This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Ferromagnetic Ordering in the Organic Radical Cation Salt BBDTA•Au(CN)₂ at 8.2 K

Wataru Fujita

An organic radical cation salt, BBDTA•Au(CN)₂, with a slipped π-stacking columnar structure and intercolumnar short contacts, shows ferromagnetic ordering at 8.2 K, the highest reported temperature among the BBDTA⁺ cation salts.

Organic radicals with sulfur-nitrogen heterocyclic rings, the so-called heterocyclic thiazyl radicals, play an important role in the development of molecule-based functional materials. In particular, heterocyclic thiazyl radical derivatives are magnetically ordered materials based on organic molecules with spontaneous magnetization. In 1996, Rawson et al. reported canted antiferromagnetism with spontaneous magnetization below 36 K in the heterocyclic thiazyl radical β-p-NCC₆H₄-CNSSN⁺. This discovery was surprising to researchers studying organic magnets, because until then ferromagnetic transition temperatures in organic radical magnets were below 1 K, except for the charge transfer complex C₆₀-TDAE. Subsequently, bulk ferromagnetic ordering below 7.0 K in the radical cation salt γ-BBDTA•GaCl₄, which is a monocation salt of benzo[1,2-d:4,5-d']bis[1,3,2]dithiazole (BBDTA, Scheme 1), was found in 2002. The transition temperature was above the temperature of liquid helium (4.2 K), which is rare for magnetic materials. In 2008, Oakley et al. reported bis-1,2,3-diselenazolyl radical derivatives with ferromagnetism below 17 K and canted antiferromagnetism below 27 K. Furthermore, heterocyclic thiazyl radicals show magnetic bistability, photo-induced phase change, unique pressure dependence, electric conductivity, and negative resistance phenomena.

This report focuses on the radical cation salt of BBDTA⁺. The BBDTA⁺ radical was first reported by Wolmershäuser et al. in 1988 as the cation salt BBDTA•FeCl₄•CH₃CN, in which BBDTA⁺ forms a face-to-face dimerized structure and has an antiferromagnetic phase transition originating from the counter anion Fe(III)Cl₆⁻ (S = 5/2) at 6.6 K. In a previous report, the crystal structure and magnetic

properties of BBDTA\textsuperscript{+} cation radical salts were systematically investigated with various anions, mainly halogens or halogenometallate ions, to determine the antiferromagnetic ordering, metamagnetic phase transition, and spin-Peierls transition.\textsuperscript{9} Additionally, ferrimagnetic states in salts with paramagnetic halogenometallate ions were realized.\textsuperscript{10}

The observed diversity in the magnetic behavior of BBDTA\textsuperscript{+} cation salts originates from the various molecular alignments of BBDTA\textsuperscript{+} cations in the crystalline states, which may be governed by effects such as Coulomb interactions between ions, interatomic S\textsuperscript{•••}N and/or S\textsuperscript{•••}S contacts between neighboring radical cations, and halogen bonds between radical cations and counter anions.

In this study, the preparation, crystal structure, and magnetic properties were determined for BBDTA\textsuperscript{+}Au(CN)\textsubscript{2}, a radical cation salt with dicyanouarate ions, which are linear with no halogen atoms. BBDTA\textsuperscript{+}Au(CN)\textsubscript{2} shows the highest ferromagnetic ordering temperature of the reported BBDTA\textsuperscript{+} cation salts. The origin of ferromagnetic interactions between BBDTA\textsuperscript{+} cations in the salt, estimated from molecular orbital calculations based on atomic coordinates obtained from the crystal data, is also discussed.

BBDTA\textsuperscript{+}Au(CN)\textsubscript{2} was prepared by the slow diffusion of BBDTA\textsuperscript{•}FeCl\textsubscript{4}\textsuperscript{0} and tetra-\textit{n}-butylammonium dicyanouarate in dry acetonitrile in a test tube at room temperature. Black needle-like crystals were formed after 1 day. The salt was stable in air and insoluble in organic solvents such as acetone, acetonitrile, toluene, and dichloromethane. In BBDTA\textsuperscript{+} salts, polymorphs are often found. For instance, there are three polymorphs in the GaCl\textsubscript{4}\textsuperscript{0} salt with dicyanoaurate ions, which are linear with no halogen atoms. For instance, there are three polymorphs in the GaCl\textsubscript{4}\textsuperscript{0} salt with dicyanoaurate ions, which are linear with no halogen atoms.

Fig. 2. BBDTA\textsuperscript{+}Au(CN)\textsubscript{2} at 500 Oe using a SQUID magnetometer; the results are shown in Fig. 2a. BBDTA\textsuperscript{+}FeCl\textsubscript{4}\textsuperscript{0} was adopted as the molar unit. The diamagnetic susceptibility was estimated to be $\chi_{p} = -0.000409$ emu mol$^{-1}$ by assuming that the magnetic properties of this material obey the Curie-Weiss law\textsuperscript{12} at high temperatures. Figure 2a shows the $\chi_{p}T$ vs. $T$ plot for this material. The $\chi_{p}T$ value at 300 K was 0.422 emu K mol$^{-1}$, which is larger than the theoretical value of 0.375 emu K mol$^{-1}$, estimated by assuming that no magnetic interactions exist between 1 mol of $S = 1/2$ (g = 2.00) spins. This discrepancy indicates that intermolecular ferromagnetic interactions between the radical cations are present. The g value of a powdered sample BBDTA\textsuperscript{+}Au(CN)\textsubscript{2} was estimated to be 2.0083 from ESR spectroscopy. Data in the range 250–300 K were fit according to the Curie-Weiss law, with $C = 0.125g^2(S(S+1)) = 0.378$ emu K mol$^{-1}$ (fixed) and $\theta = +14.5$ K, where C and $\theta$ are the Curie and Weiss constants, respectively. As the temperature decreased from 300 K, $\chi_{p}T$ increased. Below 10 K, $\chi_{p}T$ rapidly increased and became 13.2 emu mol$^{-1}$ at 7 K.
The magnetic behavior of this material can be interpreted in terms of the ferromagnetic regular chain model using the Hamiltonian in eq 1, where $J_{\text{intra}}$ is the intrachain magnetic coupling constant between neighboring magnetic molecules $i$ and $j$,

$$H = -2J_{\text{intra}} \sum S_i \cdot S_j$$  \hspace{1cm} (1)$$

The analytical expression for the paramagnetic susceptibility $\chi_{1D}$ of the $S = 1/2$ 1D Heisenberg ferromagnetic chain model\textsuperscript{13} is given as

$$\chi_{1D} = \frac{C}{T} \left( \frac{1 + a_s \cdot K + a_s \cdot K^2 + a_s \cdot K^3 + a_s \cdot K^4}{1 + a_s \cdot K + a_s \cdot K^2 + a_s \cdot K^3 + a_s \cdot K^4} \right)^{2/3}$$  \hspace{1cm} (2),$$

where $C$ (the Curie constant) $= N g^2 \mu_B^2/(4k_B a_1)$, $K = J_{\text{intra}}/(2k_B T)$, $a_1 = 5.797991$, $a_2 = 16.902653$, $a_3 = 29.376885$, $a_4 = 29.832959$, $a_5 = 14.036918$, $a_6 = 2.7979916$, $a_7 = 7.0086780$, $a_8 = 8.6538644$, $a_9 = 4.5743114$. $N$, $g$, $\mu_B$, and $k_B$ are the Avogadro’s number, the coordination number, the $g$ factor, the Bohr magneton, and the Boltzmann constant, respectively.

The interlayer magnetic interaction $J_{\text{intra}}$ in the paramagnetic susceptibility, $\chi_{p}$ of 1 then can be deduced by using a simple mean field approximation:\textsuperscript{14}

$$\chi_{p} = \frac{\chi_{1D}}{1 - \frac{2zJ_{\text{intra}}}{g^2 \mu_B^2 N}}$$  \hspace{1cm} (3),$$

where $z$ is the coordination number. The solid curve in Fig. 2(a) is the best fit with $g = 2.0083$ (fixed), $J_{\text{intra}}/k_B = +46$ K, and $zJ_{\text{intra}}/k_B = +1.2$ K.

In order to investigate the low-temperature magnetic behavior of this material, AC magnetic susceptibility measurements were carried out. Figure 2b shows the temperature dependence of real $\chi'_{ac}$ and imaginary $\chi''_{ac}$ parts of the AC susceptibility under an AC field strength of 5 Oe (100 Hz) and DC field strength of 0 Oe. $\chi'_{ac}$ reached a peak at 7.5 K and $\chi''_{ac}$ also increased in the same range, but was consistently zero above 10 K. This suggests the appearance of a ferromagnetic domain below 10 K.\textsuperscript{15} Figure 2c shows the $M$-$H$ curve of this material at various temperatures. Above 10 K, the magnetization value increased gradually with an increase in the magnetic field. The magnetization curve increased more rapidly under lower temperatures. At 2 K, the magnetization value was almost saturated at 300 Oe. The value of magnetization at 50,000 Oe was 0.900 $N\mu_B$, which is close to the theoretical value for the ferromagnetically ordered state of 1 mol of $S = 1/2$ spin species.\textsuperscript{12} Thus, the low-temperature magnetic data indicate ferromagnetic ordering around 10 K. A negligibly small hysteresis loop with a width less than 10 Oe was observed, indicating that the obtained material is a soft magnet.

The temperature dependence of the heat capacity $C_p$ of BBDTA•Au(CN)$_2$ was studied for the needle-like crystals over the temperature range 2–100 K; the results are depicted in Fig. 3. The heat capacity exhibits an anomaly at 8.2 K, supporting the occurrence of magnetic ordering at the peak temperature. The total magnetic entropy was evaluated to be 4.63 J K$^{-1}$ mol$^{-1}$ by integrating the $C_p/T$ values with respect to $T$. This value is 80.4% of the expected value of the magnetic entropy for 1 mol of $S = 1/2$ spins ($R \ln 2 = 5.76$ J K$^{-1}$ mol$^{-1}$).\textsuperscript{16}

The exchange coupling constants of intermolecular ferromagnetic interactions in assorted organic radical magnetic materials and BBDTA•Au(CN)$_2$ are summarized in Table 1. The material used in this study has stronger ferromagnetic interactions than those of other reported organic radical magnetic materials. The ferromagnetic interaction in this material is about twice as large as that of the highest organic ferromagnet. Additionally, its ferromagnetic ordering temperature is relatively high due to the simple molecular structure of BBDTA\textsuperscript{17} and lack of bulky substitution groups on the periphery of the π-conjugated system, which aids the formation of short intermolecular distances. However, many neutral sulfur-nitrogen radicals with no substitution groups form dimers with large intermolecular π-overlaps and have a diamagnetic ground state. In BBDTA\textsuperscript{18}, intermolecular columbic repulsions arising from the positive charges on the radical cations may prevent large intermolecular π-overlaps.

In conclusion, this report detailed the synthesis and crystal structure of the organic radical cation BBDTA•Au(CN)$_2$ and compared its magnetic properties with those of other organic radical magnetic materials. Ferromagnetic ordering was observed at 8.2 K, which is the highest reported ferromagnetic ordering temperature of any BBDTA\textsuperscript{19} cation salt. This material also showed the largest ferromagnetic interaction of the reported organic ferromagnets. The results also show that to construct a ferromagnet with a higher transition temperature, it is necessary to enhance the intra- and interchain magnetic interactions. Controlling the molecular alignment through a combination of organic radical cations,
appropriate anions, and/or substitution of sulfur atoms in the sulfur-nitrogen radicals to heavier atoms such as selenium or tellurium may beneficially alter the transition temperature.
