This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. This Accepted Manuscript will be replaced by the edited, formatted and paginated article as soon as this is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Ab initio study of germanium-hydride compounds under high pressure

PuGeng Hou, FuBo Tian, Da Li, ZhongLong Zhao, Defang Duan, HuaDi Zhang, XiaoJing Sha, BingBing Liu, and Tian Cui*

State Key Lab of Superhard Materials, College of Physics, Jilin University, Changchun 130012, People’s Republic of China

Motivated by the potential high temperature superconductivity in hydrogen rich materials and phase transitions, the germanium-hydride under high pressure was studied by a genetic algorithm. Enthalpy calculations suggest that the Ge and H compose Ge$_3$H, Ge$_2$H, GeH$_3$, and GeH$_4$ at about 32, 120, 280, and 280 GPa, respectively. These four germanium-hydride compounds are all stable up to at least 300 GPa. For Ge$_3$H, the most stable structure is $P\overline{3}$-Ge$_3$H at 32-220 GPa and $P6_{3}/m$-Ge$_3$H at 220-300 GPa. All the germanium-hydride compounds are metallic phases demonstrated by the band structure and density of states.
I. INTRODUCTION

In the past few decades, scientists have been trying best to seek and design high-temperature superconducting material [1-3]. And in high-pressure field, one of the most significant targets is to discover metallic hydrogen for high-temperature superconductor and the other one is to make production, transition and application of hydrogen. Theoretical works have been reported that hydrogen will metalize at about 440 GPa. However, it does not observe the experimental metallization till 342 GPa [4]. But it will lower the $T_c$ because of chemical pre-compression [5]. Recently, it was suggested that dense hydrogen-dominated metallic alloys, in strongly compressed group IV hydrides, can be potential candidate materials for a high-temperature superconductor. Disilane has been studied by Jin et al.[6], and they had explored the crystal structures of disilane in a wide pressure range from 50 to 400 GPa, and three favored structures, $P-1$, $Pm-3m$, and $C2/c$. Remarkably, the large $T_c$ of 80 K at 200 GPa for $P-1$ and 139 K at 275 GPa for $Pm-3m$ are predicted by quantitative calculations. Germane has been forecasted by Gao et al.[7], and their calculated results suggested a remarkably wide decomposition pressure range of 0-196 GPa, above which a $C2/c$ structure is stable. Then GeH$_4$ [8] and GeH$_4$(H$_2$)$_2$ [9] were studied by Chao Zhang and Guohua Zhong et al. GeH$_3$ has been predicted to be a $Ccmm$ structure by Kazutaka Abe et al. [10], and the calculation of enthalpy indicates that $Ccmm$ GeH$_3$ can be formed at about 200 GPa.

In order to search out the real conditions of Ge$_3$H, Ge$_2$H and GeH$_3$, we extensively explored the structures of germanium-hydride compounds under high pressure using an \textit{ab initio} evolutionary algorithm [11-12] for crystal structure prediction. We propose the compound of Ge$_3$H is more potential in
the pressure range of 40 ~ 300 GPa. Enthalpy calculations suggest that $P$-3 structure is the most favorite one at 40~220 GPa and $P6_3/m$ structure is the most favorite one at 220~300 GPa. Calculations of DOS indicate that all of $Pnma$ Ge$_2$H, $P$-3 Ge$_3$H, $P6_3/m$ Ge$_3$H and $Ccmm$ GeH$_3$ are metallic. For $Ccmm$ GeH$_3$, as an underlying candidate of high-temperature superconductor, the application of the Allen-Dynes modified McMillan equation [13] reveals high $T_c$ of 80.3 K at 300 GPa for this structure. Our calculations have also revealed that there will be $P$-3 Ge$_3$H under high pressure which has been considered as that it will not form any compounds of Ge and H below about 32 GPa. We predict that Ge and H will compose GeH$_3$ above 280 GPa. At the same time, it is cleared that another metallic germanium-hydride structure $C2/c$ GeH$_4$ [7] will not form before 280 GPa.

II.COMPUTATIONAL METHOD

Ab initio evolutionary algorithm [10-12], designed to search for the structure possessing the lowest free energy at given pressure conditions has been employed. The most significant feature of this method is the capacity of predicting the stable structure with only the knowledge of the chemical composition [5]. The details of the search algorithm and its first several applications have been described elsewhere. The underlying ab initio structure relaxations were performed using density functional theory within the Perdew-Burke-Ernzerhof (PBE) parameterization of the generalized gradient approximation (GGA) as performed in the Vienna $ab$ initio simulation package VASP code to calculate projected density of states [14-15]. The PAW [16] potential with the valence states 1s$^1$ for H and 4s$^2$4p$^2$ for Ge [17] has been employed with plane waves up to a cutoff energy of 720 eV, and the density of states has been calculated with a 8 x
8 x 9 k-point mesh created by the Monkhorst-Pack (MP) [18] method. Phonon dispersion and electron-phonon calculations were performed with density functional perturbation theory [19-20] using the program QUANTUM ESPRESSO [21]. Convergence tests gave the choice of kinetic energy cutoff 72 Ry and 8 x 8 x 9 Monkhorst Pack grids of k-points sampling for the electronic Brillouin Zone integration. We calculated $T_c$ using the Allen-Dynes equation. The q-point mesh in the first BZ of 4 x 4 x 4 for $Cccm$ structure is used in the interpolation of the force constants for the phonon dispersion curve calculations. A denser k-point mesh 12 x 12 x 12 for $Cccm$ structure is adopted to ensure k-point sampling convergence with a Gaussians width of 0.03Ry, which approximates the zero width limits in the calculation of EPC parameter $\lambda$. The hybrid functional calculations are implemented in the CASTEP code, together with norm-conserving pseudopotentials, and a cutoff energy of 600 eV. [22, 23]

III. RESULTS AND DISCUSSION

We performed variable-cell structure prediction simulations using the above evolutionary methodology for containing one, two, three, and four molecules in the simulation cell at 10, 30, 50, 100, 150, 200, 250 and 300 GPa, respectively. At 50 and 100 GPa, our simulations predicted a $P-3$ structure as depicted in Fig 1(a). The Ge and H atoms are depicted in violet and pink colors, respectively. Each H atom is in connection with three Ge atoms. Both of two kinds of atoms form the layered structure. Figure 2(b) shows the enthalpy curves for $P-3$ Ge$_3$H structure, and the decomposition of $Cmca$ Ge and $c2/c$ H$_2$ [24-26] with respect to our predicted $P-3$ structure. Obviously, the currently proposed structures are much superior in enthalpy than the other structures. At 200 and 250 GPa, our simulations predicted a $P6_3/m$ structure as depicted in Fig 1(b), and at 100 and 150 GPa,
a Pnma structure as depicted in Fig 1(c). It is clear that Cccm GeH₃ [10] as depicted in Fig 1(d) will not be easily formed until 280 GPa and Ge and H will compose to P-3 Ge₃H at 32 GPa. Enthalpy calculations reveal that the Cccm structure is stable at 280 GPa up to at least 300 GPa, respectively, while P-3 Ge₃H and Pnma Ge₂H are the most stable two phases from 120 GPa to 220 GPa. From 220 GPa to 280 GPa, Pnma Ge₂H and P6₃/m Ge₃H will coexist. No imaginary phonon frequencies were found in Brillouin Zones to confirm the P-3 Ge₃H structural stability of the new stable structure from 40 GPa to 220 GPa, P6₃/m Ge₃H from 220 GPa to 300 GPa and Pnma Ge₂H from 50 GPa to 300 GPa. Due to the chemical precompression [5], the GeH₃ may be a good superconductor under high pressure. To explore the superconductivity of the Cccm GeH₃, the application of the Allen-Dynes modified McMillan equation [13] reveals high superconducting temperature of 80.3 K for the Cccm phase at 300 GPa and 100.8 K at 220 GPa. At the stability field of P-3, Pnma and P6₃/m, the electronic properties, lattice dynamics, and electron-phonon coupling of P-3, Pnma and P6₃/m structure are explored. In accordance with our expectation, the superconduction transition temperatures of these three phases are very low as a result of the content of hydrogen is low. This result maybe approves that, to a great extent, superconduction transition temperature depends on the content of hydrogen in metal hydride.

To further confirm the dynamical stability of Ge₃H and Ge₂H, we calculate the phonon dispersion curves as shown in Fig. 3. No imaginary phonon frequencies were found in Brillouin Zones confirms the structural stability of the new structures. The calculated energy band structures and density of states of Ge₃H and Ge₂H are shown in Fig. 4 and Fig. 5, respectively. The overlap between the conduction and the valence bands
suggests that Ge$_3$H and Ge$_2$H are metallic. The electronic band structure and density of electronic states (DOS) of $Cccm$ GeH$_3$ are shown in Fig. 6, which shows significant overlap between the orbitals of $s$ and $p$ electrics. The band structure reveals metallic character with large dispersion bands crossing the Fermi level ($E_F$) and a flat band around $E_F$. The simultaneous occurrence of flat and steep bands near the Fermi level has been suggested as favorable conditions for strengthening electron and phonon coupling, which is essential to superconducting behavior [7]. Due to underestimation of band gaps of GGA functional, we also calculated the band structures of germanium-hydride compounds with hybrid functional HSE06 method. The band structures calculated by hybrid functional HSE06 method are the same as GGA results, suggesting that the structures at the pressures are all metallic phases.

According to the McMillan formula [13], $T_c$ is governed by three parameters: coupling-weighted phonon momentum, electron-phonon coupling, and conduction electrons near $E_F$. Conduction electrons near $E_F$ are ruled out as the main contributor for the superconductivity behavior, since there is only a low density of Ge $s$ electrons and even lower H $s$ electrons. But the shape of the density of H $s$ electrons is much like Ge $s$ electrons, which is helpful to enhance the electron-phonon coupling. The change in coupling-weighted phonon momentum under pressure is seen to be in consistent with that of $T_c$. This leaves electron-phonon coupling as the dominant reason for affecting $T_c$. We thus explain the likeness between the respective behaviors of $T_c$ and the hybridization function under pressure to be because of improvement enhancing electron-phonon coupling by the match of the energy level from Ge $p$ electrons with the peak of H $p$ electrons. The peak of Ge $p$ electrons is found too high above $E_F$, and is found close
to the $E_F$ and can therefore contribute strongly to the electron-phonon coupling. The calculated electronic band structure and projected density of states (DOS) for $Cccm$ GeH$_3$ at 280 GPa presented in Fig. 6 reveal that this structure is metallic. However, the less dispersed valence and conduction bands near the Fermi level represent a rather large electronic DOS at the Fermi level, which might favor the superconducting behavior. The calculated valence bandwidth is consistent with earlier predictions and recent theoretical results for dense hydrogen alloys [5]. The strong Ge-H hybridization can be got from the significant overlap of Ge-DOS and H-DOS. Phonon calculations performed at 280, and 300 GPa have proved the dynamical stability of $Cccm$ structure by evidence of the absence of any imaginary frequency modes in the BZ. To explore the superconductivity of this phase we suggested, the EPC parameter $\lambda$, the logarithmic average phonon frequency ($\omega_{\text{log}}$), and the Eliashberg phonon spectral function $\alpha^2 F(\omega)$ [26] have been investigated at high pressures. The resulting $\lambda$ for this phase at 220 and 300 GPa are 1.65, and 1.36, respectively, indicating that the EPC is fairly strong. The theoretical spectral function $\alpha^2 F(\omega)$ [26] and the integrated $\lambda(\omega)$ as a function of frequency at selected pressures are shown in Fig. 7. The superconducting critical temperature can be estimated from the Allen–Dynes modified McMillan equation, which has been found to be highly accurate for many materials with $\lambda < 1.5$. The $\omega_{\text{log}}$ is calculated directly from the phonon spectrum. The Coulomb pseudopotential $\mu$ is often taken as 0.1 for most metals; an appropriate one proposed by Ashcroft is 0.12 for hydrogen dominant metallic alloys that has been adopted in the works of GeH$_4$ and SnH$_4$. These current studies inevitably stimulate the future high-pressure experiments on the structural and conductivity measurements.

Extra phonon calculations show the stability range to be between 280
and at least 300 GPa [10]. Obviously, for low frequency area, Ge contributes a lot to phonon DOS, by contraries, for high frequency, all contribution come from the electrons of H atoms [27-28]. In general, the integrable function depends on the high frequency which is contributed by the electrons of H atoms.

IV. CONCLUSIONS

In summary, the structures of germanium-hydride are explored with the \textit{ab initio} evolutionary method. The \textit{P}-3 Ge$_3$H structure is the most stable one in a pressure range from 40 GPa to at least 220 GPa, the \textit{Pnma} Ge$_2$H structure will coexist with \textit{P}-3 in a pressure range from 120 GPa to at least 220 GPa and coexist with \textit{P6$_3$/m} Ge$_3$H from 220 GPa to 300 GPa. And the \textit{ab initio} calculation of energy show Ge$_3$H and Ge$_2$H will be formed more easily than GeH$_3$ below 280 GPa. The calculated band structures of the all these four phases reveal a metallic character, specially, for \textit{Cccm} GeH$_3$, with large dispersion bands crossing the Fermi level ($E_F$), which is necessary for superconductive behavior. Electron-phonon coupling calculations show that this phase is superconducting with a high $T_c$ of 80.3 K at 300 GPa. The current study will inevitably stimulate the future high-pressure experiments on the structural and conductivity measurements.
