This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Nano La$_{0.6}$Ca$_{0.4}$Fe$_{0.8}$Ni$_{0.2}$O$_{3-\delta}$ decorated porous doped ceria as a novel cobalt-free electrode of "symmetrical" solid oxide fuel cells

Guangming Yang,$^a$ Chao Su,$^b$ Yubo Chen,$^a$ Moses O. Tadé,$^b$ and Zongping Shao$^{a,b}$

Here we report that nano La$_{0.6}$Ca$_{0.4}$Fe$_{0.8}$Ni$_{0.2}$O$_{3-\delta}$ (LCFN) decorated Sm$_{0.2}$Ce$_{0.8}$O$_{1.9}$ (SDC) composite oxide, prepared by solution infiltration method, could function well as a cobalt-free electrode material of "symmetrical" solid oxide fuel cells (SOFCs). The structure, morphology, thermal expansion, oxygen reduction reaction activity and catalytic activity for methane oxidation of the as-prepared LCFN-infiltrated SDC electrode was investigated systematically. Under reducing atmosphere, the partial segregation of metallic nickel from LCFN perovskite lattice was demonstrated by SEM and STEM-EDX, and XRD results suggested the perovskite structure of LCFN was still survived. Consequently, the good anode performance is expected due to the high catalytic activity of LCFN for methane oxidation and the excellent electrocatalytic activity of nano nickel for the methane reforming and electro-oxidation of hydrogen. In air atmosphere, an area specific resistance as low as 0.12 $\Omega$ cm$^2$ was achieved at 600 °C. The SDC electrolyte supported "symmetrical" SOFC with LCFN-infiltrated SDC electrode was then fabricated and tested, which delivered attractive peak power densities of 510 and 350 mW cm$^{-2}$ at 800 °C operating on hydrogen and CH$_4$-O$_2$ fuels, respectively.

Introduction

Fuel cells are one kind of electrochemical energy conversion devices that outperform traditional power generation devices based on combustion technology, in terms of efficiency, emission and noise reduction.$^{1,2}$ There are several types of fuel cells, which can be categorized based on the conducting species of electrolyte, operating temperatures or fuels. Among them, solid oxide fuel cells (SOFCs) are of particular interest for their outstanding energy efficiency, fuel flexibility and high quality of exhaust heat, resulting from their high operation temperature ranging from 500 to 1000 °C.$^{3-5}$

Although the exact reaction mechanism in a SOFC is fairly complicated and has not yet been fully understood, the simplified process may be described as follows. Molecular oxygen in the cathode atmosphere diffuses through the gas phase to adsorb on the surface of porous cathode, where it is reduced to oxygen ions via a series of intermediate steps; then the oxygen ions transport through the electrolyte to the anode where they react with fuel to the deep oxidation product with the simultaneous release of electrons, meanwhile the electrons move through the external circuit to the cathode to form a complete charge diffusion circle. Different materials are typically selected for the anode and cathode in a SOFC due to their different operation conditions, including oxygen partial pressure, reaction type and atmosphere composition. Up to now, the most applied anode materials in the SOFCs are nickel-electrolyte material cerments, while perovskite oxides are usually selected as the cathode materials,$^{6,9}$ therefore there are two different interfaces in a conventional SOFC, i.e., the anode-electrolyte and cathode-electrolyte interfaces. The potential interfacial reaction and the mismatch in thermal expansion coefficient (TEC) between cell components could cause the performance degradation and even the failure of SOFCs. If the same material is used for both the anode and cathode, improved compatibility between cell components and reduced cell fabrication cost is expected because only one type of interface exists. According to above consideration, symmetrical SOFCs with the identical material for both electrodes is proposed and investigated recently.$^{10-14}$

To be a suitable electrode material of symmetrical SOFCs, it should meet the requirements of sufficient conductivity and thermo-mechanical stability under both anode and cathode environments.$^{10,15}$ During the past, LaCrO$_3$-based perovskite oxides were mainly investigated, which can maintain a perovskite lattice structure over a wide range of oxygen partial
however, these materials usually show poor electro-catalytic activity for oxygen reduction reaction (ORR) and low conductivity at reducing atmosphere (i.e., anode atmosphere). As a result, poor cell power output was usually obtained.\textsuperscript{10,15,17} It suggests the development of alternative materials is urgently needed in order to realize the practical use of symmetrical SOFCs. Recently, we proposed a new “symmetrical” SOFC, in which K\textsubscript{2}NiF\textsubscript{4}-type La\textsubscript{2}NiO\textsubscript{4} was applied as the material for both electrodes.\textsuperscript{18} Different from the most applied LaCrO\textsubscript{3}-based electrodes, La\textsubscript{2}NiO\textsubscript{4} was fully reduced to La\textsubscript{2}O\textsubscript{3} and Ni under the anode atmosphere (thus actually, the cell was not symmetrical in composition under the practical operation conditions). The formed metallic Ni showed a high activity for fuel electro-oxidation. In addition, the electric conductivity of anode was improved significantly as compared to conventional oxide-based anode. However, due to the large volume change associated with the phase change from La\textsubscript{2}NiO\textsubscript{4} to La\textsubscript{2}O\textsubscript{3} under the anode atmosphere, the mechanical integrity of the cell is still a big concern during the repeated redox cycles process.

In this study, we reported a nano La\textsubscript{0.4}Ca\textsubscript{0.6}Fe\textsubscript{0.8}Ni\textsubscript{0.2}O\textsubscript{2.4} (LCFN) modified porous Sm\textsubscript{0.2}Ce\textsubscript{0.8}O\textsubscript{1.9} (SDC) composite as a novel cobalt-free electrode for “symmetrical” SOFCs, which was prepared by infiltrating LCFN into a porous SDC scaffold. Under the anode condition, the LCFN in the infiltrated electrode was partially reduced with the segregation of nickel from perovskite lattice that decorated the surface of LCFN particles, but the perovskite phase structure was not destroyed, ensuring good redox cyclability. Moreover, the favorable activity of LCFN for methane oxidation and the good electrocatalytic activity of nano metallic Ni for methane reforming and electro-oxidation of H\textsubscript{2} resulted in good performance of the LCFN modified SDC as an anode. As a result, attractive cell performance was achieved with this new “symmetrical” SOFC. It thus provides a new promising electrode for symmetrical SOFCs, which may significantly promote the wide-spread application of this high temperature electrochemical device to build a lower-carbon sustainable society.

Experimental

Synthesis and fabrication

Single phase LCFN and SDC powders were synthesized via a combined EDTA-citric acid complexing method as reported elsewhere,\textsuperscript{19} and their firing temperatures for phase formation were fixed at 1000 and 800 °C, respectively. LCFN precursor solution for the infiltration was prepared by a similar way as reported in our previous work.\textsuperscript{18} Briefly, stoichiometric amounts of La(NO\textsubscript{3})\textsubscript{3}-6H\textsubscript{2}O, Ca(NO\textsubscript{3})\textsubscript{2}-4H\textsubscript{2}O, Fe(NO\textsubscript{3})\textsubscript{3}-9H\textsubscript{2}O and Ni(NO\textsubscript{3})\textsubscript{2}-6H\textsubscript{2}O (analytical reagent) were mixed with deionized water to form a mixed solution with the nominal LCFN concentration of 0.6 mol L\textsuperscript{-1}, then glycerine and ethanol were added as a complexing agent and a surfactant, respectively. To fabricate cells in symmetrical configuration for cathodic performance evaluation, the as-synthesized SDC powder was firstly pressed into disk-shaped pellets with subsequent calcination at 1400 °C for 5 h, and then both surfaces of the sintered SDC electrolyte pellets were polished by a sand paper to a thickness of 0.3 mm. For the symmetrical cells with pure LCFN or a LCFN-SDC composite electrode (weight ratio of LCFN to SDC is 30:70) prepared by physical mixing method, the electrode, well dispersed in isopropyl alcohol, was symmetrically sprayed onto both sides of as-prepared SDC electrolyte pellet, and finally calcined at 1000 °C for 2 h in air to obtain the cells. As for the fabrication of symmetrical cell with infiltrated electrode, the details were described in our previous publication.\textsuperscript{18} Briefly, a suspension comprised of SDC and soluble starch (pore former) was sprayed onto both surfaces of SDC disk and subsequently fired at 1300 °C for 5 h in air to create the porous SDC scaffold, then the as-prepared LCFN precursor solution was infiltrated into the scaffold for several repeated times to reach the final loading of ~20 wt.% during the overall infiltration. Finally, the symmetrical cells were calcined at 800 °C for 2 h in air to form desired lattice structure.

Characterization

The phase structure of the prepared samples was determined by X-ray diffraction (XRD, D8 Advance Bruker) with filtered Cu-K\textsubscript{α} radiation. The data was collected in a step-scan mode within a range of 20-90° with intervals of 0.02°. The more detailed structural information was conveyed by Rietveld refinement of the XRD patterns with GSAS-EXPGUI package. The microstructure of LCFN-infiltrated electrodes was characterized by a field emission scanning electron microscope (FE-SEM, JEOL-JEM-6800) and high resolution-transmission electron microscope (HR-TEM, JEOL-JEM-2100). Bright-field scanning transmission electron microscopy (STEM) image was obtained using an FEI Tecnai G2 F20 electron microscope operating at 200 kV. Corresponding energy-dispersive X-ray (EDX) mappings were acquired using an FEI Tecnai G2 F30 S-TWIN field emission transmission electron microscope (FE-TEM) equipped with EDX analyzer operating at 300 kV. Thermal expansion coefficient (TEC) data was collected using a Netzsch DIL 402C/3/G dilatometer in air from 200 to 1000 °C with a heating rate of 5 °C min\textsuperscript{-1}.

Catalytic evaluation

A flow-through type fixed-bed quartz-tube reactor with an inner diameter of 8 mm was employed to assess the catalytic activity for methane oxidation of the fresh LCFN powder and the LCFN powder after the treatment in 10% H\textsubscript{2}-Ar at 700 °C for 10 h. Approximately 0.2 g of catalyst particles with the size of 40-60 mesh were loaded in the middle of the reactor. The reactant,
CH\(_4\)-O\(_2\) gas mixture (2:1, volume ratio), was fed into the reactor with the flow rate of CH\(_4\) at 200 mL min\(^{-1}\) [standard temperature and pressure, STP]. The effluent gases from the bottom of the reactor were introduced into a Varian 3800 gas chromatograph for on-line gas compositional analysis, which was equipped with a Hayesep Q, a Poraplot Q, a 5 Å sieve molecular capillary columns and a thermal conductivity detector (TCD) for the separation and detection of H\(_2\), O\(_2\), CO, CO\(_2\) and CH\(_4\). The catalytic reactions were performed at 600-800 °C. The conversions of CH\(_4\) (C\(_{CH4}\)) and O\(_2\) (C\(_{O2}\)) and the selectivity of CO (S\(_{CO}\)) and CO\(_2\) (S\(_{CO2}\)) were calculated according to Eq. (1), Eq. (2), Eq. (3) and Eq. (4), respectively.

\[
C_{CH4}(\%) = \frac{[CO]+[CO_2]}{[CO]+[CO_2]+[CH_4_{outlet}]} \times 100\% \tag{1}
\]

\[
C_{O2}(\%) = \frac{0.5[CO]+[CO_2]+0.5[H_2O]}{0.5[CO]+[CO_2]+0.5[H_2O]+[O_2_{outlet}]} \times 100\% \tag{2}
\]

\[
S_{CO}(\%) = \frac{[CO]}{[CO]+[CO_2]} \times 100\% \tag{3}
\]

\[
S_{CO2}(\%) = \frac{[CO_2]}{[CO]+[CO_2]} \times 100\% \tag{4}
\]

**Electrochemical test**

The area specific resistance (ASR) of cathode materials was obtained by the electrochemical impedance spectra (EIS) measurement using a Solartron 1287 potentiostat/galvanostat in combination with a Solartron 1260A frequency response analyser. The frequency range of EIS measurement was from 100 kHz to 0.1 Hz with the signal amplitude of 10 mV. The cathode materials with a thin layer of silver as current collectors were tested under open circuit voltage (OCV) condition in air.

For the single cell test, the as-fabricated symmetrical SOFC was sealed onto a quartz tube with silver paste (DAD-87, Shanghai, China). Hydrogen (80 mL min\(^{-1}\) [STP]) or CH\(_4\)-O\(_2\) gas mixture (CH\(_4\): 100 mL min\(^{-1}\) [STP], O\(_2\): 50 mL min\(^{-1}\) [STP]) was fuelled into the anode side, while the cathode side was exposed to ambient air. The I-V polarization was measured for assessing the cell performance using a Keithley 2420 source meter. The impedance of single cell under OCV condition was also tested.

**Results and discussion**

**Basic properties**

LCFN was proved to have high electrical conductivity and good and comparable electrochemical activity for ORR to the typical mixed conducting La\(_{0.6}\)Sr\(_{0.4}\)Co\(_{0.2}\)Fe\(_{0.8}\)O\(_{3-δ}\) (LSCF) perovskite electrode at elevated temperature, but cheaper price of raw materials.\(^{20-22}\) In this study, LCFN was selected as the main component of electrodes for the “symmetrical” SOFCs. The XRD patterns of LCFN, SDC, LCFN-infiltrated SDC (calcined at 800 °C in air) and the calcined LCFN-infiltrated SDC after the treatment at 700 °C in 10% H\(_2\)-Ar atmosphere for 10 h and 95 h are presented in Fig. 1. LCFN was reported to have an orthorhombic perovskite lattice structure with space group Pnma, similar to those of LaFeO\(_3\) and La\(_{0.6}\)Sr\(_{0.4}\)FeO\(_{3-δ}\).\(^{24,25}\) All the diffraction peaks of the as-synthesized LCFN after the calcination at 1000 °C can be well indexed based on the orthorhombic perovskite structure, suggesting the successful formation of a single phase LCFN. For the XRD pattern of the LCFN-infiltrated SDC after the calcination at 800 °C for 2 h in air, all the diffraction peaks can be indexed perfectly based on a physical mixture of a perovskite phase and a fluorite phase. The lattice parameters for both phases were determined based on Rietveld refinement, and they were turned out to be a=5.48(7) Å, b=7.75(3) Å, c=5.51(3) Å for the perovskite phase and a=b=c=5.433(5) Å for the fluorite phase, which matched pretty well with that of LCFN and SDC phases, respectively.\(^{22,26}\) It suggests the reaction between LCFN and porous SDC scaffold was negligible at 800 °C. After the treatment in 10% H\(_2\)-Ar atmosphere at 700 °C for 10 h, or longer (95 h), the diffraction pattern of the sample still resembled that of the fresh one, which were well indexed based on a perovskite phase (a=5.52(2) Å, b=7.80(2) Å, c=5.55(5) Å) and a fluorite phase (a=b=c=5.435(5) Å). It suggests the main perovskite structure was survived after the treatment in reducing atmosphere. As compared to that of the fresh sample, the peak positions of the fluorite phase were almost not changed for the sample after the treatment while the peaks for the perovskite phase shifted to lower angle, indicating the expansion of the perovskite lattice. It suggests certain cation(s) in perovskite phase was/were likely partially reduced. Nevertheless, the successful survival of the main perovskite phase under reducing atmosphere could minimize internal strain during cell operation, thus benefiting the cell operation stability.

**Fig. 1** XRD patterns of (a) LCFN, (b) SDC, (c) LCFN-infiltrated SDC after the calcination in air at 800 °C and (d) calcined LCFN-infiltrated SDC after the further treatment at 700 °C in 10% H\(_2\)-Ar atmosphere for 10 h and (e) 95 h.

The expanded perovskite lattice of LCFN after the treatment in 10% H\(_2\)-Ar atmosphere was further supported by the HR-TEM observation. As shown in Fig. 2, for the fresh LCFN-infiltrated SDC (Fig. 2a), diffraction fringes with the distance of 0.263 nm were observed, which matched well to the fringe
distance of [200] plane of LCFN perovskite phase. Regarding the LCFN-infiltrated SDC after the treatment in 10% H$_2$-Ar atmosphere (Fig. 2b), the similar fringes were detected for selected particles, but the fringe distance slightly increased to 0.267 nm. It further supports that the lattice parameter was slightly increased for the LCFN perovskite phase after the treatment under reducing atmosphere.

![HR-TEM images](image)

**Fig. 2** HR-TEM images of (a) LCFN-infiltrated SDC after the calcination in air at 800 °C and (b) calcined LCFN-infiltrated SDC after the further treatment at 700 °C in 10% H$_2$-Ar atmosphere for 10 h.

Fig. 3 presents the SEM images of the porous SDC scaffold (Fig. 3a), the LCFN-infiltrated SDC composite after the calcination in air at 800 °C (Fig. 3b) and the calcined LCFN-infiltrated SDC composite after the further treatment in 10% H$_2$-Ar at 700 °C for 10 h (Fig. 3c). For the SDC scaffold, SDC grains in the size of 0.2-0.4 µm with polygonal shape were well sintered to form a continuous network with a porous architecture. After the infiltration with LCFN and calcination at 800 °C, the inner walls of the porous SDC scaffold were heavily decorated with spherical LCFN nanoparticles with a homogeneous particle size of around 80 nm. Such nanoparticles were well connected to form a continuous network, which may significantly increase the electrical conductivity of the electrode for the high conductivity of the LCFN phase. The calcined LCFN-infiltrated SDC was then subjected for the further treatment under reducing atmosphere. The overall electrode microstructure did not change significantly after the treatment. It further supported that the main perovskite structure was not collapsed under the reducing atmosphere. The main difference in morphology to that of the untreated electrode is that a lot of small particles in spherical shape with the size of approximately 10 nm appeared, which distributed homogeneously over the surface of LCFN nanoparticles. It suggests some element was likely segregated from the perovskite phase as nanoparticles to decorate the perovskite oxide surface. Previously, it was demonstrated that some elements could be segregated from perovskite oxide lattice as nanoparticles in metallic phase to decorate the surface of main perovskite oxide by chemical or electrochemical reduction. Due to the higher reducibility of nickel cation than iron cation, it was likely the formed nanoparticles are the metallic nickel phase.

![SEM images](image)

**Fig. 3** SEM images of (a) porous SDC scaffold, (b) LCFN-infiltrated SDC after the calcination in air at 800 °C and (c) calcined LCFN-infiltrated SDC after the further treatment in 10% H$_2$-Ar at 700 °C for 10 h.

To further analyse the composition of the electrode after the treatment in H$_2$ atmosphere, it was subjected for STEM analysis with the image shown in Fig. 4. The STEM image clearly shows that the large SDC grains were surrounded by small particles. The EDX analysis of the surrounding particles demonstrated the compositions of La, Ca, Fe and Ni, indicating the successful impregnation of the LCFN phase into the SDC scaffold. As compared to the other elements, the nickel showed...
less homogeneous distribution than the other elements. It implies that the nickel element was extracted from the perovskite lattice under the reducing atmosphere.

Fig. 4 STEM image and EDX elemental distribution of La, Ca, Fe, Ni and O in the LCFN-infiltrated SDC electrode after the treatment in 10% H₂-Ar at 700 °C for 10 h.

To ensure a high operational stability of SOFC, the cell components should have good thermo-mechanical compatibility. The mismatch in TECs between electrode and electrolyte layers could create large internal strain during the heating and cooling processes, which could induce the delamination of electrode from electrolyte layer, a main cause of the degradation in cell performance. Fig. 5 shows the thermal expansion curves of pure LCFN and LCFN-infiltrated SDC samples under different atmospheres. For the pure LCFN in air, the average TEC in the temperature range of 200-900 °C was calculated to be 23.0×10⁻⁶ K⁻¹ according to the dΔL/L₀ vs. temperature curve, and the TEC even reached higher than 38.4×10⁻⁶ K⁻¹ at around 550 °C (Fig. 5a). As to the LCFN-
infiltrated SDC composite at the same atmosphere, the average TEC was $11.5 \times 10^{-6}$ K$^{-1}$ between 200 and 900 °C (Fig. 5b), which was comparable to that of pure SDC (a TEC of $12.3 \times 10^{-6}$ K$^{-1}$ was reported$^{29}$, agreeing well with the fact that the TEC of infiltrated electrode was mainly determined by the porous scaffold.$^{30}$ Under reducing atmosphere, the average TEC of LCFN-infiltrated SDC was $16.4 \times 10^{-6}$ K$^{-1}$, which was a little bit higher than that of the sample tested in air. It is probable that partial nickel reduced from LCFN-infiltrated SDC affected the TEC. However, the TEC of $16.4 \times 10^{-6}$ K$^{-1}$ for reduced LCFN-infiltrated SDC was still comparable to that of SDC. The similar TECs of LCFN-infiltrated SDC to SDC provided good thermo-mechanical compatibility between the electrodes and electrolyte, ensuring a better operational stability in the real SOFC.

Electrocatalytic activity for ORR

In literature, single phase LCFN was typically used as the cathode of SOFCs.$^{20-23}$ It is well known that the electrochemical performance of a cathode is also highly dependent on the electrolyte that is deposited on.$^{22,31}$ In this study, the ASRs of the LCFN-infiltrated SDC electrode on the SDC electrolyte in air atmosphere were measured based on symmetrical configuration with the typical EIS curves at 600 °C shown in Fig. 6, while the ASRs of electrode at various temperatures were listed in Table 1. For comparison, the ASRs of the single phase LCFN electrode and a conventional LCFN-SDC composite electrode (weight ratio of LCFN to SDC is 30:70) prepared by physical mixing method were also measured and presented.

By applying the single phase LCFN as the electrode, ASRs of 11.70, 2.93, 0.89, 0.32 and 0.14 Ω cm$^2$ were achieved at 550, 600, 650, 700 and 750 °C, respectively, which were much smaller than the reported ASR of LCFN electrode on the YSZ electrolyte, for example, 85.87 Ω cm$^2$ even at 850 °C.$^{20}$ It further supported that the electrolyte had an impact on the electrochemical performance of the electrode material. For the conventional physically mixed LCFN-SDC composite electrode, ASRs of 6.72, 2.54, 1.20, 0.65 and 0.37 Ω cm$^2$ were obtained at 550, 600, 650, 700 and 750 °C, respectively, which are modestly better than that of single phase LCFN electrode. Such improvement may be explained by the increased apparent oxygen-ion conductivity of the electrode from the incorporation of SDC phase, resulting in increased electrochemically active sites for ORR. For the nano LCFN-infiltrated SDC electrode, ASRs of 0.36, 0.12, 0.053, 0.021 and 0.009 Ω cm$^2$ were achieved at 550, 600, 650, 700 and 750 °C, respectively. It indicates that the infiltrated LCFN-SDC composite electrode had the best electrochemical performance for ORR among the various LCFN-based electrodes. Such improvement can be explained by the specific electrode architecture, which provided the optimal charge transfer path. The continuous SDC scaffold provided a fast oxygen ion diffusion path to the electrolyte, while LCFN had much higher surface exchange kinetics than SDC, thus the decoration of SDC surface with LCFN effectively improved the activity for surface oxygen dissociation and surface diffusion, thus successfully improving the overall surface kinetics. In addition, it was reported that the smaller electrode particle size benefits the ORR process,$^{32}$ hence, the nano LCFN particle as obtained by the infiltration process also contributed to the outstanding performance of the current LCFN-SDC.

Activity for methane oxidation

It was reported that La$_{1-x}$Ca$_x$FeO$_{3+δ}$ perovskite oxide has high catalytic activity for methane combustion,$^{33}$ while nickel is a

good catalyst for methane partial oxidation and electrocatalytic oxidation of H\textsubscript{2} to H\textsubscript{2}O.\textsuperscript{6} By applying methane as a fuel, the indirect electro-catalytic oxidation pathway, i.e., the first internal reforming of methane to hydrogen, and then the electro-oxidation of hydrogen to generate electricity is easier to achieve a higher power output than direct electro-oxidation of methane since the electrochemical oxidation rate of hydrogen is much faster than methane over conventional anode catalysts.

"Symmetrical" SOFC performance

Based on above analysis, LCFN could be a good candidate for both the anode and the cathode of SOFCs. An SDC electrolyte-supported “symmetrical” SOFC with nano LCFN-infiltrated porous SDC scaffold as electrodes was then fabricated and tested. The electrolyte and electrodes had a thickness of around 300 and 20 µm, respectively. The cell was first subjected for operation on hydrogen fuel. As shown in Fig. 8, OCVs of 0.9-0.8 V were obtained between 600 and 800 °C, steady decrease with the operation temperature. The relatively low OCV can be explained by the partial electronic conductivity of SDC at temperature higher than 600 °C. Anyway, the OCVs were in well agreement with the literature results for cell with SDC electrolyte and Ni-SDC anode.\textsuperscript{35} It suggests the nano LCFN decorated SDC electrode performed soundly as an anode for SOFCs. The near linear response of cell voltage to polarization current at different temperatures, even at high current density, indicates the electrodes were sufficiently porous to avoid concentration polarization even at high temperature and large polarization current density conditions. Peak power densities (PPDs) of 196, 276, 362, 444 and 507 mW cm\textsuperscript{-2} were achieved at 600, 650, 700, 750 and 800 °C, respectively. Such results are highly attractive by considering large thickness of the electrolyte membrane (0.3 mm).

Fig. 7 The catalytic activity of fresh LCFN and LCFN after the treatment in 10% H\textsubscript{2}-Ar at 700 °C for 10 h for methane oxidation (CH\textsubscript{4}:O\textsubscript{2} = 2:1) between 600 and 800 °C: (a) CH\textsubscript{4} and O\textsubscript{2} conversions, (b) CO\textsubscript{2} and CO selectivity.

![Graph](image)

Fig. 8 I-V and I-P curves of the cell with the configuration of LCFN-infiltrated SDC|SDC|LCFN-infiltrated SDC operating on hydrogen.
To get information about the contribution of resistance from different cell components, the impedance of the cell under OCV condition was also measured with the typical spectra shown in Fig. 9. Although the impedance of the single cell is fairly complicated, the intercept of the impedance arc at the low frequency side with the real axis usually embodies the overall cell resistance ($R$) while the intercept of the impedance arc at the high frequency section with the real axis represents the cell ohmic resistance ($R_o$). The difference between two intercepts is a sum of the polarization resistance ($R_p$) from both the anode and cathode. From Fig. 9, it is clear that the main cell resistance was contributed from the electrolyte ohmic resistance ($R_o$), in particular at higher temperature. Table 2 listed the ohmic (or polarization) resistances of electrolyte and electrode, and the overall percentage of electrolyte resistance to the total resistance at different temperatures. The electrolyte ohmic resistance ($R_o$) accounted for 95.3% of the total cell resistance at 800 °C, while it still accounted for 82.9% at 600 °C. Thus, the obvious improvement in cell performance is expected if the electrolyte thickness could be further reduced, or the adoption of alternative electrolyte material with higher conductivity, such as the newly discovered superior oxide-ion conductor Sr$_3$Na$_{2.5}$Si$_3$O$_9$ (x=0.45).

As demonstrated previously that the reduced LCFN electrode showed improved activity for methane deep oxidation and reforming reaction. It implies the nano LCFN-infiltrated SDC electrode could also perform well for operating on methane-based fuel. Hence, the “symmetrical” SOFC was then tested using the gas mixture of methane-oxygen as the fuel. As shown in Fig. 10, PPDs of 160, 220, 280 and 350 mW cm$^{-2}$ was achieved at 650, 700, 750 and 800 °C, respectively. Although the results were little worse than that operating on hydrogen, they are still highly attractive by considering the symmetrical cell and thick electrolyte membrane configuration, and methane as the direct fuel without pre-reforming.

![Fig. 10 I-V and I-P curves of the cell with the configuration of LCFN-infiltrated SDC|SDC|LCFN-infiltrated SDC operating on CH$_4$-O$_2$ gas mixture at the molar ratio of 2:1.](image)
Finally, the thermal cycling test was conducted for investigating the thermo-mechanical stability of the “symmetrical” SOFC with LCFN-infiltrated SDC electrode. The cell was heated up and cooled down between 200 and 700 °C for ten times. As shown in Fig. 13, the thermal cycling process has little effect on the cell performance, for example, the OCV and PPD of the cell was kept at around 0.82 V and 370 mW cm\(^{-2}\) during the 10 cycling tests, indicating that the symmetrical cell with LCFN-SDC electrode possesses excellent thermo-mechanical stability.

**Fig. 13** The thermal cycling stability of the symmetrical SOFC with LCFN-infiltrated SDC electrode.

### Conclusions

We have demonstrated that the nano LCFN-infiltrated porous SDC composite is a promising electrode material for both anode and cathode of “symmetrical” SOFCs due to both the excellent anode and cathode performance. As for the anode, the nickel particles in the LCFN oxide were partially segregated from perovskite lattice under the reducing atmosphere that decorated the surface of LCFN, delivering the high catalytic activity for the chemical and electrochemical oxidation of fuels. The main perovskite structure of LCFN did not change which ensured the good mechanic-chemical compatibility of the cell components. As for the cathode, the LCFN-infiltrated SDC electrode exhibited excellent ORR activity with an ASR of 0.12 Ω cm\(^{2}\) at 600 °C in air. The peak power densities of the thick electrolyte-supported SOFC with LCFN-SDC electrode reached 510 and 350 mW cm\(^{-2}\) at 800 °C operating on hydrogen and CH\(_4\)-O\(_2\) fuels, respectively, which are highly attractive by considering the use of thick electrolyte. The electrode microstructure has hardly changed after the fuel cell test under various conditions. The cell was operated stably for over 140 h. A good thermo-mechanical stability of the cell was also demonstrated. Our study opens up a new avenue for promoting the practical application of SOFC technology.
