Hierarchical nanosheet-based NiMoO₄ nanotubes: Synthesis and high supercapacitor performance†

Zhuoxun Yin,‡ Shen Zhang,‡ Yujin Chen,§ Peng Gao,∥ Chunling Zhu,¶ Piaoping Yang∥ and Lihong Qi‡

1 Introduction

Metal (Fe, Co, Ni, and Mn) molybdates, important families of inorganic materials, have promising applications in many fields, such as catalysts,¹⁻¹¹ humidity and gas sensors,¹²⁻¹⁵ energy storage devices,¹⁶⁻²³ and so forth. In order to improve their physicochemical properties, researchers have developed several approaches in the past few years, including solid-state reactions, coprecipitation, hydrothermal and sol–gel methods, to fabricate various metal molybdate nanostructures. As a result, metal molybdate nanoparticles,⁴ nanorods,¹²,¹³,¹⁵,¹⁸ nanowires,²⁴,²⁵ and nanotubes⁵ have been successfully synthesized. However, to the best of our knowledge, the synthesis of hierarchical nanosheet-based NiMoO₄ nanotubes with a high surface area has not been reported.

Electrochemical supercapacitors (ECs) with properties intermediate to those of batteries and electrostatic capacitors have attracted more and more attention due to their good power density supply, fast charging, and excellent cycling stability, which play an important role in power-source applications such as short-term power sources and hybrid electric vehicles.²⁶⁻²⁹ In general, in terms of charge/discharge mechanism, electrochemical supercapacitors can be classified into categories: electrical double-layer capacitors (EDLCs) and Faradaic pseudocapacitors. Compared with EDLCs, Faradaic pseudocapacitors exhibit higher specific capacitance and energy density because they can provide a variety of oxidation states for efficient redox reactions. Metal molybdate nanostructures as electrode materials of ECs have been extensively investigated due to their pseudocapacitive behaviors.¹⁵⁻²¹ Mai et al reported that hierarchical MnMoO₄/CoMoO₄ heterostructured nanowires exhibited a specific capacitance of 187.1 F g⁻¹ at a current density of 1 A g⁻¹ and good reversibility with a cycling efficiency of 98% after 1,000 cycles.¹⁵ Liu et al demonstrated that CoMoO₄ nanorods had a high capacitance of 286 F g⁻¹ at a current density of 5 mA cm⁻² and 97.5% of the initial capacitance was remained after 2000 cycles.¹⁶ Xia et al fabricated CoMoO₄/graphene composites through a hydrothermal method, and the composites showed a specific capacitance of 394.5 F g⁻¹ at a scan rate of 1 mV s⁻¹.¹⁷ The specific capacitance of CoMoO₄/carbon nanotube composites was about 170 F g⁻¹ at a current density of 0.1 A g⁻¹ under an optimal experimental condition.¹¹ Plate-like CoMoO₄ nanostuctures exhibited a maximum specific capacitance of about 133 F g⁻¹ at a current density of 1 mA cm⁻² were also demonstrated.¹⁹ Nevertheless, compared with RuO₂-based materials these metal molybdate nanostructures had relatively low specific capacitances.²⁰,²¹

As reported, metal molybdates with large surface and highly ordered structure would exhibit excellent electrochemical performance.¹⁴ Herein, we developed a facile method based on an in situ diffusion reaction growth method to fabricate hierarchical nanosheet-based NiMoO₄ nanotubes with a surface area of as high as 128.5 m² g⁻¹. Applied as the electrode of ECs, the material exhibited a specific capacitance of 864 F g⁻¹ at a current density of 1 A g⁻¹, and good stability with a 71% of the initial capacitance remained after 1000 cycles.

2 Experimental Section

2.1 Synthesis of hierarchical nanosheet-based NiMoO₄ nanotubes

The synthesis of hierarchical nanosheet-based NiMoO₄ nanotubes was included a two-step process. 0.075 g of MoO₃ nanorods ¹²⁻¹⁴ was dispersed in 35 mL of water/ethanol (volume ratio = 1:1) solvent containing 0.618 g of nickel acetate under stirring for 10 min. The mixture above was then transferred into a Teflon-lined...
stainless steel autoclave with a capacity of 50 mL for hydrothermal treatment at 90°C for 5 h. As the autoclave cooled to room temperature naturally, the precipitates were separated by centrifugation, washed with distilled water and absolute ethanol, and dried in air. The products above, named as NiMoO₄ precursors for convenience, were annealed at air atmosphere at 500°C for 4 h, and then hierarchical nanosheet-based NiMoO₄ nanotubes were then obtained.

3 Results and discussion

The SEM and TEM images show that the diameter and length of MoO₃ nanorods with a single crystal nature obtained by a hydrothermal method are about 170 nm and several micrometers, respectively (Fig.S1, Electronic Supplementary Information (ESI)). The hierarchical NiMoO₄ precursors can be obtained after MoO₃ nanorods are hydrothermally treated in the nickel acetate solution containing water and ethanol at 90°C for 5 h. XRD analysis shows that the NiMoO₄ precursors contain Ni(OH)₂·0.75H₂O (JCPDS, no. 38–0715), α-MoO₃ (JCPDS, no. 35–0609), and NiMoO₄·xH₂O (JCPDS, no. 13–0128), as shown in Fig. S2. XPS measurements (Fig. S3) further confirm that the precursors contain Mo, Ni, and O elements. The atomic ratio of Mo to Ni determined by XPS is about 1.27:1.

The morphology and the structure of the NiMoO₄ precursors were investigated by scanning electron microscopy (SEM) and transmission electron microscopy (TEM) analyses. Interestingly, many nanosheets are almost grown perpendicularly on the surface of 1D MoO₃ nanostructures, forming an interesting three-dimensional (3D) hierarchical architecture, as shown in Fig. 1(a) and 1(b). It is also clearly found that the average diameter of the 3D hierarchical nanostructures (about 500 nm) is greatly increased, in comparison with the pristine MoO₃ nanorods (about 170 nm), while their lengths (about 2.5 µm) are decreased significantly which may result from the alkali etching. The inset in Fig. 1(a) indicates that the central parts of the 1D MoO₃ nanostructures are hollow due to the alkali etching. TEM image (Fig. 1(b) and 1(c)) shows that the nanosheets in the NiMoO₄ precursors have a thickness of less than 10 nm, and their height is about 150 nm. Fig. 1(d) is a typical TEM image of the basal plane of the nanosheets. It can be clearly found that many small particles are anchored on the surfaces of the nanosheets. The lattice fringes in the corresponding high-resolution TEM (HRTEM) image reveals that the small particles are of a crystal nature. The diffraction rings marked by yellow lines in the selected-area electron diffraction (SAED) of the basal plane of the nanosheets (the inset in Fig. 1(c) correspond to (006), (101) and (110) crystalline planes of Ni(OH)₂·0.75H₂O, respectively, whereas the diffraction dots marked by the green lines correspond to the crystalline planes of NiMoO₄·xH₂O with the lattice distances of 0.322 and 0.296 nm, respectively. In order to determine the phases of the nanosheets and the nanoparticles, an additional experiment was carried out, in which the experimental condition was kept the same one that was used to synthesize 3D hierarchical nanostructures except that MoO₃ nanorods were not added in the reaction system. After the hydrothermal treatment at 90°C for 5 h, the sheet-like products were obtained (Fig. S4). Thus, the nanosheets are Ni(OH)₂·0.75H₂O, while the nanoparticles anchored on their surfaces are NiMoO₄·xH₂O. To further determine the distribution of the elements in the 3D hierarchical
nanostructures, an annular dark-field (ADF) scanning transmission electron microscopy (STEM, Fig. 1(e)) and line-scan electron energy loss spectroscopy (EELS, Fig. 1(f)) were carried out. As shown in Fig. 1(f), the Mo, Ni, and O elements distribute uniformly in the whole regions of the 3D hierarchical nanostructures, which further confirms the SEAD and TEM results.

Fig. 2  a) SEM images of the products obtained in the ethanol system, b) Photograph of the solution obtained in the water system, and c) SEM and d) TEM images of the precipitate as the solution aged for above 4 h, respectively. The inset in d) showing the corresponding SAED pattern of the precipitate as the solution aged for above 4 h.

Scheme 1 Schematic illustration showing the growth mechanism of the 3D precursors.

In the terms of the analyses above, an interesting 3D nanostructures, i.e., Ni(OH)$_2$·0.75H$_2$O nanosheets with small nanoparticles anchored on their surfaces perpendicularly grown on the surfaces of 1D hollow MoO$_3$ nanostructures. The further experimental results show that the volume ratio of ethanol to water plays a very important role in the formation of the interesting 3D nanostructures. In the ethanol system any materials was not grown on the surfaces of the MoO$_3$ nanorods (Fig. 2(a)), whereas in the water system the MoO$_3$ nanorods would almost be etched totally and relatively transparent solution was obtained as the the autoclave cooled to room temperature initially (Fig. 2(b)). However, after the solution aged for above 4 h at room temperature, small amount of precipitate was formed in the bottom of the solution. The formation of the precipitate taking a period of time may be attributed to its low density. XRD analysis (Fig. S5) reveals that the precipitate consists of crystalline NiMoO$_3$·xH$_2$O, MoO$_3$, and NiMoO$_4$† SEM image (Fig. 2(c)) shows that the precipitate exhibits a rod-like morphology with porous characteristic. The porous characteristic is further confirmed by TEM observation, as shown in Fig. 2(d). The diffraction dots marked by the green lines in SAED pattern (the inset in Fig. 2(d)) marked by the green lines can be indexed to the planes of NiMoO$_4$·xH$_2$O with the lattice distance of 0.31 and 0.30 nm, respectively. In the pattern, the diffraction dots marked by the yellow lines can be attributed to orthorhombic MoO$_3$, in which the marked dots correspond to (120) and (040) planes of MoO$_3$.

Fig. 3 The structural characterization of the products obtained at different reaction stage. (a) SEM and (b) TEM images (70°C for 10 min), (c) SEM, (d) TEM, (e) HRTEM and (f) HRTEM images (90°C for 10 min), (g) SEM and TEM images (90°C for 2 h).

\[
\text{CH}_3\text{COO}^- + \text{H}_2\text{O} \rightarrow \text{CH}_3\text{COOH} + \text{OH}^- \tag{1}
\]
\( \text{MoO}_3 + 2\text{OH}^- \rightarrow \text{MoO}_2^{2+} + \text{H}_2\text{O} \)  
\( \text{OH}^- + \text{Ni}^{2+} \rightarrow \text{Ni(OH)}_2 \)  
\( \text{MoO}_2^{2+} + \text{Ni}^{2+} \rightarrow \text{NiMoO}_4 \)

In terms of the experimental results above, we proposed a mechanism for the growth of the interesting 3D nanostructures, which illustrated in Scheme 1. \( \text{OH}^- \) ions produced after the hydrolysis of nickel acetate (Equation 1) etch \( \text{MoO}_3 \) nanorods, leading to the formation of defect sites on the surfaces of \( \text{MoO}_3 \) nanorods, as shown in step 1 in Scheme 1. This is evidenced by SEM and TEM images of the product obtained at 70°C for 10 min, as shown in Fig. 3(a) and (b). XRD measurement (Fig. S6(a)) shows the product obtained at the stage is still crystalline \( \text{MoO}_3 \). The defects can serve as active nucleation sites for subsequent growth of Ni(OH)_2·0.75H_2O nanosheets (Equation 1) on the surfaces of the MoO_3 nanorods (Equation 3), as shown in step 2 in Scheme 1. During this step, small NiMoO_4·xH_2O nanoparticles are also formed (Equations 2 and 4), and deposited on the surfaces of Ni(OH)_2·0.75H_2O nanosheets. Due to the presence of Ni(OH)_2·0.75H_2O nanosheets on their surfaces, the weak alkali etching occurs more easily along axial direction of the MoO_3 nanorods, which results in void spaces in the axial direction of the MoO_3 nanorods. In order to clarify the processes, we characterized the structures of the products obtained at 90°C for 10 min and 2 h. Fig. 3(c) and (d) show SEM and TEM images of the product obtained at 90°C for 10 min. It can be clearly found that sheet-like materials with a height of 85 nm were grown on the surface of MoO_3. A high-magnification SEM image shows that there are some MoO_3 nanorods with uncoated tips. HRTEM image taken from uncoated tips of MoO_3 nanorods reveals crystal structure of the nanorods keep undamaged at the reaction stage, as shown in Fig. 3(e). The diffraction dots in the SAED pattern (the inset in Fig. 3(e)) come from orthorhombic MoO_3, in which the marked ones correspond to (001) and (100) planes of MoO_3. In addition, the diffraction rings, marked by the yellow lines, can be indexed to (101), (015) and (110) planes of Ni(OH)_2·0.75H_2O. It demonstrates that the sheet-like materials in the product are polycrystalline Ni(OH)_2·0.75H_2O. HRTEM image (Fig. 3(f)) shows that the crystallinity of Ni(OH)_2·0.75H_2O nanosheets is relatively weak. No diffraction peaks of Ni(OH)_2·0.75H_2O were observed in the XRD pattern (Fig. S6(b)), which is attributed to the weak crystallinity of Ni(OH)_2·0.75H_2O or small amount of Ni(OH)_2·0.75H_2O presented in the product compared to MoO_3 nanorods. As the reaction time increased to 2 h, the height of the Ni(OH)_2·0.75H_2O nanosheets also increased to about 130 nm, as shown in Fig. 3(g) and (h). XRD pattern (Fig. S6(c)) shows that the product obtained at 90°C for 2 h are composed of NiMoO_4·xH_2O, MoO_3 and Ni(OH)_2·0.75H_2O, similar to the product obtained at 90°C for 5 h (Fig. S6(d)). The diffraction rings marked by yellow lines in the SAED taken from uncoated tips of MoO_3 nanorods was gradually decreased due to alkali etching. It should be noted that the weak alkali etching is very important for the growth of the interesting 3D nanostructures. In the ethanol system, the concentration of OH\(^-\) ions is low, leading to very small numbers of the defect sites formed on the surfaces of the MoO_3 nanorods by the alkali etching. In the case, the nanosheets will not grow on the surfaces of the MoO_3 nanorods, as shown in Fig. 2(a). If nickel acetate was replaced with nickel nitrate or nickel dichloride, the same results were also obtained even in the ethanol/water system, as shown in Fig. 4(a) and 4(b). This further supports the conclusion above. However, in the water system, the concentration of OH\(^-\) ions is increased significantly. In this case, MoO_3 nanorods will be severely etched and small amount of products would be obtained, as shown in Fig. 2(b – d).

**Fig. 4** a) and b) SEM images of the products obtained as nickel acetate were replaced with nickel nitrate and nickel dichloride in the ethanol/water system, respectively.

![Figure 5](image_url)

**Fig. 5** XRD pattern of the hierarchical nanosheet-based NiMoO_4 nanotubes

In our previous work, we demonstrated that Fe(OH)_3@MoO_3 core/shell nanostructures could be converted into porous Fe_2(MoO_4)_3 nanorods by an in situ diffusion reaction. The transformation mechanism is similar to one based on the nanoscale Kirkendall effect which usually used to fabricate hollow inorganic nanocrystals. At a high temperature, MoO_3 diffused outward and reacted with Fe_2O_3, and then Fe_2(MoO_4)_3 gradually formed. Because MoO_3 diffused outward faster than Fe_2O_3 did inward, the void spaces would be formed in the inner part of the nanorods. In this work, we adopted a similar method to
transform the 3D NiMoO₄ precursors to hierarchical nanosheet-based NiMoO₄ nanotubes. Fig. 5 shows a XRD pattern of the hierarchical nanosheet-based NiMoO₄ nanotubes. All diffraction peaks marked with Miller indices in the pattern can be indexed to monoclinic NiMoO₄ (JCPDS, no. 86–0361, cell parameters: a = 9.566 Å, b = 8.734 Å, c = 7.649 Å, β = 114.22°). No significant peaks from NiO and MoO₂ were detected by the XRD measurement, suggesting that the precursors are fully converted into NiMoO₄ by the in situ diffusion reaction, Ni(OH)₂·0.75H₂O → NiMoO₄ + 1.75H₂O. In addition, one unknown peak marked by "*" was also observed, which needs to be further studied.

The morphology and the structure of the hierarchical nanosheet-based NiMoO₄ nanotubes were characterized by SEM and TEM analyses. SEM observations (Fig. 6(a)) show that the nanotubes have similar shape to that of the 3D precursors. Due to the in situ diffusion reaction, the region of void spaces along axial direction for the products is further enlarged compared to the precursors, as shown in the inset in Fig. 6(a). The tubular characteristic of the product is further confirmed by TEM analyses (Fig. 6(b)). The TEM analyses (Fig. 6(c)) also demonstrate that the thickness of the nanosheets grown outward is less than 10 nm. SAED pattern (the inset in Fig. 6(c)) reveals a polycrystalline nature of the hierarchical nanosheet-based NiMoO₄ nanotubes. The lattice distance marked in the inset in Fig. 6(d) is about 0.204 nm, corresponding to (330) crystal plane of monoclinic NiMoO₄. There are small many white regions in the HRTEM image (Fig. 6(d)) taken from the basal plane of the nanosheets, indicating a porous nature of the nanosheets. ADF STEM and line-scan EELS analyses (Fig. 6(e) and 6(f)) reveal that the Mo, Ni, and O distribute at the whole region of the products, and their quantities are much higher in the external region than in the inner one, also demonstrating that the products possess the tubular character.

The surface electronic state and composition of the hierarchical nanosheet-based NiMoO₄ nanotubes were investigated by XPS analysis. The survey XPS spectrum indicates that the nanotubes contain Ni, Mo, and O elements, as shown in the Supplementary, Fig. S7(a). † Fig. S7(b) shows a high-resolution Mo 3d spectrum. Deconvoluted Mo 3d doublet peaks at 232.1 and 235.4 eV suggest that molybdenum is solely in the state of Mo⁶⁺. † Fig. S7(c) shows a high-resolution Ni 2p spectrum, in which two peaks at 855.4 and 873.0 eV corresponds to Ni 2p⁰ and Ni 2p¹/₂, respectively. † Thus, Mo⁶⁺ as the only detected molybdenum species and Ni²⁺ as the only nickel species. The atom ratio of Mo to Ni is about 1:1.1, suggesting that the surface of hierarchical nanosheet-based NiMoO₄ nanotubes is Ni-rich slightly with respect to stoichiometric NiMoO₄.

![Fig. 7 Electrochemical characterizations of the hierarchical nanosheet-based NiMoO₄ nanotubes.](image)

Fig. 7 Electrochemical characterizations of the hierarchical nanosheet-based NiMoO₄ nanotubes. a) CV curves, b) Galvanostatic discharge curves of the hierarchical nanosheet-based NiMoO₄ nanotube electrode at various discharge current densities, c) Specific capacitance of the hierarchical nanosheet-based NiMoO₄ nanotube electrode at various discharge current densities, and d) Cycling stability and Coulombic efficiency of the hierarchical nanosheet-based NiMoO₄ nanotube electrode at a current density of 1 A g⁻¹.

Fig. 7(a) shows the cyclic voltammogram (CV) curves of the hierarchical nanosheet-based NiMoO₄ nanotubes at different scan rates. A pair of redox peaks is observed in each curves suggesting that the measured capacitance is mainly based on the pseudocapacitive mechanism. On one hand, the intensities of the redox peaks increase with the scan rate; on the other hand, the cathodic peak shifted towards positive potential, while the cathodic peak shifted towards negative potential. This further confirms the pseudocapacitive behavior of the hierarchical nanotubes. Furthermore, even at a high scan rate (50 mV s⁻¹), the
redox peaks are still evident, suggesting that the hierarchical nanosheet-based NiMoO₄ nanotubes are stable as electrode for ECs and exhibit good rate capability.

In order to further understand the electrochemical performances of the hierarchical nanosheet-based NiMoO₄ nanotubes, we measured the static charge/discharge curves at various current densities at room temperature, as shown in Fig. 7(b). The specific capacitance was calculated by the equation, 

\[ C = \frac{i\Delta \tau (m\Delta V)}{I} \]

where \( C \) (F/g) is the specific capacitance, \( i \) (A) is the discharge current, \( \Delta \tau \) (s) is the discharge time, \( m \) (g) is the weight of the active materials, \( \Delta V \) (V) is the voltage interval of the discharge. As shown in Fig. 7(c), the calculated specific capacitances for the hierarchical nanotubes are 864, 788, 682, and 605 F g⁻¹ at 1, 2, 3, 4 A g⁻¹, respectively. Compared with other metal molybdate such as CoMoO₄ (62.8 F g⁻¹ at 1 A g⁻¹), MnMoO₄ (9.7 F g⁻¹ at 1 A g⁻¹) and MnMoO₄ (187.1 F g⁻¹ at 1 A g⁻¹), the hierarchical nanosheet-based NiMoO₄ nanotubes exhibited superior electrochemical performances. Furthermore, the hierarchical nanotubes exhibited relatively good cycling stability even at 1 A g⁻¹. As shown in Fig. 7(d), after 1000 cycles, the capacitance retentions is still about 71%. In addition, the Coulombic efficiency during the whole cycles is in range of 95 – 100 %, as shown in Fig. 7(d).

The good electrochemical performances of the hierarchical nanosheet-based NiMoO₄ nanotubes may be related to the following factors. (i) The hierarchical nanosheet-based NiMoO₄ nanotubes have a very high Brunauer–Emmett–Teller (BET) surface area of 128.5 m² g⁻¹ (Fig. S8(a)), significantly higher than those of other metal molybdate nanostructures (MnMoO₄ nanorods: 15 m² g⁻¹; CoMoO₄ nanorods: 25 m² g⁻¹; 3D MnMoO₄/CoMoO₄ heteronanostructures: 54.06 m² g⁻¹). Such higher BET surface area allows the inner active sites of the electrode can be fully contacted with electrolyte. (ii) The high capacitance of the hierarchical nanotubes is attributed to their unique microstructures, i. e., composed of highly ordered nanosheets with an ultrathin thickness. On one hand, self-aggregation of the hierarchical nanotubes is greatly impeded; on the other hand, such microstructures can enhance the kinetics of ion and electron transport at the electrode-electrolyte interfaces and inside the electrodes. (iii) The hierarchical nanotubes grown on the NiMoO₄ nanotubes are of porous characteristic, as shown in Fig. 6(d). In addition, the average pore diameter is 11.8 nm (Fig. S8(b)), calculated from the desorption branch of the nitrogen isotherm obtaining using the Barret–Joyner–Halenda (BJH) method, and the corresponding BJH desorption cumulative volume is 0.52 cm³ g⁻¹. The porous characteristic and high pore volume make the electrolyte diffusion in/outward electrode materials easily, which is favor of the improvement of the electrochemical performances of the hierarchical nanosheet-based NiMoO₄ nanotubes.

Conclusions

In summary, a facile method was developed to fabricate hierarchical nanosheet-based NiMoO₄ nanotubes with a high surface area of 128.5 m² g⁻¹. The tubular character, highly ordered nanosheets with an ultrathin thickness, and high surface area resulted in excellent electrochemical performance of the nanotubes. As applied in ECs, the specific capacitance of the hierarchical nanotubes is up to 864 F g⁻¹ at a current density of 1 A g⁻¹, and 71% of the initial capacitance after 1000 cycles was retained. Our results demonstrate that the hierarchical nanosheet-based NiMoO₄ nanotubes are very promising for applications in energy storage and other electrochemical devices. In addition, the strategy presented here could be expended as a general method to synthesize other kinds of metal molybdate nanotubes by rational designation in nanoscale.
