This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
TransCap: a monolithically integrated supercapacitor and electrolyte-gated transistor

DOI: 10.1039/b000000x

We report the proof-of-concept of the TransCap, a monolithically integrated device that exhibits the storage properties of a supercapacitor and the low-voltage operation of an electrolyte-gated transistor. The proof-of-concept is based on coupling a polymer channel with a high surface area carbon gate, employing an ionic liquid as the electrolyte. The possibility to recover the stored energy from the TransCap permits to use it to power different microelectronic components.

The increasing demand of energy autonomy for portable electronics is triggering intensive research efforts towards the development of self-powered, sustainable electronic devices.1–3 Within this context, the coupling of electronic devices (sensors, transistors, etc.) with energy harvesters and small size energy storage systems (e.g. micro-batteries or micro-supercapacitors) is actively pursued.2

For their low-voltage operation characteristics, electrolyte-gated (EG) transistors are attractive candidates to be coupled to energy harvester/storage microsystems.4–11 EG transistors make use of electrolytes, such as polymer electrolytes, ionic liquids and ion gels, to replace conventional gate dielectrics. Ionic liquids are particularly attractive since they are available in a wide range of different molecular structures and chemico-physical properties, thus offering the possibility to specifically control the interactions between the ions and the transistor channel, in view of an optimized doping.12–15 The working principle of EG transistors is based on the high capacitance of the electrical double layer at the electrolyte transistor channel interface. Different doping mechanisms, including electrostatic and Faradic, have been proposed to explain the gating process. Polymer channel materials are typically characterized by Faradic doping.

A large number of channel materials have been applied to EG transistors, including organic single crystals, organic thin films of small molecules and polymers,5,6,16–22 thin films of metal oxides,5,6,11,23–26 mN2,27 CdSe,28 and PbSe.29 EG transistors are intensively investigated because they permit current modulations of several orders of magnitude, upon application of relatively low gate voltages. Low-voltage operation is achieved by exploiting the exceptionally high capacitance of the electrical double layer forming at the electrolyte transistor channel interface. High electrode capacitances are also exploited for charge and energy storage in electrochemical supercapacitors. Supercapacitors are high specific power systems that, for their capability to store/deliver charge in relatively short times (a few seconds), may outperform batteries in applications having high peak-to-average power demand. Different classes of supercapacitors making use of electrodes with different nature have been demonstrated. The most common supercapacitors are electrochemical double layer capacitors that use high surface area carbon electrodes, which store/deliver charge by an electrostatic process. Pseudo-supercapacitors feature battery-like electrodes (electrochemically conducting polymers, metal oxides) that are charged/discharged by fast and reversible redox processes. Hybrid supercapacitors feature positive and negative electrode materials of different nature that are charged/discharged via different electrostatic and Faradic modes.30–33

Here we report for the first time a monolithically integrated Transistor and superCapacitor (TransCap), where the typical function of a transistor is coupled with the energy storage function of a supercapacitor, within the same EG transistor structure. The proof-of-concept of the TransCap is based on coupling a polymer channel with a high surface area carbon gate, employing an ionic liquid as the electrolyte. The p-doping that brings the polymer channel from the insulating to the conducting state is a pseudocapacitive charging process.30,31 The high surface area gate electrode supplies the charge required to dope the transistor polymer channel by a fast, highly reversible, electrostatic process, referred to as double layer charging process, that is at the basis of the energy storage process in conventional electrochemical double layer supercapacitors. The use of a high surface area carbon gate electrode featuring a high double layer specific capacitance and employing an excess mass of carbon with respect to the amount required to balance the doping charge of the polymer is a valuable approach for an effective doping of the polymer channel.33 The polymer/electrolyte/carbon stacking of the EG transistor features the cell configuration of a hybrid supercapacitor, where the negative carbon electrode and the positive polymer electrode are charged by an electrostatic and a faradic process, respectively. When the TransCap is ON, the polymer transistor channel is open. The p-doped polymer and negatively polarized carbon gate electrode are storing the charge (Q) at a given gate-source voltage (Vgs), hence the system is storing energy (equal to QVgs). When the TransCap is switched OFF, the channel and the gate are discharged and the delivered energy can be used for subsequent operation of the EG transistor itself or to power other components in the electronic system. The characteristics of the TransCap have similarities with those of floating gate transistor devices.
Specifically, we report a TransCap making use, as the channel material, of a thin film of the organic electronic polymer MEH-PPV,[13] poly[2-methoxy-5-(2’-ethylhexyloxy)-1,4-phenylene vinylene], deposited on top of a SiO2 substrate pre-patterned with gold drain and source electrodes (Fig. 1 and Electronic Supplementary Information, ESI). A high surface area carbon electrode (Brunauer-Emmett-Teller, BET, specific surface area of 1850 m2/g) was used as the gate electrode. The room temperature ionic liquid N-trimethyl-N-propylammonium bis(trifluoromethanesulfonyl) imide ([N1113][TFSI]), exhibiting remarkable electrochemical stability, was used as the gating medium.

Upon application of Vgs, we observed that Ig decreases within 1 s whereas Ig, approaches its plateau value after ca 4 s (Fig. 3). This suggests that the transistor response time depends on two processes: the penetration of ions from the electrolyte in the polymer, which affects Ig, vs time, and the p-doping process in the polymer, which affects Ig, vs time.[34] While both the processes are affected by the [N1113][TFSI] ionic conductivity, they have different rates, with the former being the fastest. This result is not surprising if we consider that the MEH-PPV/[N1113][TFSI]/carbon gate stacking has a similar configuration of a hybrid supercapacitor, which typically exhibits a relatively fast response time.[35]

The energy used to bring the transistor to the ON state (EON) and stored in the TransCap is given by the integration of Ig, over time multiplied by the value of Vgs (0.8 V); this value is of 53 µJ (Fig. 3). Such energy is then delivered upon switch OFF (EOFF, calculated from the integration of Ig, over time during the switch off multiplied by 0.8 V) with an efficiency (EON/EOFF · 100) of 99.5%, due to the energy storage capability of the TransCap and the reversibility of the charging/discharging processes at the electrodes.

In our TransCap, where the carbon gate mass is in large excess with respect to that of the polymer (see ESI), the electrochemical response is mainly affected by the polymer doping/dedoping processes.

We initially performed the transistor characterization of the [N1113][TFSI]-gated MEH-PPV TransCap. The output (drain-source current, Ig, vs drain-source voltage, Vgs) and the transfer (Ig, vs Vgs) characteristics of the TransCap (Figs. 2a and 2b) demonstrate the p-type transistor operation. In the output curves, we observe that the saturation regime is achieved at ca 0.25 V. The transistor ON/OFF ratio, calculated between Vgs = –0.8 V (ON state) and Vgs = 0 V (OFF state) at Vds = –0.3 V, is about 2×105 (Fig. S1, ESI). The hole mobility, determined from the transfer linear characteristics is 2×10–5 cm2 V–1 s–1. The hysteresis of the transistor current observed in the transfer curve (Fig. 2b) originates from ion diffusion during the doping and dedoping processes, in turn affecting the device response time.[34]

Upon application of Vgs, we observed that Ig decreases within 1 s whereas Ig, approaches its plateau value after ca 4 s (Fig. 3). This suggests that the transistor response time depends on two processes: the penetration of ions from the electrolyte in the polymer, which affects Ig, vs time, and the p-doping process in the polymer, which affects Ig, vs time.[34] While both the processes are affected by the [N1113][TFSI] ionic conductivity, they have different rates, with the former being the fastest. This result is not surprising if we consider that the MEH-PPV/[N1113][TFSI]/carbon gate stacking has a similar configuration of a hybrid supercapacitor, which typically exhibits a relatively fast response time.[35]

The energy used to bring the transistor to the ON state (EON) and stored in the TransCap is given by the integration of Ig, over time multiplied by the value of Vgs (0.8 V); this value is of 53 µJ (Fig. 3). Such energy is then delivered upon switch OFF (EOFF, calculated from the integration of Ig, over time during the switch off multiplied by 0.8 V) with an efficiency (EON/EOFF · 100) of 99.5%, due to the energy storage capability of the TransCap and the reversibility of the charging/discharging processes at the electrodes. In our TransCap, where the carbon gate mass is in large excess with respect to that of the polymer (see ESI), the electrochemical response is mainly affected by the polymer doping/dedoping processes.

The supercapacitor characteristics of the TransCap, we used the polymer transistor channel together with the drain and source electrodes as the positive electrode and the high surface area carbon gate as the negative electrode. Therefore, the supercapacitor cell voltage, Vcell, corresponds to - Vgs. We performed galvanostatically charge/discharge cycles (Fig. 4a) at a current I = ±10 µA (where I = - Ig) up to 0.8 V, a cut-off cell voltage selected in agreement with the results reported in Fig. 2b. The capacitance (C) obtained by the slope of the discharge voltage profiles (C = I dt/dVcell) is 0.16 mF. The delivered energy, E, and power, P, were calculated from the galvanostatic discharge curve using Eqs. (1) and (2):

\[
E = \int V_{cell} \cdot I \, dt \quad \text{Eq. (1)}
\]

\[
P = \frac{E}{\Delta t} \quad \text{Eq. (2)}
\]

where \(\Delta t\) is the discharge time. E and P are 27.4 µJ and 4.6 µW, respectively. The capacitance, energy and power normalized to the TransCap electrode geometric area (0.36 cm2) are 0.44
mF cm$^{-2}$, 0.02 µWh cm$^{-2}$, 13 µW cm$^{-2}$. These values are of interest for energy autonomous electronic devices.$^2$

Figure 4a shows that the storage capability of the TransCap permits to keep the transistor channel open even when the transistor is not connected to a power supply. This storage capability can be affected by the presence of leakage currents, resulting in discharging of the device. The leakage currents and discharge were therefore investigated using the following protocol: galvanostatic charge at 10 µA, up to a cut-off cell voltage value of 0.8 V; voltage of 0.8 V held over 10 s; rest step (I = 0 A) over 30 s; discharge at a constant current of -10 µA (Fig. 4b). The leakage current during the step at 0.8 V reaches 3.5 µA after 10 s, thus indicating that the energy consumption to keep the TransCap in the ON state at 0.8 V is not negligible (ca 0.43 µJ). These values have to be taken into account if the TransCap is coupled to energy harvester systems that operate at low energy levels. On the other hand, the voltage behaviour over time during the rest step shows that the supercapacitor can keep its state of charge within a voltage drop of 1.4 % after 0.2 s (high resolution plot not shown here). After 30 s, the voltage decreases by 30% of its initial value. This result suggests that the TransCap can operate without being connected to an electric grid for relatively short times and that the transistor channel is still open (doped) at relatively long times. Any TransCap switch OFF following the rest step will provide an energy recovery with an efficiency depending on the duration of the previous rest step. The capability of the TransCap to store charge at the polymer/electrolyte/carbon interface holds promise for applications in the electronic industry, such as in displays where the transient switching of the display pixel is desired.

**Fig. 4.** Supercapacitor characteristics of the [N$_{1111}$][TFSI]-gated MEH-PPV TransCap: (a) voltage profile vs time when the device is galvanostatically charged/discharged at ±10 µA up to 0.8 V (data taken during the second cycle of a sequential type of acquisition: 6 s TransCap ON followed by 6 s TransCap OFF); (b) voltage (left axis) and current (right axis) vs time upon galvanostatic charging at 10 µA up to 0.8 V, followed by 10 s at 0.8 V, 30 s rest in open circuit conditions, and galvanostatic discharge at -10 µA.

**Conclusions**

We report the proof-of-concept of the TransCap, a multifunctional monolithically-integrated device that combines the characteristics of an electrolyte-gated transistor and a microsupercapacitor. The charge storage capability of the TransCap, similar to that of a floating gate transistor design, opens the possibility to use the TransCap in memory (latch) applications. The possibility to recover energy from the TransCap permits to use the stored energy to subsequently power different microelectronic components. Remarkably, for the proof-of-concept of the TransCap we used materials such as carbon and organic electronic polymers that exhibit suitable processability characteristics for portable, low-cost, flexible electronics on plastic substrates.
