This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Nitrogen-Enriched and Hierarchically Porous Carbon Macro-Spheres - Ideal for Large-Scale CO₂ Capture

Bingjun Zhu, a Kaixi Li, b Jingjing Liu, c Hao Liu, c Chenggong Sun, c Colin Snape c and Zhengxiao Guo a

Keywords: carbon-based materials, porous structures, synthesis, CO₂ capture

A facile and efficient “spheridization” method is developed to produce nitrogen-enriched hierarchically porous carbon spheres of millimeters in diameter, with intricate micro-, meso- and macro- structural features. Such spheres not only show exceptional working capacity for CO₂ sorption, but also satisfy practical requirements for dynamic flow in post-combustion CO₂ capture. Those were achieved using co-polymerized acrylonitrile and acrylamide as the N-enriched carbon precursor, a solvent-exchange process to create hierarchically porous macro-sphere preforms, oxidation to induce cyclization of the polymer chains, and carbonization with concurrent chemical activation by KOH. The resulting carbon spheres show a relatively high CO₂ uptake of 16.7 wt% under 1 bar of CO₂ and, particularly, an exceptional uptake of 9.3 wt% under a CO₂ partial pressure of 0.15 bar at 25 °C. Subsequent structural and chemical analyses suggest that the outstanding properties are due to highly developed microporous structures and the relatively high pyridinic nitrogen content inherited from the co-polymer precursor, incorporated within the hierarchical porous structures.

1. Introduction

Anthropogenic CO₂ emission from the burning of fossil fuels is considered to be a significant contributor to global climate change. Fossil fuels still provide over 85% of the world’s energy consumption today and are likely to dominate energy supply for many decades to come. Therefore, developing a practical CO₂ capture technology is critically important to mitigate climate change. Porous carbon materials have been under intensive study as CO₂ sorbents, due to their high moisture/chemical stabilities and low costs. These can also be regenerated after CO₂ adsorption either by a relatively small change of temperature or pressure with a minimum energy penalty. Such porous carbon sorbents are usually derived from natural substances or polymeric precursors and KOH is frequently used as the activation agent to enhance porosity. A sawdust-based porous carbon activated by KOH at a KOH/precursor weight ratio of 2:1 and 600 °C shows a high CO₂ adsorption capacity of 21.1 wt% (4.8 mmol g⁻¹) under 1 bar CO₂ and 25 °C, whereas a polypropylene-derived porous carbon activated and tested under the same conditions yields a CO₂ adsorption capacity of 16.9 wt% (3.9 mmol g⁻¹). Porous carbon sorbents derived from resorcinol-formaldehyde, yeast, fungi and urban wastes also show a wide range of capacities from 1 to 21 wt%. However, these studies only focused on relatively fine and irregular powder of tens of microns. For practical applications in large scale CO₂ capture, such as CO₂ capture in a fluidized-bed, the ideal sorbent is in the form of porous spheres of several millimeters in diameter for optimum flow dynamics and CO₂ sorption. Spherical carbon beads also reduce material abrasion due to smooth rotational impact. Furthermore, the flow resistance can be readily maintained, because the dynamic stacking density of carbon spheres does not change under a given set of flow conditions. A recent report shows phenolic resin-based activated carbon spheres with specific surface area of 2400 m²/g and a total CO₂ uptake of 20.2 wt% (4.6 mmol g⁻¹) at 23 °C and 1 bar CO₂, but the size of the carbon spheres is only about 0.6 µm, limited by the manufacturing method. The activated carbon spheres also rely on a rather large weight ratio of KOH/polymer (4:1) to produce a highly porous structure, leading to an extremely low carbon yield and low material strength. Such micro- and nano-sized carbon spheres are too buoyant to be effectively controlled under flue-gas conditions, and may readily clot filters during CO₂ removal. Therefore, millimeter-sized carbon spheres with effective CO₂ capture capabilities are desirable for practical CO₂ sorption applications, e.g., via a fluidized bed.

Here, we report a facile and effective method of producing mm-sized radially porous carbon spheres with an excellent CO₂ sorption capacity. Co-polymerized precursors are spheridized via the mechanism of Plateau-Rayleigh instability and solidified into a porous pre-form via a solvent-exchange process. The experimental results show that this method is effective in producing millimeter carbon spheres with excellent structural integrity and exceptional CO₂ adsorption performance.
2. Results and Discussion

2.1 Formation of Carbon Spheres

The sphericity of carbon spheres depend on several factors, which are optimized and presented in the Experimental Section. The corresponding discussion is included in ESI. The copolymer with the best spherical shape is with an acrylamide/acrylonitrile molar ratio of 1:3.3. Therefore, it is selected to produce the carbon spheres. The polymer sphere in Figure 1a shows a smooth surface: the polar diameter R1 (vertical) is 3.4 mm, slightly longer than the equatorial diameter R2 (horizontal) of 3.3 mm, which gives a roundness ratio of R1/R2= 1.03. Some scratches on the surface are indicative of the soft nature of this polymer. The cross-sectional image of the polymer sphere (Figure 1b) shows a hierarchical porous structure, typically with three regions: a relatively thin outer mantle of 0.5 mm in thickness with radial channels of about 0.08 mm in diameter, a thick inner mantle of 1 mm in thickness with radial channels of 0.3 mm in diameter and a relatively hollow core of 0.3 mm in diameter. This hierarchically and radially channeled porous structure is a direct consequence of the solvent-exchange process that takes place between the polymer sphere and the water bath as explained below.

Since dimethyl sulfoxide (DMSO) is highly miscible with water, due to the concentration gradients of DMSO and water in the sphere and the water bath, DMSO tends to diffuse from the sphere into the water bath, and vice versa. As the polymer has low solubility in water, the polymer chains tend to partition or “precipitate out” with the exchanged water. This “solvent-exchange” based mechanism is schematically illustrated in Figure 2.

The exchange process starts with a spherical drop of polymer solution. At the beginning, the concentration gradients are steep across the interface of the solvents or the surface of the sphere, which leads to dense sites (or “nuclei”) of polymer precipitates. The radial diffusion of the exchanging solvents results in radial flow channels, which become the porous channels at a later stage. As the exchange continues, the partitioned polymers at the surface region restrict the rate of further solvent exchange towards the center. This process gradually allows more polymers to cluster together, driven by the reduction in surface energy, leading to increasingly large porous channels towards the inner region. Towards the end of the process, there are relatively fewer polymers in the core region, which becomes hollow upon solvent removal. Figure 1c shows the oxidized polymer sphere maintains its original spherical shape but with a reduced diameter of 2.3 mm. The cross-sectional image (Figure 1d) indicates the radially channeled structure is retained. The interconnected porous structure allows KOH solution to diffuse across the entire structure during sample soaking. After KOH activation at 600 °C, the sample surface is significantly etched, but the shape and integrity of the sphere are preserved, thanks to the mild activation condition (KOH/sphere = 1:1). The cross-sectional image Figure 1f shows the radially channeled structure survives from the chemical activation, acting as the supporting framework of the sphere. The high resolution TEM image (Figure 1g) shows segmented graphitic platelets with well-aligned carbon layers. This observation differs from TEM images of carbon sorbents studied in previously mentioned literature, where carbon layers are randomly oriented. It is mentioned earlier that the solvent-exchange process helps to align the polymer chains radially. These aligned polymer chains form pyridine and pyridone rings after oxidation (ESI Figure S2), which directly influences the formation and alignment of carbon layers after the carbonization and activation. It can be clearly observed in the TEM image that there are nano-scale voids between edges of those graphitic platelets, which are the origins of micropores. However, too high a ratio of KOH to spheres (KOH/sphere = 2:1) leads to fragile samples and loss of sphericity (Figure 1h).

2.2 Characterization of Porous structures

The specific surface area and pore size distribution of carbon spheres were comparatively characterized by means of gas sorption, using CO₂ and N₂ probes, and mercury porosimetry, respectively for ultramicro-, micro- and meso- pores (details in Section 4). The results are summarized in Table 1.

“CSC” is the sphere carbonized at 600 °C without KOH activation. Its isotherm lies at the bottom of Figure 3a, and shows a small specific surface area of 4.5 m².g⁻¹ and pore volume of 0.006 cm³.g⁻¹. CSA-x (x= 600, 700, 800) stands for the carbon spheres activated at x °C. With KOH activation, CSA-600 starts to develop a porous structure with a specific surface area of 520.2 m².g⁻¹ and pore volume of 0.317 cm³.g⁻¹. Generally, the specific area increases with carbonization temperature, from 520 m².g⁻¹ at 600 °C, more than doubled at 700 °C, to over 2000 m².g⁻¹ at 800 °C. The emergence of the porous structure can be explained by the reaction between KOH and carbon, which is a well-studied chemical activation method of producing activated carbon. The development of porous structure at different temperatures can be attributed to different reaction mechanisms (see Electronic Supplementary Information for details). For the sample activated at 800 °C, besides the removal of carbon atoms, earlier literature suggests the formation of elementary potassium and its vaporization make it possible for elementary potassium atoms to penetrate graphene layers, expanding the distance between the layers, further enhancing the surface area and the pore volume.

In addition, Figure 3b shows that the pore size distributions of CSA-600, 700 and 800 are mainly centered at 1.2 and 2 nm, indicating pore development at both micro- and meso-pore ranges. CSA-600 possesses a relatively small volume of micro- and meso-pores, while CSA-700 shows a marked increase in the micropore volume, almost three times greater than that of CSA-600. CSA-800 exhibits an even higher peak at 1.2 nm but with an apparently enhanced peak at 2 nm and several other weak peaks distributed in the mesopore range.

In order to assess the ultra-micropore (<0.7 nm) characteristics, CO₂ was used as a probe for sorption analysis. The results show that the ultra-micropore volume (Vₛ₉₃⁰) in Table 1 is greater at a higher activation temperature, but the magnitude of increase is higher from CSA-600 to CSA-700 (by 71%) than from CSA-700 to CSA-800 (by 4.4%). The finding indicates that a higher activation temperature does not just result in an increased volume of ultra-micropores but also leads to more rapid growth of pore sizes. In addition, for the sample CSC, though its micropore volume is negligible from N₂ sorption, CO₂ sorption analysis shows that it possesses a small level of ultra-micropores, which cannot be accurately analyzed by the N₂ sorption technique.
In addition to the micro- and meso-pore analysis, Table 1 also summarizes the macropore volumes \( (V_{\text{Hg}}) \) of the carbon spheres. The large macropores originate from the hierarchical macroporous channeled structure formed during the solvent-exchange process. It is further enlarged due to more aggressive activation reactions at elevated temperatures. Such macropores should facilitate diffusion of CO\(_2\) within the carbon spheres. However, an excess level of such macropores may reduce the volume capacity of CO\(_2\) sorption in the sphere. Further study is under way to optimize the distribution of the pore sizes in those hierarchical porous carbon spheres.

### 2.3 Chemical Compositions of Carbon Spheres

The results of chemical composition analysis by XPS are summarized in Table 2. The relative FTIR and N-1s XPS spectra are presented in Figure 4. Figure 4a compares the FTIR spectra of the polymer, oxidized polymer (CSO) and activated carbon spheres. All FTIR spectra show one wider peak between 3700 and 3000 cm\(^{-1}\), which corresponds with the N-H and O-H stretching vibration bands. The polymer sphere shows three sharper peaks from 2240 to 1450 cm\(^{-1}\). The peak at 2244 cm\(^{-1}\) is attributed to the stretching vibrations of nitrite groups \((-\text{C}=\text{N})\) from the acrylonitrile units in the polymer sphere, while the peak at 1670 cm\(^{-1}\) is attributed to the stretching vibrations of primary amide groups from the acrylamide \((-\text{CO}−\text{NH}_2\text{)}\) units.\(^{16}\)

There is a small shoulder right beside the 1670 cm\(^{-1}\) peak at 1640 cm\(^{-1}\), which originates from the stretching vibrations of carbonyls \((\text{C}=\text{O})\) from the primary amide groups. The peak around 1452 cm\(^{-1}\) is assigned to the in-plane bending vibrations of methylene bridges \((-\text{CH}_2-)\) from both acrylonitriles and acrylamides. After the oxidation reaction, the peak around 2244 cm\(^{-1}\) completely disappears. In addition, the intensity of the amide peak at 1670 cm\(^{-1}\) is reduced and shifted to 1614 cm\(^{-1}\) and the shoulder at 1640 cm\(^{-1}\) disappears as well. It is consistent with the mechanism of the oxidation process whereby the nitrite and amide groups are removed through the formation of pyridinic rings in the cyclization reaction. The peak at 1614 cm\(^{-1}\) is the evidence of the emerging pyridinic rings. The intensity of the methylene peak at 1452 cm\(^{-1}\) is increased and shifted to 1440 cm\(^{-1}\), which can be attributed to the formation of carbon double bonds in the pyridinic rings.\(^{16}\)

After the activation reaction, the intensities of both peaks are greatly reduced due to further loss of nitrogen content and regular pyridinic structure due to chemical attack by KOH. Besides, there exist a range of weak peaks below 1300 cm\(^{-1}\) in the spectra. The spectrum of the polymer shows a relatively broad and weak band from 1200 to 1000 cm\(^{-1}\), which can be assigned to \(\text{C}-\text{N}\) stretching vibrations. There are also two peaks at 858 cm\(^{-1}\) and 695 cm\(^{-1}\), which can be assigned to the out-of-plane bending of \(\text{N}-\text{H}\) and deformation of \(\text{C}-\text{H}\). When it comes to the oxidized polymer CSO, multiple weak peaks appear in the range of 1300 to 1000 cm\(^{-1}\), due to the ester and other groups introduced by the oxidation process. For CSA-600, all the previously mentioned peaks below 1300 cm\(^{-1}\) disappear due to carbonization and activation reactions at the elevated temperature.\(^{16}\)

Figure 4b-d reveal how nitrogen content varies with different sample preparation conditions. The spectrum of the oxidized polymer can be deconvoluted into three major peaks at 399.3, 400.7 and 403.1 eV (Figure 4b), which correspond to the existence of pyridinic, pyrrolic and pyridinic N-oxide, respectively.\(^{17}\) The emergence of these two peaks is consistent with the mechanism of the oxidation reaction.\(^{18}\) Table 2 shows the variation of chemical composition with different preparation conditions. The carbonized sample CSC shows a high nitrogen content of 13.08 at.%. Chemical activation by KOH reduces the nitrogen content of CSA-600 to 6.81 at.%, although only a mild activation condition of KOH/sphere=1 is applied. Figure 4c and d reveal that all carbon spheres exhibit three major peaks at 398.2, 400.0 and 403.1 eV, respectively. These peaks suggest pyridinic nitrogen, pyrrolic nitrogen and pyridinic nitrogen oxides are the three major forms of nitrogen in the carbon spheres.\(^{3,17}\) The former two exist at the edge of the carbon structure, which increases the affinity of CO\(_2\) towards the carbon structure due to the acidic nature of CO\(_2\) and basic nature of the nitrogen content. Figure 4d shows all activated carbon spheres suffer severe reductions in peak intensities, compared with those of the carbonized sphere in Figure 4c. With the increasing activation temperature, the nitrogen content of CSA-600, 700 and 800 drops from 6.81 to 4.76 at.%. In addition, Figure 4d shows that the intensities of the 398.2 eV peaks are severely reduced compared with those of the 400.0 eV peaks. Table 2 also summarizes of the composition of different forms of nitrogen in carbon spheres. It is clear that the pyridinic nitrogen content is reduced with increasing temperatures from 600 to 800 °C. This implies that pyridinic nitrogen is less stable than pyrrolic nitrogen at high temperatures with the same activation conditions. The loss of pyridinic nitrogen can be attributed to more aggressive chemical activation reactions at a higher temperature as discussed in the previous paragraph. Besides the nitrogen content, another interesting observation is the existence of residual potassium. An earlier study suggests that it can help to enhance CO\(_2\) binding with the sorbent.\(^{19}\) The corresponding discussion is included in the Electronic Supplementary Information (ESI).

### 2.4 CO\(_2\) Adsorption on Carbon Spheres

Figure 5 depicts CO\(_2\) adsorption isotherms at 0 and 25 °C from 0.1 to 1 bar of CO\(_2\). The corresponding CO\(_2\) uptakes at 1 bar CO\(_2\) are summarized in Table 3. All samples have higher CO\(_2\) uptakes at 0 °C, which can be explained by the reduced kinetic energy of CO\(_2\) gas molecules at a lower temperature. At 25 °C, CSA-700 presents the best CO\(_2\) uptake of 16.7 wt% (3.8 mmol g\(^{-1}\)). It has a better CO\(_2\) uptake than CSA-600 of 9.4 wt% (2.1 mmol g\(^{-1}\)), due to much enhanced porous structure (from 520.2 to 1231.4 m\(^2\) g\(^{-1}\)), even its nitrogen content is reduced (from 6.81 to 5.94 at.%). However, even with higher surface area and larger pore volume, CSA-800 shows a lower CO\(_2\) uptake of 14.0 wt% (3.2 mmol g\(^{-1}\)) due to further reduction in the nitrogen content, especially the loss of pyridinic nitrogen (from 24.27 to 17.56 at.% in Table 2). Earlier studies have shown pyridinic nitrogen possesses higher basicity than pyrrolic nitrogen.\(^{20}\) This is because pyridinic nitrogen has a lone pair of electrons with one electron donated to the conjugated \(\pi\)-system, while pyrrolic nitrogen donates two \(\pi\)-electrons that delocalize into the conjugated \(\pi\)-system. Therefore, pyridinic nitrogen has a higher affinity towards acidic CO\(_2\) molecules than pyrrolic nitrogen.\(^{21}\) Considering the experimental results from both structural and chemical analyses, it can be concluded that both porous structures and nitrogen content influence the CO\(_2\) uptake of carbon spheres. The maximum CO\(_2\) capacity is achieved by balancing both porous structure and pyridinic nitrogen content.

The isotherms of CSA-600 and CSA-800 intersect with each other at both 0 and 25 °C (Figures 5a and b), which shows
An effective route is developed for the synthesis of hierarchically porous carbon spheres of millimeter scale. These are derived from a poly(acrylonitrile-co-acrylamide) precursor, leading to enriched nitrogen content and intercalated potassium cations in the carbon structures. The carbon spheres show a porous structure with a hollow core and hierarchical porous mantle. The activation temperature influences both the porous structure and nitrogen content of the carbon spheres.

4. Experimental Section

4.1. Synthesis of Polymer Spheres

Poly(acrylonitrile-co-acrylamide) was prepared by the copolymerization reaction of acrylonitrile (AN, 98.0%, Northern China Special Chemicals Development Center, China) and acrylamide (AM, 98.0%, Northern China Special Chemicals Development Center, China) in a 100 ml round bottom flask with dimethyl sulfoxide (25 ml, DMSO, 99.5%, Tianjin Guangfujinxi Chemical Research Institute, China). α,α′-Azoisobutyronitrile (AIBN, Shanghai No.4 Reagent & H. V. Chemical Co., China) was used as the initiator for the radical polymerization reaction and the initiator concentration was 1 wt% of the total monomers weight, i.e., 0.091 g AIBN. A range of experiments were carried out to determine the fluidity of the polymer solution for free-forming of polymer spheres under gravity. The experimental conditions were optimized for the formation of millimeter-sized polymer spheres. The solution was magnetically stirred in a water bath at a reaction temperature of 65 °C for 3 h. Several initial monomer molar ratios were used to prepare copolymers (acrylamide/acrylonitrile = 0:1, 1:10.9, 1:3.3, 1:1.5). The ratio of 1:3.3 produced a relatively spherical shape compared with the other ratios. Therefore, the corresponding polymer spheres were selected to produce carbon spheres. Theoretically, this ratio produces a copolymer with the molar ratio of monomer units acrylamide/acrylonitrile = 0.73:1.

An in-house facility was built to produce the polymer spheres, as illustrated in Figure 7. This set-up was adopted from an earlier work by Li et al.24 The polymer solution was dripping through a 2 mm diameter nozzle. A glass beaker filled with distilled water (1000 ml) was placed below. The distance between the nozzle and the water surface was selected to be 15 cm. Different amounts of DMSO were added to the reaction solution to adjust the viscosity for easy dripping and formation of spherical drops, and the optimum addition was identified to

3. Conclusions

Figure 6a shows the CO$_2$ uptake of CSA-700 in a gas mixture of 15 vol% CO$_2$ and 85 vol% N$_2$. The test result shows that CSA-700 adsorb about 1.3 wt% N$_2$ when the temperature returns to 25 °C (see Figure 6a). However, it can still adsorb 9.3 wt% CO$_2$ even when the partial pressure of CO$_2$ is greatly reduced. Hence, the sample demonstrates a very high selectivity of CO$_2$ over N$_2$. Again, this can be attributed to the relatively high nitrogen content. This is an outstanding performance, compared with materials reported in the literature and tested under similar conditions.23 Figure 6b shows the sample can maintain 91% adsorption capacity after five cycles of adsorption and desorption by temperature swing. The test condition is a simulation of the flue gas from a post-combustion power plant. Therefore, the above results further prove that such carbon spheres can exhibit exceptional performance in post-combustion CO$_2$ capture applications.
be 25 ml. Then, the solution was poured in the syringe. The polymer solution drops were formed below the nozzles due to Plateau-Rayleigh instability under gravity and fell into the water bath. The surface of the polymer drop solidified immediately upon contact with water and sank to the bottom of the beaker. All polymer spheres were left in the water bath for 24 h. The distilled water was refreshed every 24 h until the smell of DMSO was removed. Then, the polymer spheres were dried in a vacuum desiccator at room temperature.

4.2. Oxidation

The dried spheres were loaded in a vertical furnace with an air compressor constantly pumping excess air through the furnace from the bottom to the top. The temperature was increased from ambient to 100 °C at a ramping rate of 2 °C min\(^{-1}\), then at 0.1 °C min\(^{-1}\) from 100 to 200 °C and finally dwelt at 200 °C for an hour. This stage was to remove residual water and DMSO from the spheres. The slow ramping rate was to avoid violent vaporization of residual gases, which would damage the sphere. Then the temperature was again raised to 300 °C at 0.2 °C min\(^{-1}\) and dwelt at 300 °C for the 8-hour oxidation reaction. At this stage, the slow ramping rate was to allow sufficient time for the oxidation reaction to take place and to prevent violent vaporization of un-oxidized polymer from damaging the sphere. Finally, the furnace was naturally cooled to room temperature.

4.3. Carbonization and Chemical Activation

The oxidized polymer spheres (0.2 g) were soaked in the KOH solution (10 ml) in a 25 ml glass beaker. The concentrations of KOH gave effective KOH/sphere weight ratios of 1:1 and 2:1. The mixtures were left in a vacuum desiccator overnight and then dried in a vacuum oven at 80 °C. The dried samples were carbonized and chemically activated in a horizontal tube furnace at 600, 700 and 800 °C under constant nitrogen gas flow. The ramping rate was 3 °C min\(^{-1}\) and the dwelling time at the designated temperature was 1 h. After the carbonization and chemical activation, the spheres were repeatedly washed with distilled water until a pH strip showed a neutral value. Then, the wet samples were dried in vacuum at 120 °C over night.

4.4. Characterizations

Images of sample morphology and porous structure were obtained from a field-emission scanning electron microscope (SEM, JSM 6301F, JEOL, Japan). Samples were fixed with a piece of conductive carbon tab on a sample holder and then gold coated for imaging. The spheres were also cut in half by a scalpel for imaging of their cross-sectional morphology. High resolution images were obtained from a transmission electron microscope (TEM, JEOL 2100, Japan). Carbon spheres were ground and suspended in methanol. A drop of the suspension was placed on a carbon-film coated Cu grid (300 mesh) and then dried in air before being loaded in the TEM. A Fourier transform infrared spectroscopy (FTIR, NICOLET iS10, Thermo Scientific, USA) and an X-ray photoelectron spectrometer (XPS, K-ALPHA, Thermo Scientific, USA) were used to acquire the information of surface functional groups and chemical compositions. The porous structures of carbon spheres were analyzed by means of an automated gas sorption analyzer (Autosorb-iQ C, Quantachrome, USA). The N\(_2\) and CO\(_2\) sorption isotherms were obtained by N\(_2\) sorption at -196 °C (liquid nitrogen) and CO\(_2\) sorption at 0 °C (ice-water mixture), respectively. The specific pore volume (V\(_{\text{N}2}\)) was determined by the amount of nitrogen adsorbed at the relative pressure 0.99. The specific surface area (S\(_{\text{N}2}\), pore size up to 40 nm), the specific micropore surface area (S\(_{\text{Micro}}\)), micropore volume (V\(_{\text{Micro}}\)) and pore size distribution were calculated using the Non-Local Density Functional Theory (silt/cylindrical pores) equilibrium model (NLDFT). The ultra-micropore volume (V\(_{\text{CO2}}\)) was calculated by the 273 K CO\(_2\) on Carbon NLDFT model. In addition, the macro pore volume (V\(_{\text{Macro}}\), pore size up to 421 μm) was measured by means of a mercury porosimeter (AutoPore IV, Micromeritics, USA) between 0.5 and 3600 psia.

The same gas sorption analyzer was also used to plot CO\(_2\) (Carbon dioxide research grade 100%, BOC, UK) adsorption and desorption isotherms from 0.1 to 1 bar at 0 and 25 °C. The samples were firstly degassed at the degassing station at 150 °C in vacuum for 2 h. Then, they were moved to the analysis station for CO\(_2\) uptake tests. Besides the uptake tests in pure CO\(_2\) environment, to simulate the practical CO\(_2\) capture condition in post combustion power plants, CSA-700 was also tested for its CO\(_2\) uptake in a gas environment with 15 vol% CO\(_2\) and 85 vol% N\(_2\) at 25 °C. The test was carried out in a thermogravimetric analyzer (TGA, Q500, TA instruments, USA). The sample was degassed at 150 °C for an hour in a constant pure N\(_2\) flow. Then, it was cooled to 25 °C before the gas flow was switched from N\(_2\) to the mixture of CO\(_2\) and N\(_2\) to measure its CO\(_2\) uptake. The sample was also tested for its CO\(_2\) uptake over multiple cycles of adsorption and desorption by the temperature swing method. The temperatures were changed between 25 °C and 150 °C to adsorb and desorb CO\(_2\).

Nitrogen-containing millimeter-scale polymer spheres are produced from poly(acrylonitrile-co-acrylamide) with a facile and efficient spheridization method. After a mild chemical activation by KOH, the as-produced millimeter-size porous carbon sphere shows a well-preserved spherical shape, a hierarchically porous structure, high nitrogen content and thus an excellent CO₂ capture performance, indicating its great potential in large-scale CO₂ capture applications.
