This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Highly sensitive and selective fluorescent probe for Ag\(^+\) based on a Eu\(^{3+}\) post-functionalized metal-organic framework in aqueous media

Ji-Na Hao, Bing Yan*

A 3D microporous compound Al(OH)(H\(_2\)btec)·H\(_2\)O (MIL-121) containing uncoordinated carbonyl groups is chosen as a parent metal-organic framework (MOF). And because the uncoordinated carbonyl groups in the channels could act as postsynthetic modification sites, a robust luminescent lanthanide-based MOF can be constructed by encapsulating Eu\(^{3+}\) cations into the pores of MIL-121. The intense luminescence of Eu\(^{3+}\) incorporated MIL-121 products demonstrates that the framework with rigid, permanently porous structure and non-coordinated carboxyl group is an efficient scaffold for hosting and sensitizing Eu\(^{3+}\) cations. More significantly, the robust Eu\(^{3+}\)@MIL-121 shows excellent selectivity, fast detection time (< 5 min), and high sensitivity (detection limit, 0.1 µM) for Ag\(^+\) ions in aqueous solution through greatly enhancing of the Eu\(^{3+}\)-luminescence. This is a rare example to detect Ag\(^+\) in aqueous solutions based on a luminescent lanthanide MOFs.

Introduction

As heavy metal ions can cause severe risks for the environment and human health, metal ion sensing and detection are significant in life sciences, environmental science, medicine science and nuclear industry.\(^1\) Due to human activities, the Ag\(^+\) content in the vicinities of sewage outfalls, electroplating plants, mine waste sites, and silver-iodide seeded areas has increased. Ag\(^+\) can accumulate in the human body through the food chain and drinking water. What’s more, silver ions are known to bind with various metabolites, including amine, imidazole, and carboxyl groups, and inactivate sulfhydryl enzymes.\(^2\) Therefore, the deficiency of Ag\(^+\) will result in a number of pathological disorders, such as cell toxicity and organ failure. Thus, it is of considerable importance for the environment and human health to establish an Ag\(^+\) detection method with high sensitivity and high selectivity. At present, among the detection methods, fluorometric methods have gained much attention due to their distinct advantages, i.e. facilitated detection and manipulation and high sensitivity.\(^3\) Meanwhile, there is an urgent need to develop fluorescent chemosensors that are capable of determining of silver ions in various media.

Metal-organic frameworks (MOFs), a class of crystalline hybrid inorganic-organic materials constructed from organic linker molecules and metal ions, have shown a variety of potential applications, such as gas adsorption,\(^4\) separations,\(^5\) catalysis,\(^6\) and sensing.\(^7\) Particularly, among the diverse MOFs, those displaying interesting luminescence properties are receiving increasing attentions because they are useful for the development of sensing technologies.\(^8\) Of particular interest are lanthanide metal-organic frameworks (Ln-MOFs) since their fascinating optical properties, such as large Stokes’ shifts, high color purity, and relatively long luminescence lifetimes, make them especially attractive for sensing applications.\(^9\) In the past decade, studies on luminescent Ln-MOFs for sensing metal ions or organic molecules have been developed significantly. Such progress in the sensing application of Ln-MOFs guides and inspires us to rationally design and synthesize Ln-MOFs for host-guest recognition and to tune their functional properties. However, rational design and preparation of the desired Ln-MOFs still remain a great challenge,\(^11\) which is obviously because Ln\(^{3+}\) ions have higher coordination numbers and more variable nature of the Ln coordination sphere, and the open lanthanide sites formed in situ during activation/de-solvation tend to bind back with the oxygen/nitrogen donors from the organic linker to form a condensed structure. Nonetheless, the above problems did not deter researchers from exploring the luminescent lanthanide-containing MOFs. Recently, an alternative strategy to construct lanthanide-based MOFs is by postsynthetic method (PSM)\(^12\) whose chemical modification can be performed on the fabricated material rather than on the molecule precursors. This provides a new choice for building lanthanide MOFs. An increasing number of Ln-doped MOFs constructed by PSM have been made in recent years. This is the case for bio-MOF-1,\(^13\) Zn(II)-MOF,\(^14\) COMOC-4,\(^15\) MOF-COOH,\(^16\) Al-MIL-53-COOH.\(^17\) Stimulated by this, herein a lanthanide doped MOF was prepared by PSM and developed as the luminescent sensor.

In this context, as a MIL-53(Al) analogue, MIL-121 (aluminium pyromellitate or Al(OH)(H\(_2\)btec)·H\(_2\)O, H\(_2\)btec= pyromellitic acid), which contains two extra free carboxylic acid functions per ligand with interesting porosity,\(^18\) was chosen as a parent framework. The reactive nature of the uncoordinated carbonyl groups in the MIL-53(Al) analogue, MIL-121 (aluminium pyromellitate or Al(OH)(H\(_2\)btec)·H\(_2\)O, H\(_2\)btec= pyromellitic acid), which contains two extra free carboxylic acid functions per ligand with interesting porosity,\(^18\) was chosen as a parent framework. The reactive nature of the uncoordinated carbonyl...
groups as well as the high thermal and chemical stabilities of MIL-121 makes it a good candidate to bind Ln³⁺ cations. As a result, a new class of lanthanide luminescent MOFs was generated by encapsulating Eu³⁺ into MIL-121 crystals. The high luminescence of Eu³⁺ incorporated MIL-121 products (Eu³⁺@MIL-121) demonstrated that the framework with rigid, permanently porous structure and non-coordinated carboxyl was an efficient scaffold for hosting and sensitizing Eu³⁺ cations. More significantly, the Eu³⁺@MIL-121 was developed as highly selective and sensitive fluorescence probe targeting Ag⁺ ions in aqueous solutions, which could be proved by the fact that Eu³⁺@MIL-121 exhibits an impressive enhancing phenomenon upon the typical Eu-luminescence in the case of Ag⁺ ions. Although considerable efforts have been devoted for the development of fluorescent chemosensors specific for cations, there are only a handful of reports on molecular probes for Ag⁺ ions and, to the best of our knowledge, there are fewer reports about the Ag⁺ optical sensor based on the lanthanide luminescence MOFs.

Experimental section

Materials and instrumentation. The salts of LnCl₃·6H₂O were prepared by dissolving the corresponding lanthanide oxide compounds in excess hydrochloric acid (37 %) followed by evaporation and crystallization. Pyromellitic acid (98 %) was purchased from Adamas and used directly without further purification. All the other starting materials and reagents were all AR and used as purchased. The crystalline phases of the products were determined by X-ray powder diffraction patterns (XRD) using a Rigaku D/max-Rb diffractometer equipped with Cu anode. Fourier transform infrared spectra (FTIR) were recorded with a Nexus 912 AO446 infrared spectrum radiometer within the wavenumber range 4000 – 400 cm⁻¹ using the KBr pressed technique. Excitation and emission spectra of the solid samples were obtained on Edinburgh FLS920 spectrophotometer. Thermogravimetric analysis (TG) was measured using a Netzsch STA 449C system at a heating rate of 5 K min⁻¹ under the nitrogen protection. Luminescence lifetime measurements were carried out on an Edinburgh FLS920 phosphorimeter using a 450 W xenon lamp as excitation source. The outer absolute luminescent quantum efficiency was determined using an integrating sphere (150 mm diameter, BaSO₄ coating) from an Edinburgh FLS920 phosphorimeter. The quantum yield can be defined as the integrated intensity of the luminescence signal divided by the integrated intensity of the absorption signal. The absorption intensity was calculated by subtracting the integrated intensity of the light source with a blank sample in the integrating sphere.

Synthetic Procedures.

Typical synthesis of MIL-121. The compound MIL-121 was prepared by hydrothermal reaction of Al(NO₃)₃·9H₂O (1.2 g, 3.2 mmol) and pyromellitic acid (noted H₂btec, 0.4 g, 1.6 mmol) in 5 mL of deionized water at 210 °C for 24 hrs. The starting pH value was 1.41 and 0.26 at the end of the reaction. It resulted in a white powdered product, which was filtered off, washed with deionized water, and dried at 80 °C for 12 hrs in vacuum. To remove the organic species encapsulated within the pores of the open framework, the samples were activated by Soxhlet extraction in methanol for 24 h and then dried at 80 °C under vacuum overnight.

Eu³⁺@MIL-121 Preparation. Eu³⁺@MIL-121 was prepared by stirring the mixture of 100 mg of MIL-121 and 2 mmol EuCl₃·6H₂O in 10 mL ethanol at 60 °C for 48 hrs. The solid was then separated from the mixed dispersion by centrifugation, and extensively washed with ethanol to remove residual Eu³⁺ cations on the surface. Subsequently, the resulted white powder was dried under vacuum at 80 °C for 12 hrs.

Luminescence-sensing experiment. 3 mg of Eu³⁺@MIL-121 was simply immersed in the aqueous solutions of M(NO₃)₃·6H₂O (10⁻² mol L⁻¹, 3 mL) at room temperature (M³⁺ = Na⁺, K⁺, Mg²⁺, Ca²⁺, Al³⁺, Cr³⁺, Mn²⁺, Fe²⁺, Co²⁺, Ni²⁺, Cu²⁺, Ag⁺, Zn²⁺, Cd²⁺, Hg²⁺, Pb²⁺). The mixtures were then sonicated for 30 min to form the metal ion-incorporated suspension for luminescent measurements.

Results and discussion

Characterization of Eu³⁺@MIL-121

[Graph showing PXRD of MIL-121 (black line) and Eu³⁺@MIL-121 (blue line).]

The compound MIL-121 was solvothermally synthesized by mixing aluminum nitrate, pyromellitic acid, and H₂O. The powder XRD pattern of the resulted product (Figure 1) agrees well with the literature value. The MIL-121 is a three-dimensional (3D) framework containing one-dimensional (1D) channels delimited by infinite trans-connected aluminum-centered octahedral AlO₄(OH)₂ linked through the pyromellitate ligand. Here only two carboxylate arms of the pyromellitate play the role of linker while the two others remain non-bonded in their protonated form. The non-coordinated –COOH groups point toward the channels to get them an open form configuration. The free –COOH can be found in the IR spectrum of MIL-121 (Figure S1). The bands at 3015, 2659, and 2528 cm⁻¹ are assigned to the νC=O-H modes of free –COOH functions. In the range of 1600 – 1800 cm⁻¹, we can differentiate the non-bonded –COOH groups and those connected to aluminum. The peak at 1600 cm⁻¹ corresponds to the stretching vibration of carboxylate coordinated to the cation, whereas the vibrations at 1737 and 1716 cm⁻¹ are
assigned to non-coordinated functions. This structure was postfunctionalized with a solution of europium (III) chloride in ethanol. The Eu\(^{3+}\)@MIL-121 could be formed by the coordination interactions between the free –COOH of MIL-121 and the Eu\(^{3+}\) ions. As shown in Figure S2, the absorption band of MIL-121 shows a significant red-shift (~13 nm) after binding to Eu\(^{3+}\) ions. This indicates the formation of coordination bonds between the Eu\(^{3+}\) ions and free –COOH of MIL-121. After encapsulating Eu\(^{3+}\) cations into MIL-121, the material retains its crystallinity well as evidenced by the powder XRD pattern (Figure 1), and the same XRD pattern of MIL-121 and Eu\(^{3+}\)@MIL-121 is demonstrated Eu\(^{3+}\) ions incorporating Eu\(^{3+}\) and free –COOH of MIL-121.

The as-prepared Eu\(^{3+}\)@MIL-121 was also monitored by TG analysis and N\(_2\) adsorption-desorption. The TG curve of the MIL-121 in Figure 2a exhibits two events. The first one is the elimination of trapped solvent in the pores (~1.5 wt %). The MIL-121 material is thermally stable up to 400 °C, above which the total decomposition of the organic ligand (calc.68.6 %) occurs in two steps. The first weight loss of 10 wt % between 400 and 430 °C is due to the departure of two CO\(_2\) molecules from the non-coordinating –COOH groups (calc. 8 %). The second step between 430--560 °C is indicative of the decomposition of the ligand (obs. 53 wt %; calc. 60 %). As for Eu\(^{3+}\)@MIL-121, the incorporation of Eu\(^{3+}\) cations does not influence the thermostability of the framework. The TGA data demonstrates Eu\(^{3+}\)@MIL-121 is thermally stable to 400 °C, implying the good thermal stability of Eu\(^{3+}\)@MIL-121. The MIL-121 particles maintain their microporosity after guest removal, as demonstrated by N\(_2\) sorption isotherm (Figure 2b) showing the BET surface areas of 173 m\(^2\) g\(^{-1}\). The value, which is in reasonable agreement with the result reported by Christophe Volkringer et al., is much lower than the ones determined for the parent compound MIL-53 (BET: 1140 m\(^2\) g\(^{-1}\)). The decrease of the BET surface area could be attributed to the steric hindrance of the free non-coordinated carboxyl groups within the channels, which reduce the access of N\(_2\) molecules. After incorporating Eu\(^{3+}\) cations, the Eu\(^{3+}\)@MIL-121 shows a reduced BET surface area of 102 m\(^2\) g\(^{-1}\).

The room-temperature solid-state photoluminescence emission spectra of the MIL-121 and Eu\(^{3+}\)@MIL-121 are shown in Figure S3 and Figure 3, respectively. The MIL-121 displays weak luminescence with a wide band centered around 340 (360) nm when excited by 305 (315) nm. After post-synthetic functionalization of Eu\(^{3+}\), the ligand-centered (LC) emissions are significantly suppressed. Instead, a series of sharp peaks characteristic of Eu\(^{3+}\) luminescence appear at 579, 592, 614, 650, and 695 nm, corresponding to the \(^5D_{0} \rightarrow ^7F_{J}\) (J = 0–4) transitions, respectively. The 614 nm emission has maximum intensity, demonstrating that the incorporated Eu\(^{3+}\) ions occupy sites without an inversion center and have low crystal field symmetry. This is further confirmed by the presence of 579 nm emission, because this peak only occurs when Eu\(^{3+}\) symmetry is low. The diminished LC emission in Eu\(^{3+}\)@MIL-121 and the strong red luminescence under UV-light irradiation (inset of Figure 3) indicate that antenna effect occurs, that is, energy migration takes place upon ligand absorption, followed by intersystem crossing S\(_1\)→T\(_1\) and antenna T\(_1\)→f transfer, and then generating f-f emissions of Eu\(^{3+}\) ion. Moreover, Eu\(^{3+}\)@MIL-121 exhibits reasonable long lifetimes (0.31 ms) and quantum yields (6 %), which are attributed to the effective energy transfer from the ligand to the Eu\(^{3+}\).

The luminescence properties of Eu\(^{3+}\)@MIL-121 in aqueous solution have also been investigated in Figure S4. Compared to the solid-state PL spectra of Eu\(^{3+}\)@MIL-121, the ligand-centered emission of Eu\(^{3+}\)@MIL-121 in aqueous solution cannot be suppressed by the luminescence of Eu\(^{3+}\) because of the quenching effect of water molecules. However, the Eu\(^{3+}\)@MIL-121 in aqueous solution exhibits excellent fluorescence stability at room temperature. The luminescence intensity of Eu\(^{3+}\)@MIL-121 suspension has no obvious change for at least 10 days’ storage (Figure S5), implying that Eu\(^{3+}\)@MIL-121 possesses great potential as a fluorescence material for sensing in aqueous solution.

Sensing of Ag\(^{+}\) cations

To examine the potential of Eu\(^{3+}\)@MIL-121 for sensing of metal ions, the as-synthesized samples were immersed in the aqueous solutions containing different metal ions (Na\(^{+}\), K\(^{+}\), Mg\(^{2+}\), Ca\(^{2+}\), Al\(^{3+}\), Cr\(^{3+}\), Mn\(^{2+}\), Fe\(^{3+}\), Co\(^{2+}\), Ni\(^{2+}\), Cu\(^{2+}\), Ag\(^{+}\), Zn\(^{2+}\), Cd\(^{2+}\), Hg\(^{2+}\), Pb\(^{2+}\)) to form the metal ion incorporated MOF suspension for luminescent studies. As shown in Figure 4, various metal ions display markedly different effects on the luminescence of Eu\(^{3+}\) ions. For example, the luminescence intensity at 614 nm is decreased when Zn\(^{2+}\), Hg\(^{2+}\), Mn\(^{2+}\), Pb\(^{2+}\), Ni\(^{2+}\), Co\(^{2+}\), Al\(^{3+}\), Cu\(^{2+}\), Cr\(^{3+}\), or Fe\(^{3+}\)
the metal ions (K⁺, Ca²⁺, Na⁺, Cd²⁺, Mg²⁺) tested did not cause any significant change to the intensity of the luminescence. As a result, only the sample immersed in aqueous solution containing Ag⁺ provided direct information of visibly red luminescent color with naked eyes when irradiated under UV light of 254 nm, as shown in the inset of Figure 4b. These results indicate that Eu³⁺@MIL-121 can selectively sense Ag⁺ ions through fluorescence enhancement, which was quite rare in the previous reports on luminescent MOFs. In addition, the enhancement effect of Ag⁺ on the luminescence of Eu³⁺@MIL-121 was evaluated by the fluorescence decay time of Eu³⁺. Figure 5 shows that the emission lifetimes of Eu³⁺@MIL-121 significantly increase from 0.21 ms to 0.98 ms in the presence of Ag⁺. This observation is in good agreement with the results of PL spectra. The influence of other metal ions on the lifetime of Eu³⁺ was also determined. The lifetime data shown in Table S1 also agree with the responses of luminescence of Eu³⁺@MIL-121 towards various metal cations.

To investigate the time-response characteristic of the Eu³⁺@MIL-121 sensor toward Ag⁺, the fluorescence intensity of Eu³⁺@MIL-121 at 614 nm (λex = 315 nm) was measured as a function of immersion time. Figure 6 shows the fluorescence intensity as a function of time for different immersion times of Ag⁺. It can be seen that the fluorescence intensity gradually increases with the immersion time, indicating that Ag⁺ can be detected by Eu³⁺@MIL-121. The inset in Figure 6a shows the linear relationship of fluorescence intensity at 614 nm as a function of interaction time, with a correlation coefficient R = 0.9977.
function of immersion time in aqueous solution of 10 mM Ag⁺. Figure 6 shows the time-response PL spectra (a) and curves (b) within 4h, respectively. As depicted in Figure 6 (a) and (b), with the interaction time between Ag⁺ and Eu³⁺@MIL-121 increasing, the PL intensity of the sample was continuously enhanced. When the immersing time is 24 hrs, the luminescence intensity reached a constant value (Figure S6). From the inset of Figure 6a, we can see that when the Eu³⁺@MIL-121 was treated with Ag⁺ solution for 5 min, the highest peak at 614 nm was increased to more than 2.0 times as intense as the corresponding band of the original one. This indicates Ag⁺-induced fluorescence enhancement reaction is fast.

Figure 7 Fluorescence intensity of Eu³⁺@MIL-121 at 612 nm as a function of Ag⁺ concentration in aqueous solution (λex=315nm). Insert: linear relationship of Eu³⁺@MIL-121 enhanced by Ag⁺ aqueous solution.

For better understanding the response of fluorescence of Eu³⁺@MIL-121 to Ag⁺, concentration-dependent luminescence measurements were also carried out. The Eu³⁺@MIL-121 solid samples were immersed in different concentrations of Ag⁺ for 24 h, and then their luminescence spectra were recorded. As demonstrated in Figure 7, the emission intensity of Eu³⁺@MIL-121 suspension enhanced accordingly with the increase of Ag⁺ concentration from 0 to 100 µM. In other words, the fluorescence response of Eu³⁺@MIL-121 toward Ag⁺ was linear when measured in the range 0 – 100 µM of Ag⁺ (inset of Figure 7). From these data, we have estimated the detection limit of Eu³⁺@MIL-121 to be 0.1 µM. This detection limit met a 50 µg L⁻² (about 0.46 µM) standard of U.S. Environmental Protection Agency (EPA) for a maximum allowable level of Ag⁺ in drinking water.²¹

In order to make a further understanding of the phenomenon that Ag⁺-enhanced the luminescence of Eu³⁺, the powder XRD was employed to study on the structural data of the Eu³⁺@MIL-121 and Ag⁺/Eu³⁺@MIL-121 (Figure 8). The powder XRD patterns of the Ag⁺/Eu³⁺@MIL-121 are similar to that of Eu³⁺@MIL-121, suggesting that the basic frameworks remain unchanged in the compounds, namely, the presence of Ag⁺ did not affect the structure of Eu³⁺@MIL-121. It is well-known that the luminescent intensity of the Ln³⁺ relies on the efficiency of the energy transfer from the ligand to Ln³⁺ center.²² If there is efficient intramolecular energy transfer, Ln³⁺ can be excited more effectively, producing an enhanced fluorescence of lanthanides. It has been reported that the energy transfer process is more effective with the addition of certain transition metal ions.²³ Herein, we attribute the enhancement of luminescent intensity of Eu³⁺@MIL-121 to that Ag⁺ cause more efficient energy transfer from ligands to Eu³⁺ ions, as depicted in Scheme 1. This is consistent with the results of suspension-state PL spectra of Eu³⁺@MIL-121 in the absence and presence of Ag⁺. Figure S7 shows their excitation spectra monitored by emission wavelength at 614 nm, both of them show the similar broad band centered at 315 nm which can be ascribed to the π–π* electron transitions of the ligands. When excited at 315 nm, the PL emission spectrum (Figure 9a) of the Eu³⁺@MIL-121 suspension features in observation of two kinds of luminescence. One is the characteristic Eu²⁺ sharp emissions and the other is the broad ligand-centered

![Figure 8 PXRD patterns of the Eu³⁺@MIL-121 after immersing in aqueous solution with Ag⁺ ions.](image)

![Figure 9 The excitation spectra of Eu³⁺@MIL-121 in the absence (black) and presence of Ag⁺ (red) in aqueous solution. The insert is the corresponding photographs under UV-light irradiation at 254 nm.](image)
emission (370 nm). The absence of the typical intra-configurational transitions of Eu$^{3+}$ in the excitation spectra and the characteristic emissions of Eu$^{3+}$ in the emission spectra corroborate an energy transfer from the organic ligand to the metal ions, but the intense LC emission in the emission spectra indicates that the energy transfer may not of good efficiency (the intensity ratio $I_{	ext{Eu}}(614)/I_{\text{ligand}}$ of the $^5D_{0,1} \rightarrow F_2$ line at 614 nm to that of LC emission at 365 nm is 1.4). By contrast, the basically diminished LC emission and the enhanced Eu$^{3+}$-luminescence of Eu$^{3+}$@MIL-121 in the presence of Ag$^+$ (Figure 9b) indicate the energy transfer is more effective ($I_{	ext{Eu}}(614)/I_{\text{ligand}} = 12$). As a result, with the addition of Ag$^+$, the fluorescence color of Eu$^{3+}$@MIL-121 suspension changed from colorless to intense red under a 254 nm UV lamp (inset in Figure 9), which can be easily distinguished by the naked eyes.

Scheme 1 Illustration of the fluorescence enhancement of Eu$^{3+}$@MIL-121 by Ag$^+$. As luminescent probes, the Eu$^{3+}$@MIL-121 not only have highly selective and sensitive characteristics but also possesses a stable and robust structure (its frameworks still keeps unchanged in aqueous solution containing various mental ions, shown in Figure S8). It is helpful to extend the potential application of Ln-MOFs to the environment areas.

Conclusions

In summary, a new class of lanthanide luminescent MOFs was generated by postsynthetic modification of encapsulating Eu$^{3+}$ into the pores of MIL-121. The framework with rigid, permanently porous structure and non-coordinated carboxyl could serve as an efficient scaffold for hosting and sensitizing Eu$^{3+}$ cations, demonstrated by the strong luminescence with addition of reasonable lifetimes and quantum yields of Eu$^{3+}$@MIL-121 products. More significantly, the Eu$^{3+}$@MIL-121 was performs as a rare example of highly selective and sensitive fluorescence probe for Ag$^+$ ions in aqueous solutions, which could be proved by the fact that Eu$^{3+}$@MIL-121 exhibits an impressive enhancing phenomenon upon the typical Eu-luminescence in the case of Ag$^+$ ions. As a sensing material for Ag$^+$, Eu$^{3+}$@MIL-121 has features including simple preparation procedure, robust rigid structure, excellent selectivity, fast detection time (< 5 min), and high sensitivity with a detection limit of 0.1 µM. Although Ag$^+$-induced luminescence enhancement of Eu$^{3+}$@MIL-121 was shown, the principle of Ag$^+$-enhanced fluorescence might be used to improve the fluorescence of other LnMOFs. The related studies are currently under way.
