This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Exploring the meaning of sugar configuration in a supramolecular environment: Comparison of six octyl glycoside micelles by ITC and NMR spectroscopy

Jörn Schmidt-Lassen, Thisbe K. Lindhorst

A series of octyl α- and β-glycosides of the manno- galacto- and gluco-series were synthesized and employed in formation of homo- and hetero-micelles in water. Critical micelle concentrations (cmc), thermodynamic quantities of demicellation and, to some extent, the hydrodynamic radii of glycomicelles were determined by isothermal titration calorimetry (ITC) and diffusion NMR studies. The goal of this work was to determine the significance of anomeric configuration as well as of epimerisation at the sugar ring for supramolecular features of the respective glycoside. A new projection of glycoside structures is proposed to facilitate interpretation of structure-property relationships in this regard.

Introduction

Carbohydrates are constituents of every cell surface (glycocalyx) where they play crucial roles in cellular communication, both in health and disease states of an organism. A lot is known about the biological importance of the glycosylated cell surface, but little has been disclosed about the meaning of specific sugar configurations within this supramolecular environment. However, for the advancement of the medicinal chemistry of carbohydrates, it is important to improve our knowledge about the impact of sugar configuration on the cell surface biology. To date, it is not obvious how the subtle differences between biologically important carbohydrate structures, for example d-mannose, d-galactose or d-glucose, contribute to specificity and regulation in cell biology, while being embedded into a highly dynamic molecular context that expands over 100 nm width or more. Moreover, there are no direct experimental means to investigate and compare the structural effects of individual monosaccharides in vivo. Therefore, we have used glycomicelles as a highly simplified but well approved multivalent and supramolecular construct to probe how the configuration of sugars influences their interactions in water. Eventually, determination of structure-property relationships in micelle formation will allow us to draw conclusions about the impact of configurational differences in a supramolecular carbohydrate environment.

Glycomicelles are robust and well investigated supramolecular systems that have been used earlier in biological chemistry such as for the study of self-assembly properties of glycolipids, for example. They are amenable to different biophysical techniques, e.g. surface tension measurements, fluorescence spectroscopy, or various scattering methods (DLS, SANS, SAXS). In addition, methods that allow to measure kinetic and thermodynamic parameters of micelles are of relevance in a biological context.
Here, a collection of six different octyl glycosides were synthesized and employed (Figure 1) in isothermal calorimetry titrations and NMR-spectroscopic studies, including well-known octyl β-glucoside (6), which is commercially available and regularly used for the formation of glycomicelles. Two series of octyl glycosides were tested, α-d-mannoside (1), α-d-galactoside (3), and α-D-glucoside (5), and the respective β-glycosides 2, 4, and 6. Hence, the influence of the anomeric configuration on micelle formation can be compared, as well as the meaning of inversion of configuration at C2 and C4 of the sugar ring, respectively. In addition, mixed, so-called hetero-glycomicelles were formed and compared with the respective homo-glycomicelles.

Results

Synthesis

Fig. 1 Structures of the investigated amphiphilic octyl glycosides. Two series of sugars differing in their configurational characteristics were employed for glycomicelle formation: α- and β-glycosides 1, 3, and 5 and 2, 4, and 6, respectively.

The employed amphiphilic octyl glycosides 1-6 are literature-known and were synthesized according to described procedures (cf. Experimental and ESI).

ITC measurements of homo-glycomicelles

At first, isothermal titration calorimetry (ITC) was used to study homo-micelle formation of the octyl α-glycosides 1, 3, 5 and of the corresponding octyl β-glycosides 2, 4 and 6. ITC is a standard technique to determine thermodynamic parameters of molecular interactions in solution including micelle formation and determination of critical micelle concentrations (cmc). Cmc values are frequently obtained in demicellation studies employing concentrated solutions of each sample to be titrated into water. In our study, as expected, exothermic demicellation processes were observed in all cases as reflected by the obtained ITC diagrams (Figure 2); cmc values were deduced from their inflection points. The obtained data are collected in the table insert of Figure 2. Owing to its low water solubility, the cmc of αOctylGlc (5) could not be determined by ITC. The cmc of 5, however, has been reported in the literature based on tensiometric studies (Figure 2, table insert).

Fig. 2 Integrated ITC titration curves of homo-glycomicelles obtained at 298 K: Effect of anomeric configuration: a) α- and β-octyl mannose micelles formed of 1 and 2; b) α- and β-octyl galactoside micelles formed of 3 and 4. Effect of configuration of the sugar ring: c) α-anomeric micelles formed of 1 and 3, respectively (5 was not sufficiently soluble in water); d) β-anomeric micelles formed of 2, 5, and 6, respectively. Representative curves are shown. ΔH: reaction enthalpy per injection. ITC
Thus, the effect of anomeric configuration on micelle formation could be studied in the manno- as well as the galacto-series (Figure 2a and b). No significant difference between the α- and β-glycomicelles was detected in the galacto-series, but the manno-series, on the other hand, exhibits a distinctive effect with a much lower $cmc$ for the α-micelle (10.9 mM) than for the respective β-micelle (22.9 mM). Accordingly, formation of α-mannomicelles starts at ~half the concentration which is required for formation of the corresponding β-micelle. In the gluco-series, we determined a $cmc$ of 28.3 mM for the β-glucoside. Literature reports on $cmc$ values of octyl glucosides diverge to some extent, which can be due to different determination methods employed. Focher\textsuperscript{18} and Matsumura\textsuperscript{19} and co-workers used a surface tension method for $cmc$ determination, where effects of dilution and all intermolecular interactions are not taken into account. Consequently lower $cmc$ values were found. Focher et al. determined the $cmc$ value for the β-glucoside 6 as 19 mM and for the α-glucoside 5 as 6.3 mM.\textsuperscript{18} Paula et al., on the other hand, used titration calorimetry and obtained a $cmc$ of 23.0 mM\textsuperscript{16} for the β-glucoside 6. Regardless of these differences, the gluco-series shows, in analogy to the manno-case, that α-glucosides are formed at lower concentrations than β-glucosides. This effect is less pronounced in case of the galactoside micelles.

Next, the influence of configurational characteristics of the sugar ring on micelle formation was studied (Figures 2c and d). The two α-glycosides 1 and 3 show a significant difference in glycomicelle formation, with the $cmc$ of mannoside 1 (10.9 mM) being much smaller than the $cmc$ of galactoside 3 (30.2 mM). In the series of the three β-glycosides 2, 4, and 6, again the $cmc$ of the galactoside (4, 31.7 mM) was found to be the highest. Overall, within both series of α- and β-octyl glycosides a carbohydrate-specific dependency of $cmc$ values was observed, namely $cmc$(αMan) ≈ $cmc$(αGlc) < $cmc$(αGal), and $cmc$(βMan) < $cmc$(βGlc) < $cmc$(βGal).

Next, thermodynamic data of micelle formation were deduced from the measured ITC curves, using the so-called phase-separation model.\textsuperscript{16} In this model, the glycomicelle is considered as a separate microphase. At high aggregation numbers of the investigated micellar systems (assumed according to the literature\textsuperscript{16,20-22}) the Gibbs free energy of demicellulation is defined by the chemical potential of the amphiphile in water and the amphiphile in micellar phase (equation (1)). To obtain the Gibbs free energy $\Delta G$ from measured $cmc$ values, molar fractions $c$ are plugged in.

$$\Delta G^\circ_{demic} = \mu^\circ_\alpha - \mu^\circ_\beta = -RT \cdot \ln cmc'$$  \hspace{1cm} (1)

Demicellulation enthalpy, $\Delta H^\circ_{demic}$, and demicellulation entropy, $\Delta S^\circ_{demic}$, are obtained from $\Delta G^\circ_{demic}$ according to the Gibbs-Helmholtz relation (2).

$$\Delta G = \Delta H - T \Delta S$$  \hspace{1cm} (2)

The enthalpy of demicellulation ($\Delta H^\circ_{demic}$) can be calculated according to equation (3).

$$\Delta H^\circ_{demic} = \frac{c_{syringe}}{c_{mic}} \Delta R H^\circ_{demic}$$  \hspace{1cm} (3)

For this calculation, $c_{syringe}$ was considered as equal to $c_{mono}$ + $c_{mic}$. Here the approximation is used that above the $cmc$, the concentration of the monomers remains constant. Thus, the thermodynamic parameters of demicellulation could be deduced from measured $cmc$ values and are collected in Table 1.

### Table 1 Thermodynamic parameters of demicellulation ($\Delta H^\circ_{demic}$, $\Delta S^\circ_{demic}$, $T \Delta S^\circ_{demic}$ and $\Delta S^\circ_{demic}$) of homo-glycomicelles on the basis of the phase-separation model\textsuperscript{16} according to equation (1) and Gibbs-Helmholtz relation (2); $cmc'$ = critical micelle concentration in mol fractions; $T$ = 298 K; ± standard deviation.

The thermodynamic data summarized in Table 1 show that micelle formation is an exergonic process with negative $\Delta G^\circ_{mic}$ values. Enthalpy changes of micelle formation, $\Delta H^\circ_{mic}$, are positive though, but enthalpy-entropy compensation\textsuperscript{23} results in
an overall exergonic process. Positive $\Delta S^\circ_{mic}$ values indicate that micelle formation is entropically favoured, an effect which has been explained by desolvation of monomers during micelle formation. This behavior is observed for all investigated glycosides.

**ITC measurements of hetero-glycomicelles**

In the next step, we extended our project to the investigation of mixed glycomicelles, called hetero-micelles. Such systems are of particular interest as they reflect more of the carbohydrate diversity of the natural glycocalyx than homo-glycomicelles. Equally, hetero-glycocusters have become important in the glycosciences, showing unexpected, so-called hetero-glycocluster effects. To date, self-aggregation of mixed micellar systems formed of octyl glycosides and ionic surfactants have been described. Furthermore, the aggregation behavior of mixed micelles formed of alkyl maltosides with varying alkyl chain length was investigated. Also bolaamphiphiles were studied as mixed micelles with octyl glycoside doping.

Here, we have employed 1:1 mixtures of two amphiphilic glycosides of the same anomeric configuration in a first series of experiments. The standard demicellation protocol was followed to obtain ITC curves of the investigated six mixed micelles, three $\alpha$-hetero-micelles (Figure 3a) and three $\beta$-hetero-micelles (Figure 3b). Strikingly, in all cases the titration curves show exactly one point of inflection (reflecting one $cmc$ value) indicating the formation of just one type of mixed micelle. Hence, it can be concluded that the employed 1:1 mixtures form homogeneous hetero-glycomicelles and that phase separation or homo-micelle formation is not effectively competing in this self-aggregation process.

Also in hetero-micelle formation, the investigated mannosides exerted a special effect. All mannoside-containing heteromicelles had lower $cmc$ values than mannoside-free heteromicelles. In the $\alpha$-series, the mixed micelles containing octyl mannoside had $cmc$ values of 13.0±0.7 mM and 15.4±0.3 mM, whereas the mannoside-free hetero-micelle had $cmc = 25.4±0.7$ (Figure 3, Table insert). In the $\beta$-series, the analogous behaviour was observed. It should be noted, that calculation of $cmc$ values of mixed micelles has been reported in the literature. In these cases, $cmc$ values were either obtained according to a model for ideal mixing behaviour, or the employed relation was adapted for non-ideal mixing of the components using regular solution theory by Rubinging and colleagues.

In our experiments it was striking, that it was possible to employ the weakly water-soluble octyl $\alpha$-D-glucoside 5 in a binary system and to determine the $cmc$ values of the respective hetero-glycomicelles. This demonstrates that the supramolecular properties of mixed micelles can differ significantly from pure homo-micelles. Similar effects have found technical applications in other binary systems.

![Fig. 3 Integrated ITC titration curves of hetero-glycomicelles obtained at 298 K. a) Micelles formed of two different $\alpha$-glycosides ($\alpha$OctylMan 1 + $\alpha$OctylGlc 5, $\alpha$OctylMan 1 + $\alpha$OctylGal 3, $\alpha$OctylGlc 5); b) micelles formed of two different $\beta$-glycosides ($\beta$OctylMan 2 + $\beta$OctylGlc 6, $\beta$OctylMan 2 + $\beta$OctylGal 4, $\beta$OctylGal 4 and $\beta$OctylGlc 6). ITC starting concentrations c (1:1 ratio of two glycosides) and deduced average $cmc$ values are listed in the table insert; SD: standard deviation.](image-url)

In Table 2 the thermodynamic parameters of the investigated hetero-micelles are summarized which were calculated in analogy to what has been described for the homo-glyamicelles. Again, formation of hetero-glyamicelles is entropically driven leading to overall exergonic processes.

**DOSY NMR experiments**

While ITC experiments are suited to describe the equilibrium state of a micellar system, diffusion ordered NMR spectroscopy (DOSY) can be used to measure the diffusion rate of molecules or aggregates, respectively. Thus, information about the dynamics of self-assembly and the size of formed micelles can be gained.\(^{34,35}\) NMR diffusion measurements involve the so-called *pulsed field gradient spin echo* NMR experiment (PFGSE) which has found numerous applications in supramolecular chemistry. It is based on a pulse sequence, in which the intensity of an echo signal depends on molecular motion in a pulsed field gradient. Faster moving molecules lead to echo signals of lower intensity. From the signal decrease the diffusion coefficient can be calculated.\(^{36}\)

Here, the two anomic glycosides, $\alpha$- and $\beta$-octyl mannoside 1 and 2, were selected for diffusion NMR experiments, as they showed the most pronounced effect of anomic configuration on micelle formation. For determination of the diffusion coefficients $D_{\text{obs}}$, four different regions in the $^1H$ NMR spectra of the investigated compounds were used ($\delta = 4.00-3.30, 1.65-1.37, 1.36-1.00,$ and 0.90-0.60 ppm). Samples were measured at concentrations between 2.5 and 250 mM for 1, and 10 and 250 mM for 2, employing the PFGSE experiment and measured $D_{\text{obs}}$ values plotted against sample concentration (Figure 4). As expected,\(^{34}\) $D_{\text{obs}}$ values decrease rapidly with concentrations increasing beyond the $cmc$, resulting from the limited molecular motion within the micellar assembly.

All diffusion NMR experiments showed just one diffusing species. Thus, it can be concluded that the equilibrium between monomeric and micellar molecules is fast on the time scale of the NMR experiment. Consequently, the observed diffusion coefficient $D_{\text{obs}}$ is a weighted average from two states of the investigated octyl mannoside (1 or 2, respectively), monomeric and micellar. Hence, $D_{\text{obs}}$ can be expressed by equation (4)\(^{34,37}\)

$$D_{\text{obs}} = \frac{D_{\text{cmc}} \cdot c_{\text{total}}^2 - c_{\text{total}} \cdot c_{\text{mono}} \cdot D_{\text{cmc}}}{c_{\text{total}}^2 - c_{\text{total}} \cdot c_{\text{mic}} \cdot D_{\text{mic}}} \quad (4)$$

Equation (4) is valid for concentrations $> cmc$, and thus only respective data points were used. $D_{\text{mono}}$ was inserted into the equation as a fixed parameter that was obtained by NMR.
measurements at concentrations below the \(cmc\).\(^{34}\) \(c_{\text{total}}\) was inserted as an independent variable.

However, in equation (4) obstruction effects that occur at finite aggregation concentrations, are not taken into account. Therefore, according to Nilsson and Söderman,\(^{34}\) equation (4) was corrected using relation (5).

\[
D_{\text{mic}} = D_{\text{mic,0}}(1-k\phi_{\text{mic}})
\]

(5)

In (5), \(k\) is an interaction constant, representing dynamic interactions of hard spheres. According to the literature, \(k\) was chosen as 1.73.\(^{38}\) \(\phi_{\text{mic}}\) represents the volume fraction of the micelles. It was obtained using equation (6).

\[
\phi_{\text{mic}} = (c_{\text{total}} - c_{\text{cmc}}) \cdot \frac{M}{d}
\]

(6)

In equation (6), \(M\) is the molecular weight of the octylmannoside (1 or 2, respectively) and \(d\) its density (cf. ESI).

By insertion of equations (5) and (6) into (4), expression (7) is obtained that was used for fitting of the data points of the PGSE NMR experiment (cf. Figure 5).

\[
D_{\text{obs}} = \frac{c_{\text{mc}}}{c_{\text{total}}} \cdot D_{\text{mono}} + \left(\frac{(c_{\text{total}} - c_{\text{cmc}})^2 \cdot s \cdot k}{c_{\text{total}}} \right) \cdot D_{\text{mic,0}}
\]

(7)

with

\[
S = \frac{M_{1,2}}{d_{1,2}} = 0.248
\]

Thus, self-diffusion coefficients \(D_{\text{mic,0}}\) for the micellar state of octylmannosides could be determined and the obtained data are summarized in Figure 5.

![Graph showing diffusion coefficients](image)

**Fig. 5** Determination of cme values and diffusion coefficients \(D_{\text{mono}}\) and \(D_{\text{mic,0}}\) for aggregation systems formed with \(\alpha\) - and \(\beta\)-mannosides 1 and 2, respectively, at 298 K. For fitting, equation (7) and data points of \(c_{\text{total}} > c_{\text{cmc}}\) were used; a) \(D_{\text{mono}}\) at \(c_{\text{total}} = 5\) and 7.5 mM; b) \(D_{\text{mono}}\) at \(c_{\text{total}} = 15\) mM.

Both experimental methods, ITC and DOSY NMR spectroscopy, led to very similar \(cmc\) values for 1 and 2. However, the \(cmc\) values determined by diffusion NMR spectroscopy for mannoside 1 (9.1 mM) and 2, (18.8 mM) were found somewhat lower than the respective values determined by ITC (10.9 mM for 1 and 22.9 mM for 2). This finding has in principal been described before for association constants of calixpyrroles\(^{39}\) and can be explained by additional intermolecular interactions during demicellation occuring in the ITC experiment.

The diffusion coefficients \(D_{\text{mono}}\) determined for both mannosides, 1 and 2, were found equal within error limits (4.35 \(\pm\) 0.10 \(\times\) \(10^{-10}\) \(m^2/s\) for 1 and 4.21 \(\pm\) 0.21 \(\times\) \(10^{-10}\) \(m^2/s\) for 2) and similar to published data for \(\beta\)-OctylGlc (6).\(^{40}\) On the contrary, the diffusion coefficients \(D_{\text{mic,0}}\) of the respective micelles were found to differ significantly with \(D_{\text{mic,0}}\) (1) of 3.27 \(\pm\) 1.11 \(\times\) \(10^{-10}\) \(m^2/s\) and \(D_{\text{mic,0}}\) (2) of 4.42 \(\pm\) 1.21 \(\times\) \(10^{-10}\) \(m^2/s\). Hence, the \(\alpha\)-mannosidic micelle diffuses more slowly than the \(\beta\)-mannosidic micelle. This corresponds to larger aggregates in the \(\alpha\)-case than in the \(\beta\)-case. Thus, again a significant influence of the anomeric configuration of the mannosidic amphiphile on self-aggregation was revealed.

To obtain an estimate of the size of the investigated micelles the Stokes-Einstein equation (8) was employed.

\[
R_h = \frac{k_B \cdot T}{6\pi\eta D_{\text{mic,0}}}
\]

(8)

In (8) \(R_h\) is the hydrodynamic radius of the micelle, \(\eta\) the dynamic viscosity of the used solvent, \(T\) the temperature and \(k_B\) the Boltzmann constant. With the dynamic viscosity of \(D_{2O} = 1.10\ \text{mNs/m}^2\)\(^{41}\) \(R_h\) of the \(\alpha\)-mannosidic micelle was calculated as 60.7 \(\text{Å}\) and for the corresponding \(\beta\)-mannosidic micelle as 44.9 \(\text{Å}\). Thus, the \(\alpha\)-mannosidic micelle is significantly bigger.
than its β-analogue. It has to be kept in mind, however, that the Stokes-Einstein equation assumes a spherical shape for micelles, while the investigated systems might have a different form and thus other sizes than the calculated ones (vide infra).

**Discussion and Conclusion**

Glycomicelles have been employed in various research to date. This account is dedicated to glycomicelles in order to study the significance of configurational changes of glycosides in a supramolecular context. Thus, micelle formation has been investigated with the complete set of amphiphilic octyl glycosides of the manno-, gluco- and galacto-series of both anomeric configurations using ITC and DOSY NMR spectroscopy. With this selection, we were able to investigate the influence of anomeric configuration as well as of the configuration at C-2 and C-4 of the sugar ring on glycomicelle formation. Our data, in agreement with the available published work, have clearly revealed that the tendency to form micelles in water decreases from mannose over glucose to galactose (cmc(αMan) ≈ cmc(αGlc) < cmc(αGal), and cmc(βMan) < cmc(βGlc) < cmc(βGal)). Moreover, it was shown that all investigated α-configured glycomicelles form more easily than their β-analogues. Overall, octyl α-mannoside requires the lowest concentrations for micelle formation in water among the six investigated octyl glycosides (Figure 6).

The employed mannosides were also unique when employed in the formation of mixed micelles. Thus, the cmc value that is obtained for αOctylMan/αOctylGal hetero-micelles is significantly affected by the α-mannosidic component (Figure 3). Equally, the cmc values obtained for βOctylMan/βOctylGlc as well as for βOctylMan/βOctylGal hetero-micelles are particularly affected by the β-mannoside component βOctylMan, hence increasing the tendency to micelle formation.

The micellar hydrodynamic radii R_h obtained for 1 and 2 using a PFGSE NMR experiment, namely 60.7 Å and 44.9 Å, are rather large compared to reported micelle sizes (~23-27 Å). As occurring obstruction effects were taken into account in our fitting procedure, the reason for the large R_h values may be found by re-considering the shape of the investigated micelles. In the employed Stokes-Einstein equation a spherical shape of micelles is assumed, however, the herein investigated micelles might adopt a different form, probably rodlike or ellipsoidal. We will perform additional studies to specify the shape of octyl mannoside micelles and understand differences caused by the anomeric configuration (α or β).

It has become obvious in our study, that subtle structural changes such as epimerisation at C-2 of octyl glycosides lead to significant effects in a supramolecular context, including hetero-micelles. However, how structural details determine the self-aggregation process, remains a secret until this day.

It has been reasoned earlier that configuration and different tilt angles of α- and β-glycosides influence the geometry as well as the hydrophilicity of glycosides, factors that can determine glycomicelle formation. In addition, theoretical studies have highlighted the importance of variable hydrogen bonding in glycomicelle formation of glucosides. MD simulations with octyl β-glucoside and octyl β-galactoside suggested that the β-galactoside has a slightly higher tendency to form inter- and intramolecular hydrogen bonds than the corresponding β-glucoside. How this results in lower cmc values for the glucoside is not completely clear given that micelle formation is an entropically driven process.

To facilitate the interpretation of structure-property relationships, we suggest an alternative structure view on glycosides to assess the configurational characteristics of the investigated α- and β-octyl glycosides in new light (Figure 6). In the proposed projections, the relative positions of the hydroxy groups at C-2 and C-4 are depicted at respective edges of two fused triangles, forming the ‘front face’ of the glycoside, in relation to the octyl aglycone moiety in the rear of the molecule. Interestingly, this structural representation suggests that the glycosides can be considered as ‘transition’ between mannoside (low cmc) and galactoside (high cmc) features. The two front triangles of the mannosides on the one hand and the glycosides on the other, are mirror images of one another, whereas the relative position of the aglycone moiety at the far end of the molecule remains constant. The different positioning of the 2,4-dihydroxy group pair relative to the octyl aglycone in the α- and β-case, respectively, also becomes very obvious using the suggested projection. The depicted projection could even be further expanded by including the direction of the O-H bonds. This would demonstrate how the hydroxyl hydrogen atoms are exposed to the surrounding of the glycoside, featuring a particular hydrogen bonding behavior. The proposed projection could equally support the interpretation of self-aggregation of mixed micelles, which were shown to display different properties than the homo-micelles. In our further work, we will expand the present study in both an experimental and a theoretical context and we will make an attempt to draw inspiration from the proposed ‘trinity projection’ of glycosides. In particular, we have commenced MD simulations to understand the notable effects of octyl α- and β-mannosides on micelle formation.

**Experimental**

**Synthesis of octyl glycosides**

The 1,2-trans glycosides 1, 4 and 6 were synthesized according to the literature. The 1,2-cis glycosides 2, 3 and 5 were prepared using Fischer glycosylation according to modified literature procedures. Separation of anomeric mixtures was accomplished by flash column chromatography. Analytical data of the synthetic glycosides are reported in the ESI.

**ITC demicellation protocol**
ITC measurements were performed on a MicroCal VP-ITC (MicroCal, Inc., Northhampton, MA, now GE Healthcare).

Sample preparation
For ITC, highly concentrated solutions (10-fold concentration of cmc in double distilled water) were prepared in a 1 or 2 mL volumetric flask and used after ultrasonic degassing for 5 min.

Titration procedure
The cells (reference cell and sample cell) were filled with double distilled water and the amphiphilic solution was added using the injection syringe. The number of aliquots was 70 up to 93. At higher aliquot numbers an injection volume of 3 µL was used, at lower aliquot numbers 4 µL were titrated into the sample cell. An interval of 540 s was used between titration steps. The sample was stirred by the syringe during titration with stirring speed 300 rpm. Experiments were carried out at 298 K (shield 297 K) and a reference power of 10 μcal/s. Every titration was performed three times and then it was averaged (cf. ESI for representative titration curves).

Cleaning of the injection syringe and the cells
After draining off residual solution, the syringe was washed with 100 mL of double distilled water and 50 mL methanol (HPLC grade). Using the ThermoVac the syringe was dried for 10 min under vacuum and maintained at reduced pressure for at least 1 h until the next measurement was performed. The sample cell was first washed with Contrad 70 liquid detergent (10 % in double distilled water) and subsequently with double distilled water (twice 300 mL) using the ThermoVac.

Data analysis
For measurements and data analysis ORIGIN 7.2 (OriginLab) with ITC plugin was used. The reference data of a water-to-water titration were subtracted and the resulting data were plotted. From the resulting curves, the critical micelle concentration (cmc) was obtained as the maximum of the first derivative.

Diffusion NMR spectroscopy
The NMR diffusion measurements were carried out on a Bruker Avance 600 spectrometer at a temperature of 298 K. A
concentration series of octyl α,β-mannopyranoside (1, 11 concentrations from 2.5 to 250 mM) and octyl β,β-mannopyranoside (2, 12 concentrations from 10 to 250 mM) were measured in 500 μL D2O. At every concentration, a series of 1H NMR spectra was recorded (32 spectra) with a decreasing field gradient. The parameters of the duration of the gradient δ and the separation between the leading edges of the pulsed gradients Δ (diffusion time) were adjusted for each sample so that the signal intensity of the last spectra was about 10% of the starting intensity. The analysis of the diffusion series was performed using the T1/T2-relaxation routine of TopSpin 3.2 (Bruker).

Acknowledgements

We thank Prof. Dr. F. D. Sönnichsen and Dipl.-Chem. H. Kobarg for their support in NMR diffusion experiments. Valuable discussions with V. Baronin Staël von Holstein, Dipl.-Ing. are gratefully acknowledged.
