This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
We studied for the first time systematically the temperature induced amorphisation (TIA) of hexagonal ice.
Temperature induced amorphisation of hexagonal ice

Abstract

We systematically studied the competition between polymorphic transformations and amorphisation of hexagonal ice on isobaric heating from 77 K to 155-170 K at pressures between 0.50 and 1.00 GPa. This competition is analysed here systematically by in situ dilatometry and ex situ X-ray diffraction and calorimetry. Volume vs. temperature curves were analysed using a novel fitting approach in order to understand the underlying mechanism. Hexagonal ice undergoes solid-state-transformation to ice IX/III at 0.50 and 0.60 GPa and to a mixture of ices IX/III and IV at 0.70 and 0.80 GPa. Possibly a tiny fraction of amorphous intermediate is transiently formed in this pressure range. At 0.85 GPa the amorphisation process becomes competitive, and leads to very high-density amorphous ice (VHDA) as by-product. At 0.90 and 0.95 GPa VHDA is the main product and at 1.00 GPa only VHDA is found. This represent the first observation of temperature induced amorphisation (TIA) for hexagonal ice using diffraction methods. Our analysis suggests TIA to be a first-order phase transition which, by contrast to pressure-induced amorphisation (PIA), does not involve a precursor process. We suggest interpreting TIA as thermodynamic melting of ice followed by immediate vitrification rather than as mechanical collapse of hexagonal ice. The activation energies for amorphisation and polymorphic transformation are equal at ~0.75 GPa. At 1.00 GPa the activation energy for amorphization of hexagonal ice is lower by about 6 kJ/mol than the activation energy for polymorphic transitions.
Introduction

Amorphisation of crystalline material at high-pressure conditions is a rather unusual phenomenon. Most materials actually experience the reverse transformation from amorphous to crystalline at high-pressure conditions. Pressure-induced amorphisation (PIA) was so far only demonstrated for just a few materials. These materials, e.g., silica, zeolites, GeSe, silicon or water, have in common that they show anomalous properties such as the density maximum in the liquid or the negatively sloped melting line. The discovery of high-density amorphous ice (HDA) in 1984 marked the first example of PIA. Mishima described this process as thermodynamic melting of hexagonal ice, whereas later calculations suggest to interpret the process as crystal-breakdown due to mechanical instability. In this latter view the product is not liquid-like, but shows crystal-like behaviour. In fact, there might be a cross-over from a thermodynamic melting at higher temperatures to mechanical melting at lower temperatures. Extrapolations of inelastic neutron scattering experiments are consistent with the idea of mechanical melting, and more recent studies point towards a change in mechanism between 80 and 100 K. Lately, rapid decompression experiments showed PIA from Ice VII to HDA. In addition to PIA the anomalous materials mentioned above might also experience temperature induced amorphisation (TIA) upon heating the material at high-pressure conditions. There are only a few scattered studies about this possibility. Interestingly, not all materials showing PIA also show TIA. In case of the zeolitic material ZIF-8 PIA was observed, whereas TIA could not be observed. A MD Study on ZIF-8 by Ortiz et al. suggested that shear-mode softening is required for amorphisation to occur, which in ZIF-8 is only experienced upon pressurizing, but not upon heating the material isobarically. In case of ice temperature induced routes to amorphous ices have so far been barely investigated. Amorphisation was reported for some high-pressure ice forms upon heating at ambient pressure conditions. It was found that ices VII, VIII and XII experience a temperature-induced transition to low-density amorphous ice (LDA) at ambient pressure. Also a pressure induced path to LDA was found on decompression of ice VII. In these cases the amorphisation is a transient phenomenon, which can only be observed in a rather narrow temperature window and accompanies the polymorphic crystal-crystal transition ultimately resulting in cubic ice. In fact, it is questionable whether the amorphous form produced transiently is closer to HDA or LDA. In our opinion it is also possible that the transient amorphous ices produced on the way from the high-pressure ice forms to cubic ice are in fact materials, in which the oxygen atoms have become mobile prior to the transition and have moved to off-lattice positions in the course of the high-density crystal to low-density crystal transition. To our knowledge the only TIA from hexagonal ice to HDA was reported by Gromnitskaya et al., who have claimed that amorphisation of hexagonal ice can be achieved under isobaric conditions. In fact, they claim TIA only for a single instance, namely for heating of hexagonal ice at 0.77 GPa. This study was done using the propagation of ultrasound through the sample as a probe, so the crystalline or amorphous nature of the sample was inferred indirectly. The process of TIA of hexagonal ice at isobaric high-pressure conditions as suggested by Gromnitskaya et al. results in HDA, just like the process of PIA of hexagonal ice at isothermal conditions. From their analysis, they concluded that elastic softening precedes solid-state amorphisation. More precisely, the softening of the transverse acoustic phonons at the Brillouin zone boundary is followed by instability. At high-pressure conditions hexagonal ice may either transform to high-pressure ice polymorphs or amorphise. Here, we investigate the competition between the two high-pressure mechanisms by investigating temperature induced transformations of hexagonal ice at 0.5GPa≤p≤1.0GPa using high-precision high-pressure dilatometry. A systematic analysis of this competition is lacking so far and, thus, is the focus in this work. Rather than establishing the nature
of the phases from an ultrasonic study as done by Gromitskaya et al. \(^{26}\) we here analyze the microscopic structure of the sample directly by means of powder X-ray diffraction and the thermal properties by differential scanning calorimetry. The mechanism of the high-pressure transformations is analyzed by a novel method of fitting the volume vs. temperature curves.

**Methods**

250 µl of ultrapure water were frozen to hexagonal ice at 77 K in a preformed indium container made from about 400 mg indium foil of thickness 0.1 mm. Then the sample container was pushed into a steel cylinder of bore diameter 8 mm, compressed at 77 K to 1.0 GPa and subsequently decompressed to 0.50≤\(p\)≤1.00 GPa. Compression and decompression rates were either 0.20 or 0.14 GPa min\(^{-1}\). After this procedure the sample can be described as a compact, air-free pressurized cylinder of polycrystalline hexagonal ice without microcracks or micropores. Temperature-induced phase transformations were followed thereafter by recording piston displacement (volume) changes on isobaric heating at 3 K min\(^{-1}\) to ~155 K (0.70≤\(p\)≤1.00 GPa), ~165 K (0.60 GPa) or ~170 K (0.50 GPa). The samples were then quenched to 77 K by immersing the setup in liquid nitrogen and recovered to ambient pressure. The quench-recovered materials were finally characterized ex situ by powder X-ray diffraction (XRD) and differential scanning calorimetry (DSC). To that end, the samples were cold-loaded under liquid nitrogen to the cold (77 K) sample holder in the XRD-chamber and to DSC-crucibles placed into the DSC-instrument, which was pre-thermostatted at 93 K. Diffractograms were recorded at 77 K in the range 10 ≤ \(2\theta\) ≤ 54 ° at ~80 K and at approximately 10\(^{-1}\) mbar using Cu-K\(_\alpha\) radiation (1.541 Å), following the standard procedure employed in many studies in the past in our group (for recent reviews see refs. 27-29). The phase compositions of crystalline samples containing more than one polymorph were determined using the program PowderCell (version 2.4, BAM, Bundesanstalt für Materialforschung und -prüfung, Berlin, Germany). The appearance of traces of hexagonal ice in some diffractograms is attributed to ice condensation from humid air during sample transfer into the XRD chamber. Therefore, hexagonal ice features are neglected for interpretation. The relevant structural data were taken from references 30,31 (ice IV) and 32 (ice IX/III). Thermograms were recorded by performing two scans with a heating rate of 10 K min\(^{-1}\): The first scan from 93 to 233 K to record the latent heat of phase transformation(s) and a second scan from 93 to 293 K which serves both as baseline and to calculate the sample mass from the melting endotherm of hexagonal ice. Volume curves were calculated from dilatometry data and corrected for the apparatus behaviour by subtracting a blind experiment\(^{33}\) and using the density of ice at 77 K and 1 bar (0.932 g cm\(^{-3}\); 19.3 cm\(^3\) mol\(^{-1}\))\(^{34}\). Furthermore the pressure dependence of the molar volume of hexagonal ice was determined by a polynomic fit of fifth order to compression data of hexagonal ice from a measurement up to 1 GPa at 77 K. Molar volumes calculated from this polynomial serve as initial values for the isobaric heating curves.

For an in-depth analysis the volume curves were fitted by a custom function. This function has been obtained by an ansatz analogous to the one described by Moynihan \(^{35}\):

\[
\frac{d(V_m - V_{m,e})}{dt} = -k(V_m - V_{m,e})
\]  

(1)
where $V_m$ is the molar volume at time $t$, $V_{m,e}$ is the molar volume in equilibrium and $k$ is the rate constant. In the experiments shown here temperature is varying and, therefore, also $k$. The temperature dependence of $k$ is given by $^{36,37}$

$$E_A = RT^2 \left( \frac{\partial \ln k}{\partial T} \right)_p$$

where $R$ is the ideal gas constant and $E_A$ the activation energy. Integration and substitution of $k$ by the inverse of the relaxation time $\tau_R$ $^{35}$ in equation (2) leads to

$$\tau_R = \tau_{R,\infty} \cdot e^{E_A/R}$$

where $\tau_{R,\infty}$ is the relaxation time at infinite temperature, which results from the integration constant in above integration and yields the Arrhenius equation. Combining equations (1) and (3) yields

$$\frac{d(V_m - V_{m,e})}{dt} = -\frac{1}{\tau_{R,\infty}} \cdot e^{E_A/R} (V_m - V_{m,e})$$

Separation of variables, substitution of the time dependent temperature $T$ by $(T_0 + qt)$ where $T_0$ is the starting temperature and $q$ the heating rate and formulation of the integral from the starting volume $V_{m,0}$ at time 0 to the volume at $t$ leads to

$$\int_{V_{m,0}}^{V(t)} \frac{d(V_m - V_{m,e})}{V_m - V_{m,e}} = -\frac{1}{\tau_{R,\infty}} \int_0^t e^{-E_A/(R(T_0+qt))} dt$$

The left side of this equation is easy to solve, whereas the right side can only be solved numerically, by means of the exponential integral $\text{Ei}(x)$, which is defined by

$$\text{Ei}(x) = \int_{-\infty}^x \frac{e^\xi}{\xi} d\xi$$

Therefore the solution of the above differential equation is

$$\ln \frac{V_m(t) - V_{m,e}}{V_{m,0} - V_{m,e}} = -\frac{\Xi(t)}{Rq\tau_{R,\infty}}$$

where the function $\Xi(t)$ is

$$\Xi(t) = E_A \left[ \text{Ei} \left( -\frac{E_A}{RT} \right) - \text{Ei} \left( -\frac{E_A}{RT_0} \right) \right] + R \left[ T(t) \cdot e^{-E_A/RT} - T_0 \cdot e^{-E_A/RT_0} \right]$$

with $T(t) = (T_0 + qt)$ . Rearrangement and use of $\Delta e V_m = V_{m,e} - V_{m,0}$ and $\Delta V_m(t) = V_m(t) - V_{m,0}$ leads to

$$\Delta V_m(t) = \Delta e V_m \left( 1 - e^{-\frac{\Xi(t)}{Rq\tau_{R,\infty}}} \right)$$

Finally two empirical changes were made. First a linear term $\propto V_m^p (T(t) - T_0)$ was added to account for the fast relaxation (cf. $^{35}$) and second an exponent $\beta_p V_m$ similar to the KWW function (cf. eg. $^{35,38}$) was added which leads to the fit function used here
\[ \Delta V_m(t) = \Delta e V_m \left( 1 - e^{-\left( \frac{E}{R(T_m)} \right)} \right) + \alpha V_m (T(t) - T_0) \]  

\[ (10) \]

The volume curves were fitted as functions of temperature with the Curve Fitting Toolbox of MATLAB R2013a.

**Results**

Exemplary volume curves of the isobaric heating step are shown in Figure 1. All curves shown in Figure 1 exhibit a densification step, which shifts to lower temperature with increasing pressure. All steps mark solid-solid transformations analyzed in more detail below. The reproducibility for these curves and the location of the steps is excellent in general. However, in case of 0.90 and 0.95 GPa we found two distinct set of curves, in which the location of the step is shifted by about 10 K. It seems there are two possible solid-solid transitions, one resulting in a step at low temperature (solid lines in Figure 1), and the other resulting in a step at high temperature (dashed lines in Figure 1). We did not find a way of controlling this competition between two phase transformations at 0.90 and 0.95 GPa.

Representative diffractograms are shown in Figure 2, and the phase-compositions of the ice samples are summarized in Table 1. Up to 0.85 GPa the heating leads to predominantly crystalline material, which is ice IX/III or IV. This is in contrast to the result presented by Gromnitskaya et al., who claim temperature-induced amorphisation at 0.77 GPa and 130–140 K. Samples heated at higher pressures show amorphous X-ray patterns with only minor crystalline amounts. At 0.50 and 0.60 GPa only ice IX/III occurs, at 0.70–0.85 GPa both ice IX/III and ice IV appear, where the ice IV fraction increases with pressure. Please note that ices III and IX can not be distinguished based on powder X-ray diffraction measurements, because they share the same network of O-atoms and only differ in terms of proton-ordering. Ice IV, just like HDA, transforms to ice VI at higher-temperatures. Since Gromnitskaya et al. did not consider ice IV at all in their study, we think that it is possible that the ultrasonic properties reported in their Figure 3b do not indicate the TIA process followed by transformation to ice VI, ice Ih→HDA→ice VI, but rather the polymorphic transition sequence ice Ih→ice IV/III/X/IX→ice VI. As detailed below at most some transient traces of HDA might appear, which immediately crystallise in the temperature/pressure region investigated by Gromnitskaya et al. At 0.90–1.00 GPa, only amorphous ice or amorphous ice with traces of ice IV occurs. Ice IV is known to crystallise from amorphous ice at high-pressure conditions, but has never been observed to crystallise from hexagonal ice or any other ice polymorph. By contrast, ice IX/III may crystallise from hexagonal ice or from ice V. The amorphous halo peak, also called first sharp diffraction peak by some, is found at 2θ=32.5° (see dotted grey line in Figure 2), which corresponds to the position found in very high-density amorphous ice (VHDA). That is, amorphous ice produced by isobaric heating experiments at >0.85 GPa corresponds to VHDA. The samples heated at 0.90 and 0.95 GPa, which exhibit the low transition temperature (solid line in Figure 1) show pure VHDA patterns, whereas the samples which exhibit the high transition temperatures (dashed line in Figure 1) show traces of ices IV and IX/III in addition to VHDA.

The same conclusions can be drawn from the representative thermograms shown in Figure 3. Only one exotherm is found for samples prepared at <0.85 GPa, whereas two or three exotherms are found for samples prepared at ≥0.85 GPa. In the former case the exotherm is observed between 150 and 160 K. While the exotherm is symmetric at 0.50 and 0.60 GPa it is asymmetric at 0.70 and 0.80
GPa. (cf. Figure 3(a)). This exothermic event is attributed to the transformation from ice IV and/or ice IX/III to cubic ice judging from the phase-composition (Table 1) deduced from the XRD measurements (Figure 2). A symmetric peak with onset temperature 156±1 K results if single phase ice IX/III converts to cubic ice. The latent heat associated with the IX/III→Ic transition as calculated from the peak area amounts to -269±36 J/mol. This compares with earlier determinations of -300 J/mol by Bertie and Whalley and of -340 J/mol deduced by Handa et al. The additional presence of ice IV results in the asymmetry of the exotherm, more precisely in the low-temperature shoulder, and a lower onset temperature of 154±1 K. The asymmetry is more pronounced for the case of 0.80 GPa than for the case of 0.70 GPa, thereby qualitatively corroborating the analysis of phase-composition of 30±5% ice IV at 0.80 GPa and 10±5% ice IV at 0.70 GPa (cf. Table 1). The phase composition estimated from the area of the exotherm indicating transformation to cubic ice is 28±4% ice IV and 72±4% ice IX/III for 0.70 GPa and 34±21% ice IV and 66±21% ice IX/III for 0.80 GPa using -269±36 J/mol for pure ice IX/III and -938±14 J/mol for pure ice IV. For the IV→Ic transition an onset temperature of about 149 K was found for a 5 K min⁻¹ heating rate and 156 K for 30 K min⁻¹ heating rate, which compares with 154±1 K at 10 K/min found in this work. For the IX→Ic transition an onset temperature of 143 K for a 10 K h⁻¹ heating rate and ~150 K for the III→Ic transition when heated with 1.1 K min⁻¹ were found, which compares to 156±1 K at 10 K/min found in this work. That is, the onset temperatures found in this work at 10 K/min heating rate are where they would be expected from the trends with changing heating rates seen in earlier work. Therefore, the transition temperatures for samples heated at 0.50 and 0.60 GPa are attributed only to ice IX/III (cf. also Table 1).

The DSC scans of samples heated above 0.85 GPa in contrast show two exotherms as expected for amorphous ices of high density. First, the exothermic polymorphic transition to low-density amorphous ice (LDA) takes place with an onset at 129±1 K, which in turn exothermically crystallises to cubic ice with an onset at 166±0.5 K. The comparison with the known onset temperatures of uHDA, e-HDA and VHDA in Figure 3(b) shows a match with that of VHDA, which again is consistent with the XRD results. The latent heats for the (pure) VHDA→LDA and LDA→Ic transformations are found to be -685±77 J/mol and -1333±114 J/mol, respectively. This compares to -640±10 J/mol and the average value -1314±93 J/mol from various literature sources and independent measurements done in this work, respectively. While the diffractograms show the presence of traces of crystalline material for the samples showing the low transition temperature at 0.90 and 0.95 GPa, the DSC scans do not reveal the presence of crystallinity. That is, XRD is much more sensitive for the detection of crystalline material than DSC, whereas DSC is much more sensitive for the detection of amorphous material. Additionally only small parts of the samples were used for the DSC scans, i.e., in case the sample was heterogeneous, grains which do not reflect the overall sample composition were possibly picked.

The sample heated at 0.85 GPa finally shows a DSC trace which contains all three exotherms including both the signatures of the polymorphic and polymorphous transitions of ices IV and IX/III. The latent heats of transformation of -175±68 J/mol (VHDA→LDA) and -593±179 J/mol (LDA→Ic) indicate that about 45±14 % of the material are amorphous at 0.85 GPa, even though the diffractogram (Figure 2, 0.85 GPa) is dominated by sharp Bragg reflections. The latent heat for the second exotherm to ice Ic is found to be -442±123 J/mol, which indicates that the crystalline fraction 1

is indeed composed of a mixture of ice IV and ice IX/III. Therefore, 0.85 GPa delineates temperature-induced polymorphic transitions at the low-pressure side from temperature-induced amorphisation at the high-pressure side.

The results obtained from the DSC and XRD analysis are summarized in Figure 4. Isofaric heating of hexagonal ice at 0.50 and 0.60 GPa leads to ice IX/III. An intermediate amorphous state can be excluded, because ice V would be expected if HDA crystallised. At 0.70 and 0.80 GPa a crystalline mixture of ice IX/III and ice IV results, where ice IV was either formed from a small fraction of intermediated formed HDA or crystallised from hexagonal ice. The isobaric crystallisation of HDA at different heating rates and 0.71 GPa and 0.81 GPa was studied before. In these studies the onset for crystallisation to ice IV was determined to be ~145 K for slow heating rates of 0.5 K/min. Judging from Figure 1 the onset of VHDA formation is ~111 K at 1.0 GPa and ~122 K at 0.9 GPa. It thus seems plausible that VHDA slowly forms at <145 K at 0.70 and 0.80 GPa. Once formed it then slowly crystallises to ice IV at >145 K. This slow process of VHDA formation and crystallisation is then immediately truncated once the sharp transition from the remainder of hexagonal ice to ice IX/III kicks in at ~149 K. Judging from Figure 1 the ice Ih → IX/III transition is quite rapid and takes place at ~155 K at 0.50 GPa and 152 K at 0.60 GPa. However, for heating rates of 4 K/min Salzmann et al. marked ~162 K rather than 145 K as the starting temperature for slow crystallisation of ice IV from HDA at 0.81 GPa. It thus remains unclear from the present study done at heating rates of 3 K/min whether or not ice IV crystallises from incipient VHDA or directly from ice Ih. The latter option was not reported in literature before, and so it seems more likely that slow amorphisation indeed takes place even at 0.70 and 0.80 GPa. Whereas it is not entirely clear whether slow amorphisation plays a role at 0.70 and 0.80 GPa, the formation of crystalline and amorphous material compete without a doubt at ≥ 0.85 GPa. At pressures ≥ 0.90 GPa formation of amorphous ice, VHDA, dominates, which we call temperature-induced amorphisation (TIA). The competition between temperature-induced polymorphic transformations and TIA is analyzed more quantitatively in the following based on the observed changes in volume.

Analysis of the volume curves

It is possible to relate the shape of the volume curves shown in Figure 1 to the phase(s) formed after isobaric heating. The two curves labelled 0.50 and 0.60 GPa show a very sharp step, which indicates the polymorphic transition to ice IX/III. The transition temperature of 155 and 152 K, respectively, is in good agreement with the results obtained by Mishima for emulsified ice samples and with in situ ultrasonic measurements of the isobaric heating of hexagonal ice at 0.65 GPa. The two curves labelled 0.70 and 0.80 GPa show a gentle begin at ~120-150 K followed by a sharp jump at 150 K and 149 K, respectively, which is interpreted as slow amorphisation and slow crystallisation to ice IV and subsequent rapid crystallisation to ice IX/III. This finding is consistent with the occurrence of ice IV (see above) and also with Mishima’s findings (Region C in ref. 9). The comparison with the ultrasonic study reveals slight differences. During isobaric heating of hexagonal ice at 0.77 GPa the sequence ice Ih → HDA → ice VI was claimed, although the latter transition occurred at higher temperatures than reached here. Nevertheless, neither ice IX/III nor ice IV was mentioned by them, which might be the reason why their density of ice VI was different from the literature density of ice VI. In our case, ice VI forms upon continued heating from metastable ice IX/III and ice IV rather than from HDA. This actually suggests that Gromnitskaya et al. might not have observed TIA in hexagonal ice, but similar
to ice Ih→ice IV/III/IX→ice VI, maybe with slow amorphisation preceding the transition to ice IV. The next curve at 0.85 GPa shows a lower transition temperature, (Region D in ref. 9), where only amorphisation occurs in emulsified samples upon isothermal compression. The bulk samples studied here transform to both amorphous and crystalline material. Whereas in emulsion crystallisation of the pressure-amorphised ice is efficiently suppressed at 155 K, we here observe crystallisation in temperature-amorphised ice at 155 K. The curves at even higher pressures become progressively less steep and the resulting product is amorphous. Since the crystallisation temperature of amorphous ice increases by ~2 K/0.1 GPa near 1 GPa, crystallisation at 155 K is suppressed at ≥ 0.9 GPa. Ignoring the claims by Gromnitskaya et al. for the reasons mentioned above this then represents the first observation of temperature-induced amorphisation of hexagonal ice.

For an in-depth analysis the volume curves were fitted by equation (10) described in the methods section. An exemplary fit is shown in Figure 5, and all fit parameters are summarized in Table 2. The values obtained for the activation energy are depicted in Figure 6. Most significantly the activation energy drops by about 10 kJ/mol between 0.80 and 1.00 GPa, as a result of amorphisation taking over. At 0.90 and 0.95 GPa again the two-fold behaviour is obvious: either the trend set at lower pressures is followed or the jump to the low activation energy found at 1.00 GPa is observed. This is in agreement with the two sets of diffractograms obtained for these samples (see above). At ~0.75 GPa the two linear fits to the data in Figure 6 cross, indicating equality of activation energies for amorphisation and polymorphic transformation. At 1.00 GPa the activation energy for amorphisation is about 6 kJ/mol lower than the activation energy for the polymorphic crystal-to-crystal transformation. The exponent $\beta_p^{V_m}$ is used to distinguish first order phase-transitions from other processes, $\beta_p^{V_m} ≥ 1$ is interpreted to indicate a first order phase-transitions, whereas $\beta_p^{V_m} < 1$ indicates higher-order phase-transitions. Table 2 lists $\beta_p^{V_m} < 1$ for the transformations at 0.90, 0.95 and 1.00 GPa. This means that TIA is slower than expected for a first-order transition. If one expects the TIA to be thermodynamic melting, one would ad hoc assume a first-order phase transition. However, the transition from hexagonal ice to solid VHDA could also be a higher-order phase transition as it is tantamount to an order-disorder transition of the oxygen-lattice. By contrast, values of $\beta_p^{V_m} > 1$ are listed in Table 2 for the transformations at <0.90 GPa, namely the polymorphic transition Ih→IX/III at 0.50 and 0.60 GPa and the crystallisation of the amorphous intermediate at 0.70, 0.80 and 0.85 GPa.

Finally we compare our data presented here to PIA experiments to see how those two processes are related, by employing an analysis used previously to compare TIA and PIA for zeolites. For this purpose a characteristic transition time $\tau_A$ was determined from the volume curves and subsequently used to obtain a reduced time axis. Besides the isobaric curves (Figure 1) we evaluated isothermal PIA curves at 77, 120 and 139 K. For this purpose, one sample with 300 µl water and two with 250 µl were precompressed up to 1.1 GPa at 77K and decompressed. The first sample was thereafter compressed up to 1.7 GPa, where PIA occurred. The other samples were compressed to 1.1 GPa, one at 120 K and one at 139 K, where also PIA occurred. All curves (PIA and TIA) were plotted against time and temperature $T_A$ or pressure $p_A$ at half step height were determined. Then the intersection points $T_e$ and $p_e$ of tangents at these points with tangents at the zero step height were determined. From these values and the respective heating- $q$ or compression-rate $\pi$ the characteristic transition time $\tau_A$ was calculated as follows:

$$\tau_A = \frac{T_A-T_e}{q} \text{ or } \tau_A = \frac{p_A-p_e}{\pi}$$
Figure 7 shows such a plot against the reduced time $t_{TA}$, where curves lying on top of each other mark the same process. Three distinct sets of curves can be identified in this plot: one for the polymorphic transformation of hexagonal ice at $\leq 0.80$ GPa, one for amorphisation of hexagonal ice by TIA at pressures $\geq 0.85$ GPa, and one for the amorphisation of hexagonal ice by PIA in the middle. The former set of curves related to the crystal-crystal polymorphic transition stands out most profoundly, whereas the two other blocks marking TIA and PIA are in close proximity. Therefore the two blocks at low reduced times seem to emanate from an –at least– similar process transforming the crystal to an amorphous solid. The TIA block is furthermore more or less ordered in the sense that the highest pressure (1 GPa) shows the lowest reduced time and the lowest pressure (0.85 GPa) the highest reduced time. The curves in between relate to the experiments at 0.95 and 0.90 GPa, where the two lower ones show a lower transition temperature (cf. above) and the two higher ones a higher transition temperature. For the transformations to the crystalline polymorphs in contrast no correlation between pressure and reduced time is observed. Interestingly the process of PIA is found to be composed of two processes, a slow volume relaxation in the beginning, which is then followed by a sudden jump in volume. Gromnitskaya et al. named elastic phonon softening to be the common precursor for the solid-state amorphisation induced by pressure. The initial slow volume decrease in Figure 7 may be a hallmark of elastic softening. By contrast, TIA shows only the sharp volume change, but not the slow densification in the early stages of amorphisation. That is, temperature-induced amorphisation may take place without appreciable elastic softening prior to the sharp volume change. For this reason, TIA comes closer to represent thermodynamic melting than PIA. This finding on ice amorphisation is in contrast to the interpretation given by Ortiz et al. in case of zeolitic material (ZIF-8), who state that TIA does not take place because of the absence of elastic softening. The transition itself takes place at higher pressures and higher temperatures when compared with the conditions at which hexagonal ice and HDA are calculated to be of same chemical potential. In our interpretation the overpressurization/superheating is a result of a kinetic barrier, e.g., a nucleation barrier, which needs to be overcome at rather low temperature. Such kinetic barriers are hallmarks for first-order transitions. However, we do not extract the order of the transition directly from our data, and so we cannot rule out the possibility of a higher-order transition.

**Conclusions**

We have analysed the competition between polymorphic transformations and temperature-induced amorphisation (TIA) for hexagonal ice at 0.50–1.00 GPa. Isobaric heating of hexagonal ice between 0.50 and 0.60 GPa leads to a solid-solid transition to ice IX/III. At 0.70 and 0.80 GPa hexagonal ice presumably first slowly transforms to a transient amorphous phase, which slowly crystallises to ice IV, and this slow process is terminated by abrupt transformation from ice I, to IX/III. At higher pressures (0.85–1.00 GPa) the amorphisation finally becomes the dominant process. The change in mechanism to obtain a predominantly amorphous product (VHDA) takes place between 0.85 and 0.90 GPa, which is corroborated by the mathematical fits to the observed volume vs. temperature curves. The shape of the isobaric volume curves is dominated by polymorphic transformations up to 0.80 GPa, whereas it is dominated by amorphisation at higher pressures. This means that the polymorphic transformations are slowing down at high-pressure, whereas amorphisation accelerates. We claim that this represents the first clear observation of TIA of hexagonal ice in literature. The only other case of TIA of hexagonal ice claimed in literature by Gromnitskaya et al. might have been afflicted with simultaneous formation of ice IV/III/IX.
Experiments at 0.90 and 0.95 GPa show that at these pressures apparently two possibilities exist. Either pure amorphisation or amorphisation with partial crystallisation may take place. This is reflected in either a low or high transition temperature, respectively. This again corroborates that there is severe competition between polymorphic transformation and amorphisation, which is dominated by polymorphic transitions at pressures below, but dominated by amorphisation at pressures above. What parameters exactly determine the course of the experiment at 0.90 and 0.95 GPa remains unclear at this juncture and is beyond our control at the moment. Metastability and an unknown trigger or nucleus inducing amorphization seem to play an important role in this context. These are hallmarks of first-order phase transitions, and so we suggest TIA to be a first-order, discontinuous transition, resembling the melting transition, which requires some overpressurization/superheating. We think that a nucleation barrier of the disordered phase in the crystal is at the origin of the kinetic hindrance, but we cannot exclude elastic instabilities. The absence of a pre-cursor process in Fig.7 for TIA disfavours elastic instabilities, though. This absence of the pre-cursor process is the main difference in mechanism between PIA taking place at low temperatures and TIA taking place at higher temperatures.

For the transitions at 0.50 and 0.60 GPa we rule out an intermediate amorphous state. This is based on the fact that the crystallisation of HDA at 0.51 GPa at a heating rate of 3.5 K min\(^{-1}\) is known to lead to mainly ice V, but the ice V polymorph was not observed in the present work at similar heating rate. Similarly, ice XII would be expected on crystallizing amorphous ice at 0.50-1.00 GPa, but also the ice XII polymorph was not observed in this work. According to Salzmann et al. there are two crystallisation channels for HDA: a slow one at lower temperatures and a fast one at higher temperatures. In our experiments here we only observe the first, slow crystallisation channel at lower temperatures. E.g., at 0.71 GPa ice XII crystallises abruptly at 160 K, but we here only heated to a maximum temperature of 155 K. According to literature ice IX/III is not expected as a product of HDA crystallisation at 0.81 GPa, but it appears in this study both at 0.80 and at 0.85 GPa. This can be explained by the parallel appearance of the amorphisation and the \(\text{I}_h\rightarrow\text{IX/III} \) transition, consistent with the change of mechanism in this pressure regime. At higher pressures solely ice IV appears in accord with former studies.

Finally, PIA and TIA seem to be intimately related processes, and so conclusions can be drawn whether PIA should either be regarded as thermodynamic melting or as mechanical collapse. Strässle et al. suggested mechanical collapse to be a temperature independent process. We here observe TIA at \(T > 100 \text{ K} (T_e^{\text{TIA}} (1.00 \text{ GPa}) \geq 103 \text{ K})\). This is higher than the crossover temperature of 80-100 K, above which thermodynamical melting was inferred for PIA in earlier work. Since TIA is obviously a temperature dependent process our study corroborates that PIA at > 100 K can indeed be considered as thermodynamic melting. By contrast to the volume curves related to PIA, we do not find a slow precursor process attributable to elastic softening from our analysis of volume curves related to TIA. This again suggests that the process of temperature-induced amorphisation reported here actually reflects thermodynamic melting of ice followed by immediate vitrification, as suggested originally also for the process of pressure-induced amorphisation of hexagonal ice at 77 K by Mishima.

This process of temperature-induced amorphisation of ice may actually not only be of importance in our understanding of anomalous water properties. In the interior of ice-covered bodies in outer space, TIA may actually be of relevance. Ganymede for instance is well-differentiated into a rocky...
core and a mantle of relatively pure water-ice, which is about 900 km thick. At the moon’s surface the temperature is close to 80 K and rises to about 300 K at the bottom of its icy interior, where the pressure is about 2.5 GPa. It, thus, seems plausible that in a depth of a few hundred kilometres, there is a competition between amorphisation to VHDA and polymorphic transformation to ice III/IX. Thus, amorphous ice VHDA might exist in the interior of Ganymede and experience phase transformations or show viscous flow, similar to water ice-lava.

Table 1: Summary of the phase-composition deduced from XRD measurements after isobaric heating of hexagonal ice at the respective pressures. $2\theta_{\text{max}}$ stands for the maximum of the amorphous halo peak, X for crystalline contributions and $X_A:X_B$ for the relative proportion of different crystalline polymorphs in mainly crystalline samples. Each line represents analysis of an individual diffractogram.

Table 2: Fit-parameters obtained by fitting the data in Figure 1 using Equation (10). The starting temperature $T_0$ was given and $R^2$, RMSE and SSE are statistic measures. Values without errors have been fixed by MATLAB at the bounds.

Figure 1: Molar volume $V_m$ at isobaric heating of hexagonal ice at elevated pressures. The initial values were calculated by a polynomial fit of a compression curve of hexagonal ice (cf. text). Cooling curves are omitted for clarity. Also the molar volumes of HDA and VHDA at 1 bar \(^{48}\) as well as at higher pressures (from Figure 5 in ref. \(^{27}\)), ice IV at 1 bar \(^{31}\) as well as at higher pressures \(^{41,63,64}\) and ice IX \(^{65}\) are shown. Thermal expansion was neglected due to the marginal influence on the scale shown.

Figure 2: XRD measurements at ambient pressure and 77 K of samples recovered after isobaric heating of hexagonal ice at elevated pressures. The diffractograms were recorded at ambient pressure from samples quench-recovered after the isobaric heating shown in Figure 1 (corresponding XRD measurements and volume curves in Figure 1 have the same colour). The grey diffractograms in the lower part show calculated diffractograms for ices Ih, IV, IX/III and XII as well as for the sample holder (SH) made from nickel-plated copper. The dotted line at $2\theta = 32.4 / ^\circ$ indicates the halo-maximum of VHDA produced by heating u-HDA at 1.1 GPa to 160 K with 3 K min\(^{-1}\) and subsequent quench-recovery to 1 bar \(^{48}\).

Figure 3: Part (a): Exemplary DSC curves at ambient pressure of samples recovered after isobaric heating of hexagonal ice at elevated pressures. The calorigrams were recorded at ambient pressure from samples quench-recovered after the isobaric heating shown in Figure 1 (corresponding DSC measurements and volume curves in Figure 1 have the same colour). The top five measurements are magnified by a factor of 4, to achieve comparable signal heights. The dotted lines at 117, 130 and 136 K mark the onset temperatures of the u-HDA, VHDA and e-HDA→LDA transitions, respectively. The u-HDA sample was produced by PIA at 77 K and the VHDA sample as explained in Figure 2. For e-HDA VHDA was decompressed at 140 K to 0.1 GPa and then quench-recovered. Finally the dotted line at 166 K marks the onset temperature of the LDA→I\(_c\) transition. Part (b): Large grey symbols mark onset temperatures $T_e$ and black ones peak temperatures $T_p$. The diamonds indicate the polymorphic transition ice IX/III→ice I\(_c\) (0.5 & 0.6 GPa) and IX/III & IV→ice I\(_c\) (0.7 & 0.8 GPa), the circles the polymorphic transition VHDA→LDA (0.85-1.00 GPa) and the triangles crystallisation of LDA (0.85-1.00 GPa). LDA crystallisation seems to be composed of two types of kinetics as also noted earlier in literature \(^{54}\). Downward triangles indicate the first (low temperature) kinetics and upward triangles the second (high temperature) kinetics. The dotted lines again represent the onset temperatures of the u-HDA, VHDA and e-HDA→LDA transition, respectively as well as the onset temperature of the LDA→I\(_c\) transition.

Figure 4: Mean values of the percentage of crystalline material (left scale, red downward triangles) and percentage of ice IV of the crystalline amount (right scale, black upward triangles) in the
samples. No crystallinity implies pure VHDA and no IV indicates that solely ice IX/III constitutes the crystalline amount. The lines are guides to the eye.

**Figure 5:** Example for the fit (red line) of the 0.95 GPa data from Figure 1 (black line) using Equation (10).

**Figure 6:** Activation energies obtained by fitting the volume curves of the isobaric heating of hexagonal ice with Equation (10). The two linear fits correspond to the activation energies for temperature-induced polymorphic transitions (top line) and for temperature-induced amorphization (bottom line). Upon extrapolation the two lines cross at ~0.75 GPa.

**Figure 7:** Change of the molar volume during PIA (black lines) and isobaric transitions of hexagonal ice (grey lines) as a function of reduced time (see Equation (11)).
