This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Hydrothermal synthesis of octahedra-based layered niobium oxide and its catalytic activity as a solid acid

Toru Murayama, Junli Chen, Jun Hirata, Keeko Matsumoto and Wataru Ueda

Layered-structure type niobium oxides were synthesized by the hydrothermal method by using ammonium niobium oxalate as a precursor. The synthesized niobium oxide showed characteristic peaks at 20 = 22.7° and 46.2° in an X-ray diffraction pattern (Cu-Kα), indicating linear corner-sharing of NbO₆ octahedra in the c-direction. From Raman measurement, the layered-structure type niobium oxide was composed of NbO₆ octahedra and {Nb₆O₂₁} pentagonal units. The presence of micropores was confirmed by N₂ adsorption at low pressure (1.0 × 10⁻³), indicating that the arrangement of the a-b plane was an interconnection of crystal structure motifs of {Nb₆O₂₁} units and micropore channels but without long-range order (deformed orthorhombic). Ammonium cation and water were desorbed from the deformed orthorhombic niobium oxide by calcination at 400 °C, and Brönsted acid sites were formed. The deformed orthorhombic niobium oxide showed high catalytic activity as a solid acid compared to the catalytic activities of other crystalline niobium oxides. The order of catalytic activity for the alkylation of benzyl alcohol and anisole was: deformed orthorhombic Nb₂O₅ > TT-Nb₂O₅, amorphous Nb₂O₅ >> T-Nb₂O₅, pyrochlore Nb₂O₅.

Introduction

Niobium oxide is widely used in catalysis and in electrochromic and photoelectrochemical devices.¹, ² Niobium oxide (or hydrated niobium oxide) has been used especially as a water-tolerant solid acid catalyst for many reactions such as alkylation, esterification, hydrolysis, dehydration and hydration.³, ⁴ Hydrated niobium oxide (Nb₂O₅·nH₂O, niobic acid) has a high acid strength (H₆ ≤ -5.6) and possesses Lewis and Brönsted acidity. Therefore, much effort has been focused on the preparation of new morphologies of nanocrystalline niobium oxide (or hydrated niobium oxide) in order to obtain the niobium oxide with a high surface area, such as nanoparticles,⁵, ⁶ rods,⁷, ⁸ wires,⁹ and nanoplates.¹⁰-¹² Niobium oxide forms different polyhedra structures and transforms its phase depending on heat treatment. Amorphous niobium oxide, Nb₂O₅·nH₂O, possesses distorted NbO₆ octahedra, NbO₇ pentagonal bipyramids and NbO₈ hexagonal bipyramids as structural units.¹³, ¹⁴ With heat treatment of Nb₂O₅·nH₂O, pseudohexagonal niobium oxide (TT-Nb₂O₅) is formed at 300-500 °C, orthorhombic niobium oxide (T-Nb₂O₅) at 700-800 °C and monoclinic niobium oxide (H-Nb₂O₅) is formed at temperatures higher than 1000 °C. With increases in the heat treatment temperature and the degree of crystallinity, catalytic activity as a solid acid (Brönsted acidity) and surface area are decreased.¹⁵ Therefore, not the protons formed on ordered crystalline structure but the protons formed on distorted polyhedra in amorphous Nb₂O₅·nH₂O have been regarded as active sites as Brönsted acid.

For improving the Brönsted acidity and catalytic properties of niobium oxide, modification of niobium oxide or supported niobium oxide with sulfate and phosphate has been tried.¹⁶-¹⁸ Complex metal oxide such as layered HNbMoO₆ (M = Ti, Mo, W) has been reported as a strong solid catalyst, and M(OH)Nb was regarded to represent a strong Brönsted acid site.¹⁹, ²⁰ Some researchers reported that the acid centers were due to isomorphous substitutions of Nb⁵⁺ by the higher-valence cation M⁶⁺ (Mo, W) in the mixed oxide.²¹, ²²

We have long studied the relationship between the crystalline structure of complex metal oxides and their catalytic activity.²³-²⁵ Studies on crystalline metal oxides of MoₓVO₃ have demonstrated that the oxidation activities depend on their crystalline arrangement of the pentagonal {Mo₆O₂₁} units and MOₓ oxahedra in the a-b plane. These materials contain heptagonal channels in their structure. For the synthesis of these catalysts, the formation of a pentagonal {Mo₆O₂₁} unit in the precursor solution was important, and the pentagonal unit assembled further into a complex metal oxide under hydrothermal conditions.²⁶, ²⁷ A complex metal oxide that possess a similar layered-structure in the c-direction by corner-sharing of MO₆ (M= Mo, W, V, Ta, Nb) octahedra has been synthesized by a hydrothermal method.²⁸-³⁰ These catalysts were found to function as solid acids, the property of which was understood from the structural point of view.
We report herein the synthesis of niobium oxide by a hydrothermal process from niobic acid and niobium oxalates precursors. The Nb atom has a pentagonal bipyramidal environment in the crystal structure of $\text{NH}_4\text{NbO}_6\text{(C}_2\text{O}_4\text{)}_2\text{(H}_2\text{O}\text{)}_2\cdot n\text{H}_2\text{O}$, and under hydrothermal conditions, pentagonal $\{\text{Nb}_5\text{O}_{17}\}$ units may be formed by the hydrolysis of $[\text{NbO(C}_2\text{O}_4\text{)}_2\text{(H}_2\text{O}\text{)}_2]$ and then be self-assembled into niobium oxide. The structure and catalytic activity of the obtained niobium oxides were investigated. Various crystalline niobium oxides including pseudohexagonal (TT phase), orthorhombic (T phase), pyroclore, and amorphous niobium oxide were also prepared, enabling us to discuss the relationships between the crystalline structure and their catalytic activity and acidity.

**Experimental**

**Preparation of niobium oxides**

Layered-structure type niobium oxides were synthesized by a hydrothermal method from ammonium niobium oxalate ($\text{NH}_4\text{[NbO(C}_2\text{O}_4\text{)}_2\text{(H}_2\text{O}\text{)}_2] \cdot n\text{H}_2\text{O}$), denoted as NbO-ANO. Typically, ammonium niobium oxalate (supplied from CBMM) containing 6 mmol Nb was dissolved in 40 mL of deionized water and then sealed in a 60 mL Teflon liner stainless-steel autoclave. Hydrothermal reaction was carried out at 175°C for 3 days. The obtained solid was filtered, washed thoroughly with deionized water, and dried at 80°C overnight. The same type of niobium oxide was obtained from ammonium niobium oxalate (Aldrich), and similar characterization results were obtained (Table S1). Pseudohexagonal niobium oxide and pyroclore niobium oxide were also synthesized by a hydrothermal method using a niobic acid ($\text{Nb}_2\text{O}_5\cdot n\text{H}_2\text{O}$, Sokawa Chemicals) precursor, denoted as NbO-NA(d) and NbO-NA(c), respectively. 4 mmol based on Nb of niobic acid dispersed in 40 mL deionized water for NbO-NA(c) and 0.25 mmol for NbO-NA(d). The hydrothermal conditions and the following process were the same as these for NbO-ANO. The yields of niobium oxides calculated as Nb$_2$O$_5$ were more than 90% for all of the catalysts. The samples were calcined at 400°C for 4 h under air before using as catalysts. The rate of temperature increase was 10°C min$^{-1}$ from room temperature. For comparison, amorphous niobium oxide was prepared by calcination of niobic acid at 400°C for 4 h under air (denoted as NbO-cal).

As-synthesized material (NbO-ANO, 0.3 g) was dispersed in 15 mL of KNO$_3$ solution (0.1 mol L$^{-1}$) for ion-exchange treatment. The dispersed sample was stirred at 80°C for 8 h. The resulting solid was collected by filtration. Then the sample was washed with water (3 × 100 mL) and dried at 80°C overnight. The obtained sample was denoted as NbO-ANO (K$^+$). A NbO-ANO (K$^+$) sample treated with NH$_4$NO$_3$ solution was denoted as NbO-ANO (NH$_4^+$). NbO-ANO (NH$_4^+$) was prepared by ion-exchange treatment of NbO-ANO (K$^+$) in 15 mL of NH$_4$NO$_3$ solution (0.1 mol L$^{-1}$) at 80°C for 8 h.

**Alkylation reaction**

A 50 mL round-bottom three-neck flask equipped with a reflux condenser was used as a stirred bed reactor to test the catalytic activities. Typically, a mixture of benzyl alcohol (1 mmol), anisole (50 mmol), and an internal standard, decane (0.5 mmol), was added to the reactor and reaction temperature was adjusted to 100°C. Then 0.1 g of a catalyst and a Teflon-coated magnetic stir bar were loaded into the reactor. Aliquots (each 0.1 mL) were collected at intervals. The concentrations of the reactant and product were measured by gas chromatography using a flame ionization detector (GL science GC390B) with a ZB-1 column.

**Characterization**

The catalysts were characterized by the following techniques. Powder XRD patterns were measured with a diffractometer (RINT Ultima+, Rigaku) using Cu-Kα radiation (tube voltage: 40 kV, tube current: 20 mA). Diffractions were recorded in the range of 4–60° with 5° min$^{-1}$. Morphology was investigated by using a scanning transmission electron microscope (HD-2000, Hitachi) at 200 kV and 30 μA and a transmission electron microscope (JEM-2100F, JEOL) at 200 kV. The samples were dispersed in ethanol with ultrasonic treatment for several minutes, and drops of the suspension were placed on a copper grid for STEM and TEM observations. Raman spectra were obtained using a spectrometer (in Via Reflex, Renishaw, 2 cm$^{-1}$ spectral resolution) under the conditions of wavelength of 532 nm and collection time of 10 s. N$_2$ adsorption isotherms at liquid N$_2$ temperature were measured by using an auto adsorption system (BELSORP MAX, BEL JAPAN) for the samples. The samples before the reactions were heat-treated in air at 400°C for 2 h (300°C for the NbO-NA(c) sample). Prior to N$_2$ adsorption, the catalysts were evacuated under vacuum at 300°C for 2 h. External surface area was calculated by a multipoint Brunauer-Emmett-Teller (BET) method and the t method. Temperature-programmed desorption (TPD) of ammonia, NH$_3$-TPD, was employed to measure oxide surface acidity. The experiment was carried out using an auto chemisorption system (BEL JAPAN). The experimental procedure was as follows. The catalyst (ca. 50 mg) was set between two layers of quartz wool and pre-heated under helium (50 mL min$^{-1}$) at 400°C for 1 h (300°C for the NbO-NA(c) sample). Then ammonia was introduced at 150°C for 30 min. The desorption profile from 150 to 700°C was recorded with a mass spectrometer under helium flow (50 mL min$^{-1}$). Temperature-programmed decomposition mass spectrometry (TDP-MS) measurements were performed from 40 to 700°C at a heating rate of 10°C min$^{-1}$ in helium flow (50 mL min$^{-1}$). The decomposed gas molecules were monitored by a mass spectrometer (ANELVA, Quadrupole Mass Spectrometer, M-100QA, BEL Japan), collecting several mass fragments: CO$_2$ (44), O$_2$ (32), CO and N$_2$ (28), H$_2$O (18, 17, 16) and NH$_3$ (17, 16, 15). XPS (JPC-9010MC, JEOL) with non-monochromatic Mg-Kα radiation was used for measuring binding energy values of Nb. Binding energy was referred by Au 4f7/2 (84.0 eV) deposited by an auto fine coater (JFC-1600, JEOL). Measurements of thermogravimetric-differential thermal analysis (TG-DTA) were performed on a TG-8120 (Rigaku) thermogravimetric analyzer. Dry air provided by a pressure tank with a flow rate of 30 mL min$^{-1}$ was used as the carrier gas. The
Several niobium precursors were used for hydrothermal synthesis of niobium oxides, and the results of characterization results of the obtained niobium oxides are summarized in Table 1. Fig.1 shows XRD patterns of the obtained niobium oxide samples. When 0.15 mol L\(^{-1}\) of ammonium niobium oxalate (NH\(_4\)\(\text{NbO}(C_2\text{O}_4)_2\)(H\(_2\text{O}\))\(_2\)) dissolved in 40 mL of water was used as a precursor solution (NbO-ANO), the XRD pattern of NbO-ANO calcined at 400 °C showed only a tense and sharp peak at 2θ = 22.7° and a relatively weak peak at 2θ = 46.2°. The peaks at 2θ = 22.7° and 46.2° can be attributed to (001) and (002) planes, respectively. The XRD pattern of NbO6ANO was very similar to that of amorphous MoO\(_3\) (Fig. S1), which possess a layered structure. Several niobium precursors were used for hydrothermal synthesis. Crystalline niobium oxides were collected to confirm the crystal structure (Fig. 2a). The layer distance in the c-direction was estimated to be 3.91 Å from HRTEM images, which is in good agreement with the results obtained from the XRD pattern of that catalyst. Leite et al. reported the synthesis of pseudohexagonal niobium oxide nanorods by hydrothermal treatment (140 °C) of a niobium peroxo complex precursor formed by ammonium niobium oxalate (NH\(_4\)[NbO(C\(_2\)O\(_4\))\(_2\)](H\(_2\)O\(_2\))\(_2\)) and hydrogen peroxide\(^2\). It is thought that these different phases of the layered-type and pseudohexagonal niobium oxides were formed due to the different niobium precursors and hydrothermal conditions.

Niobic acid, which is often used as a solid acid, was also subjected to hydrothermal synthesis. Crystalline niobium oxides possessing a pseudohexagonal phase (NbO-NA(d)) and pyrochlore phase (NbO-NA(c)) were synthesized by adjusting the amount of niobic acid in the precursor solution, and their diffraction patterns are shown in Fig. 1. Fig. S2 shows the effects of the amount of niobic acid on the XRD patterns of niobium oxides obtained before calcination. The sample obtained from 0.25 mmol Nb\(_2\)O\(_5\) in 40 mL deionized water (NbO-NA(d)) gave diffraction peaks at 2θ = 22.5, 28.3, 36.5, 46.0, 50.1, 54.9°. This pattern was in agreement with the pseudohexagonal structure called TT-Nb\(_2\)O\(_5\) phase (JCPDS 28-0317, lattice constants: c = 3.94 Å and a = 3.64 Å). The structure of TT-Nb\(_2\)O\(_5\) is shown in Fig. 2c. The a-b plane is comprised of edge-shared NbO\(_6\) and NbO\(_2\) units. These are linked by corner-sharing polyhedra along the c-axis to form the three-dimensional structure.\(^{35-35}\) The XRD patterns for niobium oxide obtained from 4 mmol Nb\(_2\)O\(_5\) in 40 mL deionized water (NbO-NA(c)) gave diffraction peaks at 2θ = 14.5, 28.0, 29.2, 33.9, 37.0, 41.8, 44.5, 48.7, 51.1, 57.1, 57.9° (Fd-3m(227), JCPDS 61-0608), which are ascribable to a pyrochlore type crystalline structure (Fig. 2d). The pyrochlore structure is comprised of corner-shared NbO\(_6\) octahedra. There are a few reports for pyrochlore H\(_4\)Nb\(_5\)O\(_{19}\). Wu et al. reported photocatalytic activity over pyrochlore H\(_4\)Nb\(_5\)O\(_{19}\) obtained by a hydrothermal method,\(^2\) and Nalbandyan et al. described a method for synthesis by a solid state reaction in the JCPDS data base. In the case of ammonium niobium oxalate precursor, regardless of the concentration in the range from 0.0125 to 0.25 mol L\(^{-1}\), the XRD patterns of the niobium oxide samples gave the same peaks at 2θ =

*Calculated by the BJH method.
For niobium oxide synthesis by a hydrothermal process, the as-synthesized NbO-ANO showed peaks at 2θ = 22.7° and 46.2° as in the case of pseudohexagonal (TT Nb$_5$O$_5$) structures. The peaks based on the pyrochlore structure were decreased by calcination at 200°C. The samples were heat-treated at different temperatures under air in order to examine their thermal stability. Fig. 3 shows the effect of calcination temperature on XRD patterns of NbO-ANO and NbO-NA(c). The XRD patterns of the as-synthesized NbO-ANO showed tense and sharp peaks at 2θ = 22.7° and 46.2° as described above. The structure of layered niobium oxide was maintained after 500°C treatment. When NbO-ANO was calcined at 550 and 700°C, the peaks at 22.7° shifted to lower angles and diffraction peaks based on orthorhombic niobium oxide (T- Nb$_5$O$_5$, Pbam (55), JCPDS 30-0837) appeared. The orthorhombic (T- Nb$_5$O$_5$) phases are difficult to distinguish in terms of structure. The T phase is thought to be simply a more ordered structure of the TT phase (Fig. 2c). The pyrochlore sample was not stable for heat treatment. The positions of the diffraction peaks of samples heat-treated at 200 and 300°C for 4 h did not shift, but intensities of the peaks decreased with increase in the calcination temperature. The diffraction pattern of pyrochlore niobium oxide calcined at a temperature higher than 400°C was hexagonal phase, revealing a phase transition. And the monoclinic phase was observed in the sample calcined at 800°C. In order to evaluate the characteristic of pyrochlore structure, NbO-(c) was treated at 300°C. Raman spectroscopy was performed to confirm the

Niobium oxide was also synthesized under hydrothermal conditions from a mixture of niobic acid and oxalic acid. Oxalic acid was added to a niobic acid (2 mmol)-dispersed solution. By the addition of more than 0.125 mol L$^{-1}$ oxalic acid, niobic acid was completely dissolved. Fig. S4 shows the effects of the ratio of oxalic acid and niobic acid on the XRD pattern of niobium oxide. In the case of only niobic acid, the diffraction pattern was a mixture of layered, pseudohexagonal and pyrochlore structures, and the peaks based on the pyrochlore structure were decreased by calcination at 400°C, while the peaks based on the pseudohexagonal phase remained as described later. The peaks based on the pyrochlore and pseudohexagonal structures were decreased by the addition of oxalic acid, and peaks of the pyrochlore and pseudohexagonal structures were not observed by the addition of 0.25 mol L$^{-1}$ oxalic acid. This sample was denoted as NbO-NA(o). The XRD pattern of the NbO-NA(o) sample showed peaks at 2θ = 22.7° and 46.2° as in the case of NbO-ANO. For niobium oxide synthesis by a hydrothermal process, it is considered that niobium oxide is formed through a dissolution-crystallization mechanism and rearrangement of niobium polyhedra occurs. In the presence of oxalic acid, Nb forms pentagonal bipyramidal units with an oxalate ligand in the precursor solution, and the pentagonal \{Nb$_5$O$_5$\} units would be formed under hydrothermal conditions. The pentagonal units play an important role in the formation of a new crystalline structure under hydrothermal condition.
niobium oxide structure of the NbO-ANO catalyst. The Raman band in the 500-800 cm\(^{-1}\) is assigned to symmetric stretching modes of slightly distorted NbO\(_6\) octahedra, and associated bending modes of Nb-O-Nb linkages appear in the low wavenumber region around 200 cm\(^{-1}\).\(^{13, 14}\) In the case of pseudohexagonal (TT\(_6\) phase) Nb\(_2\)O\(_5\), the Raman band of symmetric stretching modes of NbO\(_6\) octahedra is observed in around 700 cm\(^{-1}\). The weak broad Raman band around 900 cm\(^{-1}\) is assigned to the symmetric stretching mode of Nb=O terminal Nb\(_6\)O for the pyrochlore NbO\(_6\).\(^{61}\) The Raman band at 710 cm\(^{-1}\) was assigned to translational modes of Nb, and the Raman band at 860, 940 cm\(^{-1}\) was assigned to the symmetric stretching mode of terminal Nb-O for the pyrochlore NbO-NA(c).\(^{66}\) The Raman band at 710 cm\(^{-1}\) of the pseudohexagonal NbO-NA(d), which possesses NbO\(_6\) octahedra and NbO\(_7\) in its structure, is assigned to the symmetric stretching mode of polyhedra. The Raman band at 230, 970 cm\(^{-1}\) was assigned to the bending modes of Nb-O-Nb linkage and the symmetric stretching mode of Nb=O, respectively. The Raman band of NbO-ANO was almost the same as that of NbO-NA(d), indicating that NbO-ANO also consists of NbO\(_6\) and NbO\(_7\). For the NbO-cal and NbO-NA(o) samples, the band of the symmetric stretching mode of polyhedra shifted to 690 cm\(^{-1}\). For the NbO-NA(o) sample, the band of the symmetric stretching mode of polyhedra was broadened compared to that of the NbO-NA(d) sample, indicating that these samples contain distorted NbO\(_6\) octahedra, NbO\(_7\) pentagonal bipyramids and NbO\(_8\) hexagonal bipyramids.\(^{13}\)

The XRD pattern and Raman spectra of NbO-ANO indicated that NbO-ANO is a layered-structure composed of NbO\(_6\) octahedra and NbO\(_7\) pentagonal bipyramids interconnected in the a-b plane. This structure can be regarded as a niobium bronze structure based on pentagonal \{NbO\(_2\)\} building units. Lundberg et al. reported orthorhombic Cs\(_x\)(Nb,W)O\(_{14}\)\(^{22}\) that possesses a tungsten or niobium bronze structure based on the pentagonal unit. This Cs\(_x\)(Nb,W)O\(_{14}\) was synthesized by solid state reaction at a high temperature, so that a small surface area (3 m\(^2\) g\(^{-1}\)) is inevitable and it is difficult to remove the cesium cations in the heptagonal channel.\(^{28}\) We have reported that the molybdenum bronze based on the pentagonal \{MoO\(_2\)\} unit of orthorhombic Mo\(_6\)VO\(_{14}\) obtained by a hydrothermal method. Ammonium cations derived from the precursor are located in the heptagonal channel and they can be removed as ammonia by calcination. After calcination, the heptagonal channel acts as a micropore.\(^{23}\) Therefore, the presence of micropores confirms the formation of a bronze structure as orthorhombic phase (Fig. 2b). In order to investigate the microporosity, \(N_2\) adsorption of NbO-ANO, NbO-Nb(d), NbO-NA(c), NbO-NA(o) and NbO-cal was examined (Fig. S6), and calculated data are summarized in Table 1. The orthorhombic Mo\(_6\)VO\(_{14}\) showed \(N_2\) adsorption at a relative pressure \(P/P_0\) lower than 1.0 \(\times\) 10\(^{-3}\), revealing microporosity. The NbO-ANO sample also showed \(N_2\) adsorption at low pressure (1.0 \(\times\) 10\(^{-6}\)), suggesting the formation of micropores like heptagonal channels. In addition, the difference in surface area between the BET method and the \(t\)-method indicates the existence of micropores. After the adsorption at 1.0 \(\times\) 10\(^{-6}\), the amount of adsorbed nitrogen gradually increased with nitrogen pressure for NbO-ANO, suggesting that the micropores formed within NbO-ANO are partially non-uniform. NbO-NA(o) and NbO-NA(d) also adsorbed \(N_2\) at relatively low pressure, but the adsorption volume increased gradually, implying that the size of micropores was not ordered. NbO-NA(c) and NbO-cal did not show

\(^{a}\) Acid amounts were calculated by \(NH_2\)-TPD and BET surface area, \(^{b}\) formation rate of benzyl anisole per BET surface area for condition II, \(^{c}\) reaction condition I: benzyl alcohol (1.0 mmol), anisole (50 mmol), catalyst (0.1 g), 100 °C, 30 min, \(^{d}\) reaction condition II: benzyl alcohol (10 mmol), anisole (100 mmol), catalyst (0.1 g), 100 °C, 120 min.
Benzyl alcohol conversion and benzyl anisole yield were observed NH\textsubscript{3}\% in all experiments. The NbO\textsubscript{6}ANO (deformed orthorhombic) anisole and dibenzyl ether. Carbon balance was always more than alcohol and with 94\% yield (benzyl anisole) catalyst had the highest activity, with 100\% conversion of benzyl synthesized NbO\textsubscript{6}ANO can be expressed as an interconnection of crystal structure motifs such as \{Nb\textsubscript{6}O\textsubscript{4}\textsubscript{1}\} pentagonal units and micropore channels but without any long-range order. In order to confirm the structure, TPD-MS, TG and XPS were carried out (Fig. S7, S8). From these analyses, the formula of as-synthesized NbO-ANO can be expressed as H\textsubscript{19.9}O\textsubscript{5}(NH\textsubscript{4})\textsubscript{2}Nb\textsubscript{6}O\textsubscript{31}·3.6H\textsubscript{2}O, calculated on the basis of a lattice unit of the orthorhombic phase. The elemental composition is expressed as A\textsubscript{1}M\textsuperscript{V/VI}\textsubscript{6}\textsubscript{a}O\textsubscript{112}·nH\textsubscript{2}O (A: cation, M: metal) for the orthorhombic structure. The ratio of ammonia cation to metal was matched from a structural point of view. This result indicated that NH\textsubscript{3} is located in the heptagonal channel.

NH\textsubscript{4}\textsuperscript{+} formed by NbO\textsubscript{6} octahedra (NH\textsubscript{4}-ONb) in the heptagonal channel can be released by calcination, and Brønsted acid sites (HO-Nb) will be produced. Thus, the solid acid catalytic activity was examined about the relationship between the structure and catalytic activity. Results for the Friedel-Crafts alkylation reactions of anisole with benzyl alcohol over various niobium oxides are presented in Table 2 and Fig. S9. Several catalysts showed 100\% conversion under the condition I, therefore catalytic test were also conducted under the condition II in order to compare the catalytic activity. Acid amounts of niobium oxides were measured by NH\textsubscript{3}-TPD (Fig. S10 and Table 2). The products were benzyl anisole and dibenzyl ether. Carbon balance was always more than 97\% in all experiments. The NbO-ANO (deformed orthorhombic) catalyst had the highest activity, with 100\% conversion of benzyl alcohol and with 94\% yield (benzyl anisole) under the condition I. Catalyst reuse experiment was tested under the condition II for three runs(Fig. S11). The collected catalyst was repeatedly rinsed with acetone and dried in the oven at 80 °C. No significant decrease in benzyl alcohol conversion and benzyl anisole yield were observed after three reuses of the catalyst. The conversion of benzyl alcohol decreased with increase in the heat treatment temperature, and the NbO-ANO sample calcined at 550 °C showed 31\% conversion with 29\% yield, NbO-ANO calcined at 700 °C (orthorhombic, T-T\textsubscript{NbO\textsubscript{3}}) showed no catalytic activity. NbO-NA(d) (pseudoorthorhombic) samples (83\% conversion, 78\% yield) and NbO-cal (amorphous) samples (12\% conversion, 9\% yield) showed less activity.

NbO-NA(c) (pyrochlore) showed no catalytic activity as a solid acid, even though it adsorbed many NH\textsubscript{3} molecules as revealed by NH\textsubscript{3}-TPD. The amount of absorbed NH\textsubscript{3} was 1.36 mmol g\textsuperscript{-1} when NH\textsubscript{3} was adsorbed at 150 °C, and this value corresponded to (NH\textsubscript{4})\textsubscript{8}Nb\textsubscript{6}O\textsubscript{3}·H\textsubscript{2}O. The adsorbed NH\textsubscript{3} would be located inside the hexagonal channel like other pyrochlore type A\textsubscript{2}Nb\textsubscript{2}O\textsubscript{7},\textsuperscript{37–39} and this site potentially acts as a solid acid site, but the hexagonal channel is too small for an organic substrate to access. The NbO-NA(a) samples showed less activity than that of NbO-ANO under the condition II (Table 2). Fig. 5 shows the results of characterization and alkylation reaction for niobium oxide obtained from the mixture of niobic acid and oxalic acid. By the addition of oxalic acid to niobic acid, the BET surface area and acid amount increased, and with an increase in the concentration of oxalic acid, the BET surface area and acid amount gradually decreased. On the other hand, the yield of benzyl anisole increased with increase in the oxalic acid concentration in the precursor solution. Although NbO-NA(o) showed an XRD pattern similar to that of NbO-ANO, the catalytic activities were different under the condition II. From the Raman spectra of NbO-NA(o), the band of the symmetric stretching mode of niobium polyhedra was broad (Fig. 4) and the N\textsubscript{2} adsorption at low pressure indicated that micropores based on the heptagonal channel were not formed orderly. In the case of orthorhombic Mo\textsubscript{6}VO\textsubscript{4}, the cation in the precursor solution acts as a stabilizer and a structure-directing agent under hydrothermal conditions.\textsuperscript{40} For niobium oxide, it is considered that the ammonium cation has an important role in the formation of a uniformed crystalline structure and micropores based on the heptagonal channel. These results also suggested that a stronger Brønsted acid site was formed around the open mouth of the heptagonal channel after desorption of ammonia.

A comparison of the formation rates of benzyl anisole per surface area showed that the order of catalytic activity was NbO-ANO (deformed orthorhombic)\textsuperscript{>}, NbO-NA(a)\textsuperscript{>}, NbO-NA(d) (TT-Nb\textsubscript{2}O\textsubscript{5}), NbO-cal (amorphous)\textsuperscript{>}, NbO-ANO(T-T\textsubscript{NbO\textsubscript{3}}), NbO-NA(c) (pyrochlore). It is difficult to relate the acid amount to alkylation activity because the acid amount calculated by NH\textsubscript{3}-TPD includes both Lewis acid and Brønsted acid sites. It is known that the activity of alkylation of anisole and benzyl alcohol over niobic acid can be promoted on Brønsted acid sites.\textsuperscript{16–22} To demonstrate the effect of Brønsted acid site, ion exchange treatments were conducted. After K\textsuperscript{+}-exchange treatment (NbO-ANO(K\textsuperscript{+})), 85\% of NH\textsubscript{4}\textsuperscript{+} in the niobium oxide was ion-exchanged by K\textsuperscript{+} as confirmed by TPD measurement (Fig. S12). IR spectra also confirmed that NH\textsubscript{4}\textsuperscript{+} existed in the NbO-ANO precursor and NH\textsubscript{4}\textsuperscript{+} was removed by
the ion exchange treatment. In addition, after NH$_4^+$-exchange treatment of NbO-ANO(K$^+$), the amount of NH$_4^+$ in NbO-ANO(NH$_4^+$) was 81% of NbO-ANO. NbO-ANO (K$^+$) showed no activity for alkylation reaction of benzyl alcohol. On the other hand, NbO-ANO(NH$_4^+$) showed activity similar to that of NbO-ANO (Table 2). These results suggested that the NbO-ANO possess the ion-exchange capacity. The ion exchange treatment by K$^+$ deactivated the Brönsted acid sites but these sites were recovered by the further ion-exchange by NH$_4^+$ and the calcination.

NbO-ANO (H$_{19.9}$(NH$_4$)$_{14.1}$Nb$_{58}$O$_{122}$$\cdot$3.8H$_2$O) desorbed NH$_3$ and water during calcination at 400 °C without changing its structure. A Brönsted acid site would be formed around the open mouth of the heptagonal channel after desorption of ammonia. This acid site of NbO-ANO can explain the solid acid activity for crystalline niobium oxide. A more crystalline niobium oxide must be prepared for its exact structure analysis. However, layered-structure niobium oxide formed by NbO$_6$ octahedra and NbO$_7$ pentagonal bipyramids, possessing a crystalline structure such as an orthorhombic structure, would form exceptional acid sites.

Conclusions

Crystalline niobium oxides (deformed orthorhombic, pseudohexagonal (TT-Nb$_2$O$_5$), orthorhombic (T-Nb$_2$O$_5$) and pyrochlore niobium oxides) were synthesized by a hydrothermal process. The NbO-ANO sample obtained from ammonium niobium oxalate showed a layered-type structure, in which NbO$_6$ octahedra were corner-sharing in the c-direction. Raman spectra indicated that the layered niobium consisted of NbO$_6$ octahedra and NbO$_7$ in its structure. Adsorption results showed the presence of micropore channels, indicating the formation of a high-dimensional structure in the a-b plane. From these results, we concluded that the structure of NbO-ANO was deformed orthorhombic phase. As-synthesized NbO-ANO was expressed as H$_{19.9}$(NH$_4$)$_{14.1}$Nb$_{58}$O$_{122}$$\cdot$3.8H$_2$O, and NH$_3$ and water were desorbed by calcination at 400 °C, forming Brönsted acid without changing its structure. This material showed the high catalytic activity as a solid acid. The layered-structure niobium oxide composed of NbO$_6$ octahedra and {Nb$_2$O$_{21}$} pentagonal units forms exceptional Brönsted acid around the open mouth of the heptagonal channel.
