TiO$_2$@C nanospheres synthesized by pyrolysis demonstrate enhanced performance as an anode for lithium-ion batteries.
**TiO$_2$@C Composite Nanospheres with an Optimized Homogeneous Structure for Lithium-ion Batteries**

Jun Zhang,$^{a,c}$ Jiangfeng Ni,$^{b}$ Jing Guo$^a$ and Bingqiang Cao$^{a,*}$

Homogeneous TiO$_2$@C composite nanospheres are synthesized by a direct pyrolysis strategy using Ti-containing organic-inorganic polymers as the precursor. The TiO$_2$@C composite nanospheres possess uniform distribution of tiny TiO$_2$ nanoparticles confined in carbon matrix with a homogeneous structure. The carbon phase can not only improves the conductivity but also prevents the aggregation of TiO$_2$ nanoparticles. When evaluated as an anode for lithium-ion batteries, the TiO$_2$@C nanocomposites demonstrate high reversible specific capacity of 207 mAh g$^{-1}$ at 0.5C (1C = 250 mA g$^{-1}$) after 50 cycles and stable cycling performance in comparison to pure TiO$_2$ nanospheres. This work offers a new pathway for realization of carbon-based composite materials for use as high performance anodes in LIBs.

**Introduction**

Lithium-ion batteries (LIBs) have been considered as one of the most promising energy storage and conversion technology to fulfill the ever-growing demand in both small consumer electronic devices and large-scale applications, such as electric vehicles (EV), hybrid electric vehicles (HEV), and stationary energy storage. Practical applications of LIBs critically relied on the electrode materials with high capacity, high rate capability, good stability and safety. The current widely used anode in LIBs is graphite. In spite of its excellent electrical conductivity, graphite anode suffers from low Li-ion diffusion coefficient and risk of lithium dendrites formation, which might cause serious safety problems.

TiO$_2$ as one of the most investigated semiconductor metal oxides, has attracted considerable attention for application in many fields, such as solar cells, photocatalysis, gas sensors, and LIBs. For use as an anode for LIBs, TiO$_2$ features by a series of merits including the low cost, low toxicity, high capacity, high current rate performance, and improved electrochemical stability. However, the poor electronic and Li-ion conductivity have significantly limited its potential application in LIBs. To alleviate such problems, many strategies have been developed to improve the performances of TiO$_2$ anodes. For example, the controllable fabrication of TiO$_2$-based nanomaterials with desired structures or morphologies has proved to be very effective to improve the LIBs performances. Lou et al. have demonstrated that TiO$_2$ hollow nanostructures could deliver better properties in terms of higher capacity, better rate capability, and good cycling performance. TiO$_2$ nanosheets with engineered (001) crystal facets have manifested enhanced electrochemical performances due to the accelerated Li-ion diffusion kinetics in specific crystal direction and adequate electrode–electrolyte contact. Decreasing the particle size from micrometer to the nanometer scale is also a key to improved Li-ion diffusion because of the reduced diffusion length. Ren et al. have shown that TiO$_2$ nanoparticles with the ever smallest size (< 4.3 nm) are superior in Li-ion and charge storage compared with other bulk, nanowires, and nanotubes morphologies.

While great progress has been obtained by the nanostructuring strategy, a well-established and more reliable approach is to fabricate composite electrode materials by coating or mixing a host material with guest additives such as conductive carbon. Great improvement in the specific capacity, rate performance, and cycling stability can be expected, because the carbon additive could significantly improve the surface electronic conductivity and the electric contact between electrodes and surrounding active agents. Zhao et al. have proposed to incorporate a 3D carbon mixed conducting network in electrode materials, which allows for both fast Li-ion and electron migration. TiO$_2$@carbon composite nanofibers prepared by combination of electrospinning and subsequent thermal treatments also exhibited excellent cycling stability and rate capability as an anode material. Park et al. have reported carbon-coated TiO$_2$ nanotubes with very low carbon content synthesized could manifest high rate capability and power performance. Wang and Guo et al. have reported mesoporous TiO$_2$/C composite anodes with excellent rate capability and cycling performance. Very recently, Petkovich$^{15}$ and Wang$^{26}$ et al. used one-pot pyrolysis to produce 3DOM TiO$_2$/C and CNT@TiO$_2$-C composite materials for LIBs anodes with high rate performance. To further optimize the electrochemical performance of TiO$_2$-based anodes with low cost, it is desirable...
to develop a simple procedure for synthesizing TiO$_2$@carbon composite anode materials, in which nanometer-sized TiO$_2$ particles are homogeneously dispersed in conductive carbon matrix. Such an optimized structure would enable fast electron transport between nanoparticles, thus improving the electrochemical performance.

In this work, we propose a direct pyrolysis route at moderate temperature to prepare homogeneous TiO$_2$@C composite nanospheres by using Ti-containing colloidal organic-inorganic polymers as the precursor. The new attempt using organic-inorganic polymer spheres as both carbon and TiO$_2$ sources has advantages of generation of carbon phase closely coated on TiO$_2$ nanoparticles and suppression of the particle growth to yield homogeneous conductive nanocomposite. When evaluated as the anodes for LIBs, the TiO$_2$@C composite nanospheres manifest excellent charge–discharge properties with relatively high capacity, good rate capability, and stable cycling performance.

**Experimental Section**

**Synthesis of homogeneous TiO$_2$@C composite nanospheres**

Organic-inorganic polymer nanospheres containing Ti were prepared according to the literature method with some modifications. In a typical synthesis, 2 mL tetrabutyl titanate (TBT) was added to 50 mL ethylene glycol (EG) under magnetic stirring for 10 h, then the mixture was transferred into a solution containing 2.7 mL water and 170 mL aceton. After further stirring for 1 h, the white colloidal organic-inorganic polymers were harvested by centrifugation and washing with water and ethanol several times, and dried at 80 °C. The as-obtained organic-inorganic nanospheres are indeed titania glycobates polymers and have an amorphous structure. Homogeneous TiO$_2$@C nanocomposites were readily obtained by pyrolysis of the organic-inorganic nanospheres in N$_2$ atmosphere at 500 °C for 4 h. For comparison, pristine TiO$_2$ nanospheres were also synthesized by annealing the polymers in air at 500 °C for 4 h.

**Characterization**

The crystal phase and structure of samples were identified by powder X-ray diffraction (XRD) using a Bruker diffractometer (D8-Advance) with Cu K$_\alpha$ radiation of 1.5418 Å. Thermal-gravimetric analysis (TG) was performed on Mettler-Toledo TGA/DSC 1/1600HT at a heating rate of 5 °C/min in air. The size, morphology and composition of the samples were characterized by scanning electron microscope (SEM, Quanta FEG 250, 30 kV) and transmission electron microscope (TEM, JEM-1011, 100 kV), high resolution transmission electron microscope (HRTEM, JEOLE-1011, 200 kV), energy dispersive X-ray spectroscopy (EDS, JEOLE-1010, 200kV), and N$_2$ adsorption–desorption (JW-BK122W).

**Electrochemical characterization**

2032 coin-type cells were used for electrochemical test. The composite electrode sheets consisting of 70 wt.% active material, 20 wt.% acetylene black, and 10 wt.% polytetrafluoroethylene (PTFE) was used as cathode. Lithium metal foil was used as counter and reference electrodes. The electrolyte solution is 1M LiPF$_6$ dissolved in a mixture of ethylene carbonate (EC) and dimethyl carbonate (DMC) with a volume ratio of 1:1. Galvanostatic tests were carried out using a Land battery test system at 28 °C (1 C was defined as 250 mA g$^{-1}$). Electrochemical impedance spectroscopy (EIS) tests were performed on a Zennium electrochemical workstation tester.

**Results and discussion**

**Morphology and structure investigation**

The Ti-containing organic-inorganic polymer nanospheres were prepared by an improved sol–gel method, by which the hydrolysis of TBT was controlled to occur slowly to obtain a homogeneous nucleation and growth. Fig. 1a shows that the polymer nanospheres have a sphere-like shape, and some spheres are seen to fuse together. The inset of Fig. 1a is the size distribution histogram, which indicates the nanospheres have a diameter in the range of 250-550 nm, with an average size of 377 nm. After calcination at a moderate temperature of 500 °C in N$_2$, the organic-inorganic polymers can be converted into TiO$_2$@C nanospheres. Fig. 1b displays the SEM image of the composite TiO$_2$@C nanospheres, revealing that the TiO$_2$@C nanospheres well preserve the spherical morphology after thermal annealing. Interestingly, the TiO$_2$@C nanospheres have a smaller size as compared with the polymer precursor of Fig. 1a. The reduced size and dimension of the composite nanospheres is probably caused by remove of water and decomposition of organic component under the annealing process, resulting in the shrinkage of precursor spheres.

ethylene glycol in the polymers between 150 and 400 °C. The curve for TiO$_2$@C spheres also contains two steps of weigh loss of water evaporation and combustion of the thermally decomposed carbon phase. The carbon content in the TiO$_2$@C spheres is about 32.2%.

![Fig. 2. TG analysis of Ti-containing organic-inorganic polymer and TiO$_2$@C nanospheres.](image)

The crystalline phase of the polymer precursor and TiO$_2$@C nanospheres has been studied by XRD. Fig. 3 demonstrates that the polymer precursor has an amorphous structure, while the TiO$_2$@C sample shows a dominant structure of rutile TiO$_2$ (JCPDS No.65-0190) and a trace amount of anatase TiO$_2$ (JCPDS No. 21-1272) indicated by an asterisk. The crystallite size of TiO$_2$@C is estimated to be 11.2 nm from the full width at half maximum (FWHM) of (211) diffraction peak by using Scherer equation. After annealing under N$_2$ atmosphere, the organic compounds in the precursor would be carbonized through pyrolysis and eventually transform into carbon.

Detailed structure and morphology of the samples have been further characterized by TEM. Fig. 4(a-d) exhibits the representative TEM images of TiO$_2$@C nanospheres with different magnifications. As can be seen in Fig. 4a and b, the TiO$_2$@C particles have a sphere-like morphology. Closer observation from the individual nanosphere in Fig. 4b reveals that the TiO$_2$@C nanosphere shows a homogenous structure. From Fig. 4c, it is seen that the sphere contains many discrete nanoparticles confined in carbon matrix with a small size of 8-18 nm. Under annealing in N$_2$, the organic molecules cannot burn off and subsequently convert into carbon through pyrolysis. During the carbonization process at 500 °C in N$_2$, TiO$_2$ nanoparticles are formed with better crystallization and simultaneously carbon phase is formed around the TiO$_2$ nanoparticles, leading to the formation of a homogeneous nanocomposite of TiO$_2$@C with TiO$_2$ nanoparticles highly distributed in carbon. The inset of Fig. 4c illustrates the homogeneous structure of the TiO$_2$@C composite nanospheres. Fig. 4d shows the HRTEM image of a TiO$_2$@C nanosphere. A carbon layer around the sphere edge can be seen clearly, as indicated by the arrows. The clear lattice fringes reveal the high

![Fig. 4. (a-c) TEM, (d) HRTEM images and (e) Element mapping of TiO$_2$@C nanospheres.](image)
crystalline nature of the TiO\(_2\) nanoparticles confined in carbon. The interplane spacing of 0.32 nm corresponds to the (110) planes of rutile TiO\(_2\). The elemental composition of the sample was further studied by the local EDS element mapping technique mounted to HRTEM. The results are shown in Fig. 4e. It is apparent that the particle has uniform distributions of all the elements (C, O, and Ti), further demonstrate the homogeneous structure of TiO\(_2@C\) composite nanospheres.

For comparison, pure TiO\(_2\) nanospheres were also prepared by directly anneal the Ti-containing organic-inorganic polymer nanospheres in air. Fig. 5(a-c) exhibits the SEM images of pure TiO\(_2\) nanospheres. As can be seen in Fig. 5a and b, the TiO\(_2\) particles also possess a sphere-like morphology. By closer observation from the individual nanospheres in Fig. 5b and 4b, it reveals that the former has a relatively rough surface. Nanoparticles with different diameters can be easily distinguished out due to the image contrast. Fig. 5c indicates the TiO\(_2\) nanosphere is comprised of numerous aggregated nanoparticles with a size range of 14–27 nm. When calcined in air, the organic component in the polymer spheres could be completely removed and TiO\(_2\) nanoparticles nucleated and grew together to constitute the spheres. The inset schematic illustration of Fig. 5c simulates the structure of pure TiO\(_2\) nanospheres, which is assembled by many TiO\(_2\) nanoparticles with different size. The XRD pattern in Fig. 5d suggests the pure TiO\(_2\) nanospheres have an anatase structure, with all the diffraction peaks being consistent with JCPDS 21-1272. The mean crystallite size estimated from the full width at half maximum (FWHM) of the (101) peak is ca. 17.7 nm, which is much larger than that (11.2 nm) of TiO\(_2@C\) composites. This indicates that the annealing atmosphere has a significant influence on the crystallite size of the products. Annealing in air is able to burn off the organic component and obtain pure inorganic TiO\(_2\) nanospheres. If the annealing process is performed in N\(_2\), the organic compounds will be carbonized through pyrolysis and eventually transform into carbon. It is deduced that the formed carbon around the TiO\(_2\) could effectively suppress the growth of TiO\(_2\) nanoparticles. Recent

Fig. 5. (a-c) TEM images and (d) XRD pattern of pure TiO\(_2\) nanospheres obtained by calcination of the Ti-containing polymers in air, and N\(_2\) adsorption-desorption analysis of (e) TiO\(_2\) and (f) TiO\(_2@C\).
works by Petkovich and Huang et al. reported the similar result at temperature of 800 and 1100 ºC. The Brunauer–Emmett–Teller (BET) specific surface area and porous structure of TiO$_2$ and TiO$_2$@C have been obtained by N$_2$ adsorption–desorption, which is shown in Fig. 5e and f. The BET surface area of TiO$_2$ is evaluated to be 36.8 m$^2$/g, which is a little larger than that (31.1 m$^2$/g) of TiO$_2$@C composite. This is because the pure TiO$_2$ nanospheres are an aggregation of TiO$_2$ nanoparticles with rich inner-particle space. Furthermore, the insets in Fig. 5e and f are the Barrett–Joyner–Halenda (BJH) pore size distribution, revealing both samples have a mesoporous structure with pore size in the range of 2-50 nm.

**Electrochemical performance**

Such a TiO$_2$@C structure is very promising for use as LIBs anode materials, as the carbon component can greatly enhance the electronic conductivity between the TiO$_2$ nanoparticles. In addition, the carbon matrix can also effectively prevent the aggregation of nanoparticles during cycling.

![Fig. 6](image_url)  
**Fig. 6.** (a) Discharge/charge voltage profiles at 0.2C, (b) cycling performance at 0.5C, (c) rate capability from 0.1C to 2C, and (d) Nyquist plots of TiO$_2$ and TiO$_2$@C nanospheres.

We thus further evaluate the electrochemical performances of these unique homogeneous TiO$_2$@C nanospheres for LIBs. Fig. 6a shows the first three consecutive discharge/charge voltage profiles of the TiO$_2$@C composite nanospheres at a 0.2C rate in the voltage range of 1.0-3.0 V. The initial discharge and charge capacities are found to be 293.6 and 219.3 mAh g$^{-1}$, indicating an initial coulombic efficiency of 74.7%. Such an initial discharge capacity is even higher than the theoretical capacity (233 mAh g$^{-1}$) of TiO$_2$@C nanospheres. The theoretical capacity of TiO$_2$@C nanospheres is calculated based on the weight content and theoretical capacity of TiO$_2$ (67.8 wt%, 168 mAh g$^{-1}$) and carbon (32.2 wt%, 372 mAh g$^{-1}$). The extra lithium storage capacity might be associated with the phenomenon of interface storage due to the unique composite structure and the carbon phase. While for the second and third cycle, the discharge and charge capacities are 212.2 and 205.4 mAh g$^{-1}$ and 212.3 and 205.7 mAh g$^{-1}$, corresponding to a coulombic efficiency of 96.7% and 96.8%. Compared with the initial discharge capacity (293 mAh g$^{-1}$), the second discharge shows an irreversible capacity of 80 mAh g$^{-1}$. The capacity loss may be caused by the inserted Li-ions in the irreversible sites of TiO$_2$ nanoparticles and other side reactions arising from trace water absorbed on electrode materials at the first stage of discharge-charge process. Similar phenomenon has also been previously observed for various TiO$_2$ polymorphs, such as TiO$_2$(B) and rutile.

The cycling performance of pure TiO$_2$ and TiO$_2$@C composite nanospheres has been tested at 0.5C. As shown in
Fig. 6b, although both TiO$_2$C and TiO$_2$ exhibit good cycling stability, the TiO$_2$C nanocomposite possesses apparently much higher capacity than pure TiO$_2$. The higher capacity of TiO$_2$C might be due to the carbon phase, which has a higher theoretical capacity than TiO$_2$. After 50 cycles of discharge/charge at 0.5C, the TiO$_2$C nanospheres can still deliver a high reversible specific capacity of 207 mAh g$^{-1}$, which is much higher than that (145.6 mAh g$^{-1}$) of pure TiO$_2$ nanospheres and is also better than the reported results for TiO$_2$/C nanocomposite$^{20,24,35,36}$ and TiO$_2$ nanotubes$^8$ and nanoparticles$^{17}$ at a similar current density. In addition, the pure TiO$_2$ nanospheres have an anatase structure, which is generally considered to be more electrochemically active than the rutile polymorph for Li-insertion$^{38,39}$. The above results clearly demonstrate the superior lithium storage performance of rutile TiO$_2$-based composite to anatase as an anode material.

The rate capability of the TiO$_2$C nanospheres is also tested at different current densities. As shown in Fig. 6c, the TiO$_2$C anode is observed to exhibit much higher reversible capacity and good cycling stability than TiO$_2$. The TiO$_2$C nanocomposite presents very good cycling response to continuously varying current rates from 0.1 to 2C. At various current densities, the TiO$_2$C composite anode can retain discharge capacities of 242.6, 216.2, 197.1, 165.5 and 134.3 mAh g$^{-1}$ after 5 cycles at each current rates of 0.1, 0.2, 0.5, 1 and 2C, respectively, while the pure TiO$_2$ nanospheres only deliver discharge capacities of 215.5, 196.7, 172.1, 147.3 and 110.6 mAh g$^{-1}$. Furthermore, when the discharge-charge test is re-cycled at 0.2C after 2C, the TiO$_2$C nanocomposite can still deliver a discharge capacity of about 220 mAh g$^{-1}$. This value is almost identical to the former 0.2C test, suggesting a high electrochemical stability of the homogenous TiO$_2$C nanocomposites.

In order to understand the improved performance of TiO$_2$C nanocomposites, the electrochemical impedance spectra (EIS) tests for both TiO$_2$C and pure TiO$_2$ have been performed. As displayed in Fig. 6d, the Nyquist plots of both TiO$_2$C and pure TiO$_2$ consist of one semicircle in the high-frequency region and a bias line in the low-frequency region. The radius of the semicircle is correlated with the charge-transfer ability of the corresponding electrode. Apparently, the TiO$_2$C electrode possesses a much lower resistance (50 Ω) than the pure TiO$_2$ electrode (81 Ω), as a result of the good electrical contact between TiO$_2$ and carbon. This indicates that the TiO$_2$C composite electrode possesses lower charge-transfer impedance due to the uniform carbon matrix around TiO$_2$ nanoparticles. Consequently, both the Li$^+$ diffusion and electron transfer are effectively expedited at high cycling rates for the TiO$_2$C composite electrode, leading to superior capacity retainment at different current rates in comparison to pure TiO$_2$ nanospheres.

Based on the above discussion, the TiO$_2$C nanocomposite has demonstrated much better performance than the pure TiO$_2$ anode. Several factors may account for the enhanced lithium storage properties. First, the TiO$_2$C has higher electronic conductivity for electron transfer due to the uniform carbon coating$^{20,24,30,35,40}$. Second, the small size of TiO$_2$ nanoparticles confined in carbon also provides a short path for lithium intercalation and de-intercalation$^{14,31}$. Third, the optimized homogeneous TiO$_2$C structure might also contribute to the improved performance, as it delivers a higher capacity during cycling when compared with other forms of TiO$_2$/C nanocomposite$^{24,35,36}$, possibly because the carbon matrix could effectively prevent the aggregation of TiO$_2$ nanoparticles.

Conclusions

In summary, a direct pyrolysis strategy has been proposed to realize an optimized structure of homogenous TiO$_2$C nanocomposite by using Ti-containing organic-inorganic polymers as the precursor. The organic component can be easily converted to carbon, which can effectively suppress the growth of nucleated TiO$_2$ nanoparticles and simultaneously make the TiO$_2$ nanoparticles highly distributed in the carbon matrix. Electrochemical tests demonstrate the as-synthesized TiO$_2$C composite nanospheres exhibit improved Li-ion storage performance in terms of higher capacity, better cycling performance and rate capability compared with pure TiO$_2$ nanospheres. The enhanced properties can be ascribed to the unique homogeneous structure of TiO$_2$C, small size of TiO$_2$ nanoparticles, and improved conductivity due to the carbon matrix. It is expected that the proposed direct pyrolysis route in this work can also be utilized to fabricate other composite electrode materials for high performance lithium-ion batteries.
