$ and D$_2$ are also Ce$^{3+}$ peaks, with the final state of 2p4f$^15d^2\nu$. As can be seen in Figure 4, the edge energy for the spectra of Ce$_{1.0}$Cu$_{0.0}$O$_{2.8}$ samples is close to the edge energy of standard spectrum, indicating a predominance of Ce$^{4+}$.

![Figure 4. XANES spectra at Ce $L_{III}$-edge for Ce$_{1.0}$Cu$_{0.0}$O$_{2.8}$ nanorods.](image)

The concentration of Ce$^{3+}$ ions in the samples ([Ce$^{3+}$]) can be estimated from the feature labeled as B at white line of the spectra. XANES spectra of all the samples were fitted with Gaussian functions and an arctangent function as the edge jump. The estimative of [Ce$^{3+}$] was taken by the relative intensity of the integrated area of peak B (inset equation in Figure 5). The results of these analyses are shown in Figure 5, the [Ce$^{3+}$] is around 7% for Ce$_{1.0}$Cu$_{0.0}$O$_{2.8}$ samples. In spite of the fitting errors, we can identify an increasing tendency of [Ce$^{3+}$] as Cu content increases, a variation of around 1% of the [Ce$^{3+}$] with the insertion of 10% of Cu into the CeO$_{2.8}$ matrix, in good agreement with the calculated and measured variation obtained by Chen et. al for Ca$^{2+}$ doped CeO$_{2.8}$ samples. As pointed out before, the proportional amount of Ce$^{3+}$ in the CeO$_2$ system is explained in terms of the Ce$^{4+}$ reduction to Ce$^{3+}$ due to oxygen vacancies. Therefore, this behavior confirms the XRD and Raman previous results concerning the introduction of oxygen vacancies into the CeO$_{2.8}$ matrix by the Cu-doping due to the charge compensation process and the increasing of the Ce$^{3+}$/Ce$^{4+}$ proportion.

![Figure 5. [Ce$^{3+}$] concentration calculated from integrated areas (inset equation) obtained by a Gaussian fit of the XANES spectra as a function of Cu concentration. Inset graph presents, as an example, the fitted spectrum for the undoped CeO$_{2.8}$.](image)
XANES spectra at Cu K-edge were also measured for single phase samples, \( x = 0.01, 0.03 \) and 0.05. The valence of the dopant ions can be analyzed and calculated by comparing their resulting edge structure from those obtained from reference samples.\(^{55}\) Figure 6 shows the XANES spectra obtained for our samples and for oxides with different Cu oxidation states, CuO and Cu2O. The Cu K-edge spectrum is characterized by a single well-defined peak at white line which is due to the 1s → 3p electronic transition; the pre-edge peak is due to the dipole-forbidden, quadrupole-allowed 1s → 3d electronic transition and represents a significant feature for Cu\(^{2+}\) because there is no 3d vacancy in the Cu\(^{2+}\). The comparison with the spectra from our samples and the calculated oxidation state \((+2±0.1)\) indicates that Cu assumes predominantly the 2\(^{+}\) oxidation state, which corroborates the previous analysis.

![Figure 6. XANES spectra at Cu K-edge for the single phase Cu doped CeO\(_2\) nanorods (\( x = 0.01, 0.03 \) and 0.05). Spectra of CuO (valence 1\(^{+}\)), and Cu2O (valence 2\(^{+}\)) are also shown for comparison. The inset highlights the details of the white-line peak.](Image 8)

The short-range structural data provided by EXAFS offer an element-specific insight, giving quantitative information about the number, position and identity of atoms surrounding the absorbing element as well as structural disorder within the coordination spheres. Figure 7 shows the modulus of \( k^2 \) weighted Fourier transform of single phase Ce\(_{1−x}\)Cu\(_x\)O\(_{1.9}\) samples \((x = 0, 0.01, 0.03\) and 0.05\) extracted from Ce \(L_{\text{III}}\)-Edge EXAFS spectra \((\chi(k))\). In order to obtain quantitative information of the local structure around Ce atoms, Fourier transform curves were then back Fourier transformed between 1.5 and 4.5 Å to obtain the experimental EXAFS spectra to fit using a theoretical model calculated from FEFF9 code and crystallographic information according the XRD measurements. In all fits, the number of free parameters was kept smaller than the number of independent points, which is defined as \( N_{\text{ind}} = 2\Delta R\Delta k/\pi \), where \( \Delta R \) is the width of the R-space filter windows and \( \Delta k \) is the actual interval of the fit in the \( K \) space.\(^{57}\) The reliability of the fit, determined by a quality factor \((Q)\),\(^{57}\) the interatomic distances \((R)\) and Debye-Waller factor \((\sigma^2)\) relatives to the best fits are shown in Table 2.

According to the structural model, the more intense peak, between 1.5 and 2.5 Å in the Fourier transforms of Ce\(_{1−x}\)Cu\(_x\)O\(_{1.9}\) samples, corresponds to single scattering interaction between the first eight O atoms around absorber atom. The single scattering interactions relative to Ce-Ce and Ce-O (beyond the first O neighbours) paths correspond the peaks and shoulders observed between 3.0 and 5.0 Å. This region also includes multiple scattering paths such as Ce-O-O, Ce-O-Ce-O, Ce-O-Ce-O, Ce-O-O-O and Ce-Ce-O interactions. It is important to mention that the \( L_{\text{III}}\)-edge is short in energy, limiting the adjustment and leading to error bars relatively important. The extracted parameters confirm the assumption that Cu doping do not introduce high order disorders into the structure. The radial distance \((R)\) and the coordination number \((N)\) for the first two shells do not change considerably as Cu content increases. However, we can trace an increase of oxygen vacancies following the average coordination number \((N)\) for the second O-shell. As the Cu content increases the coordination number decreases due to the increase of the oxygen vacancies. The observance of this behavior at the EXAFS data is a indirect evidence that the introduced oxygen vacancies stay close together to the Cu\(^{2+}\). It is well known that oxygen vacancies in the interior of CeO\(_{2−d}\) tend to migrate to the surface\(^{57,60}\). However, it is also reasonable to state that the Coulombic attraction energetically favors close proximity between the oxygen vacancies induced by doping and the Cu\(^{2+}\) ions forming defect associates (or defect clusters).\(^{4,35,61,62}\) Recently, experimental and theoretical reports have shown that the oxygen vacancies are attracted to cation dopants that are smaller than the host ions\(^{63,64}\), in our case, attracted to the Cu\(^{2+}\). These analyses led us to an important conclusion, that considering a homogeneous distribution of the Cu\(^{2+}\) ions, the introduced oxygen vacancies by the Cu-doping are pined along the volume of the CeO\(_{2−d}\) nanorods, avoiding any age process due to oxidation at the surfaces of the nanorods. The homogeneous distribution of the Cu\(^{2+}\) ions over the volume of the samples was further confirmed by magnetic analyses.

3.5 Magnetic Characterization. The measurements of the magnetic moment ($M$) as a function of magnetic field ($H$) are presented in Figure 8. The sample holder magnetic contribution to the raw data was carefully subtracted following standard procedures. For the undoped CuO$_{2.8}$ sample the results at 300 K (Figure 8(a)) show a typical diamagnetic behavior, however at 2 K (Figure 8(b)) the obtained $M(H)$ curve reveals also a relative small paramagnetic component. The diamagnetic phase of the undoped CuO$_{2.8}$ matrix is associated to the Cu$^{2+}$ ions, while the paramagnetic component come from the Ce$^{3+}$ ions. Considering that the concentration of Ce$^{3+}$ ions in the samples is almost constant (Figure 5), the paramagnetic properties associated solely to the Cu$^{2+}$ ions can be obtained by subtracting the diamagnetic (Ce$^{3+}$) and the paramagnetic (Ce$^{4+}$) background determined by the measurements of the undoped CeO$_{2.8}$ sample. Figures 8(a) and 8(b) also present the obtained $M(H)$ curves for the Cu-doped samples after subtract the CeO$_{2.8}$ matrix magnetic components. All Cu-doped samples present only paramagnetic behavior. It is important to stress that any evidence of a ferromagnetic phase could be observed, even for the undoped CeO$_{2.8}$ sample. Figure 8(b) shows that the saturation magnetization from the paramagnetic response of the Ce$^{3+}$ in CeO$_{2.8}$ matrix is at least 20-fold smaller than in the Cu-doped samples. The large difference observed validate the procedure of subtraction of the CeO$_{2.8}$ response from the Cu-doped ones even though the paramagnetic component associated to the Ce$^{3+}$ ions in the former.

The inverse of the dc magnetic susceptibility as a function of temperature is presented in Figure 8(c). We shall analyze this result according to the discussion by Spalek et al. The inverse of the susceptibility were fitted in the range of high temperature using the Curie-Weiss law: $g(T - \Theta) = C/(T - \Theta)$, where $C$ is the Curie constant per gram and $\Theta$ is the Curie-Weiss temperature per gram. $C$ and $\Theta$ are both linear function of the Cu content $x$: $C = cx_0$, and $\Theta = \Theta_0x$, where $C_0 = N(\mu_B)^2/3k_B$ and $\Theta_0 = 2S(S+1)/k_B$. Here, $N$ is the total number of cations per gram, $g$ the effective Landé factor of the Ce ions, we assumed $J = S = 1/2$, $\mu_B$ is the Bohr magneton, $z$ is the number of nearest-neighbor cations ($z = 12$ in the fluorite structure), $J_1$ is the effective exchange integral constant, and $\Theta_0$ is the Boltzmann constant. From our data we obtain the two main magnetic parameters for Cu$^{2+}$: $g = 2.0 \pm 0.1$ and $J_1 = -57 \pm 7$ cm$^{-1}$. These values are in good agreement with the experimental data found in the literature. The negative value for $J_1$ indicates an antiferromagnetic coupling between the Cu$^{2+}$ ions. Below 100 K, the inverse susceptibility deviates from the linear dependence, Curie-Weiss law, toward zero. This feature is due to additional antiferromagnetic interactions related to distant neighbors, which become considerable at those values of low temperature. This feature is also observed for different DMO’s.

The low temperature $M(H)$ curves (Figure 8(b)) are also consistent with the existence of antiferromagnetic coupling between Cu$^{2+}$ ion moments. These data were fitted by a Modified Brillouin Function (MBF) expressed as $M = M_0 B_{\text{MBF}}(gH/2k_B(T+\Theta_0))$ where $B_{\text{MBF}} = B_{\text{MBF}}(gH/2k_B(T+\Theta_0))$ corresponds to a correction term of the measurement temperature $T$ and it is due to distant neighbor interactions) and $M_0$ is the technical saturation magnetization, not the theoretical saturation magnetization $M_0$. We have assumed from the susceptibility results $g = 2$ and $S = 1/2$ for the Cu$^{2+}$ ions. The two main parameters extracted from the MBF fitting for the samples, $M_0/M_0$ and the correction term of the temperature, $\Theta_0$, are presented in Figure 8(d). The line represents the theoretical $M_0/M_0$ ratio calculated for a cluster model considering a random distribution of the magnetic dopants (Cu$^{2+}$) over a fcc matrix structure (CeO$_2$ fluorsite structure) with antiferromagnetic exchange interaction between only the first neighbors. The observed good agreement between the obtained experimental $M_0/M_0$ ratio with theoretical curve in Figure 8(d) is a strong evidence for a random distribution of the Cu$^{2+}$ ions in the studied samples with an antiferromagnetic coupling between them. The random distribution of the Cu$^{2+}$ ions over the volume of the samples confirms the previous assumption related to their homogeneous distribution. We also extract from the MBF fitting of...
$M(H)$ curves, positive $T_B$ values for all the samples; we also observe that $T_B$ values increase as Cu$^{2+}$ contents increase (inset table on Figure 8(d)). These results are quite in line with other reports for different DMO's, and reflect that the distant-neighbor antiferromagnetic interactions have considerable magnitude as compared to the temperature of the measurements (2 K) and are directly proportional to the doping amount.

As mentioned before, the main papers concerning the origin of ferromagnetism in CeO$_{2.8}$ nanoparticles assume that it may be associated to oxygen $^{9, 19}$ or cerium $^{9, 25}$ vacancies, both located at the surfaces of the nanoparticles. The cerium vacancies must be ruled out for the CeO$_{2.8}$ system, since in the equilibrium conditions its formation energy is relatively higher as compared to the formation energy of others defects. $^{25}$ Considering the oxygen vacancies under the scope of the FCE theory, Chen et al. $^{19}$ explained the observed RTFM by the formation of magnetic centers composed by oxygen vacancies and trapped electrons donated by adsorbed elements on the surface/interfaces of the nanoparticles. Moreover, Ge et al. $^{20}$ verified that CeO$_{2.8}$ nanocubes exhibit stronger ferromagnetic behavior than CeO$_{2.8}$ nanoparticles. They presented first-principles calculations of oxygen vacancies sites in {100} CeO$_{2.8}$ surfaces and bulk, showing that the magnetic moment associated to the oxygen vacancies is higher when the oxygen vacancies are located at the {100} surface. However, their calculated bulk magnetic moment is still significative, 1.41 $\mu_B$ for the bulk compared to 1.98 $\mu_B$ for the {100} surface.

Although that according to our structural analysis, all of our samples presented oxygen vacancies, which number increases with the inclusion of Cu$^{2+}$ ions, our undoped sample reveals to be diamagnetic while the single phase Cu-doped samples present only a paramagnetic behavior. Remembering that the introduced oxygen vacancies are mainly distributed in the bulk of the samples, we can state that, contrary to Ge et al., $^{20}$ oxygen vacancies on the bulk of the CeO$_{2.8}$ matrix cannot be responsible for the reported RTFM on the literature. Nevertheless, we would also expect oxygen vacancies at the surfaces of the nanorods due to oxygen losses to the environment that would lead to an observation of a RTFM, once we may conclude that oxygen vacancies and defects at the surfaces dominate the mechanism for the RTFM. Here we have to regard that our nanorods were grown on the surfaces of the nanorods due to oxygen losses to the environment.

The microwave-assisted hydrothermal method is an efficient way for the synthesis of Ce$_{1-x}$Cu$_{x}$O$_{2.8}$ up to 5% of Cu content. HRTEM shows nanorods with size between 10 nm in diameter and 70 nm in length and single cubic CeO$_{2.8}$ phase with exposed {111} crystallographic plane. The structural analysis shows that Cu$^{2+}$ doping does not change the CeO$_{2.8}$ cubic structure, but the inclusion of Cu$^{2+}$ leads to the increase of O vacancies in the system. XANES spectra reveal also that the incorporation of Cu$^{2+}$ in the CeO$_{2.8}$ matrix leads to an [Ce$^{3+}$] increase, contributing also to the increase of O vacancies. From the EXAFS results we could state that the introduced O vacancies by the Cu doping is located close to the Cu$^{2+}$ ions in the bulk of the nanorods. The magnetic characterization reveals a diamagnetic phase associated to a paramagnetic phase for the undoped sample and only a paramagnetic behavior for the Cu-doped samples, contrary to some reports. Any ferromagnetic phase could be observed. This leads us to conclude that the presence of oxygen vacancies is not a sufficient condition to mediate ferromagnetic order in CeO$_{2.8}$ samples, since their location site on the structure also plays a vital role.

ACNOWLEDGEMENTS

Support from agencies FAPEMIG, CNPq, CAPES (PNPD-2011), FINEP, MINECO (MAT2012-33483) and FAPESP are gratefully acknowledged. We also thank CNPq and CAPES for research fellowships (ACD, AOZ and AM). The authors also acknowledge LNLs for the XAS measurements and Prof. Dr. F. Ikawa and Profa. Dra. M. J. S. Brasil of the Universidade de Campinas (UNICAMP) for the Raman measurements.
