This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Bacterial Detection With Amphiphilic Carbon Dots

Introduction

Detection and microscopic visualization of bacteria are essential for numerous applications. Current bacterial detection methods generally rely on indirect detection of bacterially-secreted metabolites or visualization of bacterial colonies (rather than individual bacterial cells). Imaging of bacterial cells has been carried out through the use of varied staining techniques, using either fluorescent dyes, or in some cases by semiconductor quantum dots. While these strategies are widely used and many bacterial detection and imaging agents are commercially available, there is still a need for versatile platforms that could be employed for broad range of bacterial species, would be technically simple and inexpensive, and would provide morphological details on bacterial cells. Here, we present a novel scheme for detection and microscopic visualization of bacterial cells using amphiphilic carbon dots.

Carbon dots (CDs) are small (<10 nm), quasi-spherical crystalline graphitic nanoparticles, and have attracted considerable interest due to their unique structural and photophysical properties. CDs exhibit a multitude of colors (e.g. excitation/emission wavelength pairs), fluorescence up-conversion, and high quantum yield. CDs have been proposed as useful vehicles for biological studies since they are chemically stable, can be readily surface-functionalized, and their broad excitation/emission spectral range and low photo bleaching are beneficial for imaging applications.

CDs can be readily derivatized with varied molecular residues consequently endowing them with diverse functionalities. We have recently demonstrated that CDs displaying long hydrocarbon chains – i.e. amphiphilic CDs - can be employed as useful fluorescent probes for membrane analysis. Moreover, amphiphilic CDs were shown to exhibit high affinity to actual cellular membranes, thereby enabling multicolor microscopic imaging of cells and intracellular organelles. Here, we show that amphiphilic CDs serve as effective fluorescent markers of bacterial cells. Importantly, we show that the fluorescence emission was modulated by the specific bacterial strain to which the CDs were attached – providing a powerful vehicle for distinguishing among different bacteria, even in mixtures of more than a single bacterial species. The new CD labelling method was further employed for visualizing “poles” within dividing bacterial cells, pointing to utilization of the technology for analysis of cellular events.

Experimental section

Materials.

Phosphate buffered saline (PBS) was purchased from Sigma-Aldrich. Luria-Bertani (LB) agar was purchased from Pronadisa (Spain).

Bacterial growth

The bacteria used in the studies were Escherichia coli MGLY wild type, Salmonella typhimurium (strain ATCC14028), Pseudomonas aeruginosa PAO1 wild type, Bacillus cereus, Bacillus subtilus PET28a-FtsA-GFP strains. The plasmid was pet28a plasmid having T7 promoter. Transformation efficiency was calculated by fluorescent microscopy and it was 75-80% of the whole cell population. The bacteria were grown aerobically at 37 °C on a sterilized solid LB medium composed of 13.5% yeast extract, 27% peptone, 27% NaCl, and 32.5% agar at pH 7.4. After overnight growth, a colony from each bacterial strain was taken and added to 10 mL sterilized LB medium and incubated at 37 °C. Bacterial growth was monitored at the desired time points through measuring the concentration of the bacteria by visible spectroscopy (10⁵ CFU/mL when optical density at 600 nm was 1.0).

Synthesis of amphiphilic carbon dots

Synthesis of amphiphilic carbon dots followed a recently published procedure [full experimental details presented in Figures 1-9, SI and in ref. 11]. Briefly, we synthesized 6-O-acetylated fatty acid ester of D-glucose (prepared by reacting D-glucose with O-O’-di-lauroyl-tartaric acid anhydride) which then underwent carbonization to produce amphiphilic CDs. Purity of end products was confirmed by NMR spectroscopy. NMR conforms complete carbonisation during the course of the reaction. FT-IR (Figure 7, SI) and XPS (Figure 8, SI) spectra reveal the chemical composition of the as-synthesized CDs. Two dominant peaks at 281.7 and 530.4 eV in the XPS survey spectrum were attributed to C 1s and O 1s, suggesting the existence of only carbon and oxygen elements in as-synthesized CDs (atomic content of carbon and oxygen was 72% and 28% respectively). The measured C 1s spectrum can be deconvoluted into five surface components, corresponding to sp² (C=C) at binding energy of 284.7 eV, sp³ (C–C, C–H) at 285.3 eV, C–OH at 286.8 eV, C=O at 287.6 eV and O–C=O at 286.8 eV. In the deconvoluted O 1s spectrum the appearance of peaks at binding energies of 529.9 eV, 530.8 eV and 531.6 eV corresponding to C=O, C–O, OH–C=O groups, respectively, is consistent with the FT-IR spectrum indicating presence of oxygen containing hydrophilic functional groups on the surface of the as-synthesized CDs. The transmission electron microscopy (TEM) images in Fig. 9, SI further confirm the crystallinity of the CD product. Quantum yield of the amphiphilic CDs was 16.5%, 9.4%, and 4.7% in chloroform, hexane, and NaH₂PO₄ buffer, respectively (full details in SI document).

Bacterial labelling with amphiphilic carbon dots

All bacteria were grown overnight at 37 °C in LB medium. After overnight growth, a colony from each bacterial strain was placed into 10 mL falcon tubes and the optical density was measured at 600 nm and adjusted to 1.0 (10⁸ cells/mL). The bacterial cells were centrifuged for 20 min at 2300 rcf, washed twice with the sterilized PBS (pH 7.4), and the cell pellet was re-suspended in 1 mL solution of amphiphilic CDs dissolved in PBS buffer (pH 7.4) under gentle vortexing (CD concentration 1 mg/mL). The bacteria / CD suspensions were kept at 37 °C for 3h with gentle shaking. After incubation, the mixture was centrifuged to pellet the CD-labeled bacteria, the supernatant was discarded and the pellet was re-suspended in PBS buffer. The process was repeated twice to remove all unbound amphiphilic CDs. Finally, the pellet was suspended again in 1 mL PBS and 900 µL of such aliquot was taken in quartz cuvette and subjected to fluorescence spectroscopy studies.

Fluorescence microscopy, binding curves and sensitivity test

For the fluorescence microscopy experiments, 50 µL of above prepared amphiphilic CD labeled cell suspension was placed in microscope slides coated with 100 µL of 5% agarose gel. For measuring binding curves of the amphiphilic CDs to different bacteria, the same procedure was carried out with different concentrations of amphiphilic CDs (from 0.1 mg/mL to 1.5 mg/mL) in PBS buffer. The best-fit curve was obtained by using SigmaPlot dynamic curve fitting software for fitting experimentally-obtained points in an equation that corresponds to the curve merging a maximum number of experimental points with reduces Chi-square value and R² closest to 1. For binding curve experiments and sensitivity test each data point was repeated three times.

Sensitivity assay

The procedure was repeated with different concentration of bacteria (10⁸ CFU/mL to 10² CFU/mL) prepared through dilution and incubated with the same concentration of amphiphilic CDs (1 mg/mL). For visualization of membrane domains of E. coli, the bacterial cells were grown together with amphiphilic CDs solution in LB medium (concentration 1 mg/mL) at 37 °C for 3h. For microscopic visualization of membrane domain thin cover glass slide was coated with 100 µL of 5% agarose gel and the bacteria were placed on the treated surface.

Fluorescence spectroscopy and microscopy

Steady-state fluorescence spectra were recorded using a Fluorolog 3 (Jobin-Yvon) steady-state Spectrometer. Fluorescence microscopy experiments were carried out on an Olympus IX70 microscope (Japan), equipped with a Roper Scientific Inc. MicroMAX camera with an UPlanFL100x/1.4 objective. Images were processed with "WINView" software.

Results and discussion

Fig. 1A illustrates the new bacterial detection approach using amphiphilic carbon dots (CDs). We recently demonstrated that these CDs, which display hydrocarbon chains upon the particle surface, exhibit high affinity to cell membranes. As depicted in Fig. 1A, the bacterial detection scheme relies upon incubation of bacteria with the amphiphilic CDs (for 3-4 h); after subsequent washing, CDs attached to the bacterial cells render them highly fluorescent, thereby easily detectable by fluorescence spectroscopy / microscopy.
Fig. 1B depicts representative fluorescent microscopy images recorded after incubation of E. coli bacterial cells with the amphiphilic CDs. The images in Fig. 1B show brightly fluorescent bacterial cells due to attachment of the amphiphilic CDs (the fluorescence threshold was adjusted to subtract the auto-fluorescence of the bacteria).13, 14 Importantly, the multicolor fluorescence apparent in Fig. 1B reflects the broad excitation/emission range of CDs.15, 16 This distinctive property enables, in principle, selection of desired excitation and emission wavelengths for bacteria visualization, depending upon instrument features, auto-fluorescence levels of the tested bacteria in specific wavelengths, and/or the presence of other fluorescence dyes.

To investigate labelling and interactions of different bacterial species with amphiphilic CDs, we incubated the carbon nanoparticles with four widely-studied bacterial strains, Gram-negative (E. coli, P. aeruginosa, S. typhimurium) and Gram-positive (B. cereus). Fig. 2A-D present the emission spectra recorded following incubation of the same concentrations of amphiphilic CDs with the four bacterial strains. Previous studies have shown that the CDs’ fluorescence is sensitive to their molecular environments.6–11 The distinct wavelength-dependent shifts of the CDs’ fluorescence (Fig. 2A-D), apparent for each bacterial strain, likely indicate that the CDs exhibit different affinities and interactions with the bacterial cell membranes.

Fig. 3: Amphiphile carbon dot binding curves to bacteria. The curves depict the relative levels of fluorescence emission (excitation at 350 nm) induced by increasing concentrations of the amphiphilic CDs in bacterial suspensions (10⁵ cells/mL). Black: experimental results; red: best fit curves. A. E. coli; B. S. typhimurium; C. P. aeruginosa; D. B. cereus.

Fig. 3 attests to attachment of the CDs to the bacterial cells; in all four bacterial strains, after the initial fluorescence increase due to binding of the fluorescent CDs to the cells, the fluorescence intensities reach plateaus – reflecting maximal available binding sites for the amphiphilic-CD upon the cell surface (i.e. saturation levels).

An important observation in Fig. 3 is the distinct binding profiles of the amphiphilic CDs associated with each bacterial strain. The differences are clearly apparent upon comparison of the best-fit binding curves shown in red (calculated through SigmaPlot dynamic curve fitting software). Indeed, the slope and concentration thresholds for bacterial labelling, and overall shapes of the curves in Fig. 3 indicate that the binding mechanisms of the amphiphilic CDs vary among the bacterial species. Echoing the fluorescence emission spectra in Fig. 2, this result likely reflects the variation in cell surface properties among the bacterial strains examined (i.e. different lipid compositions, molecular organization, and macroscopic structures of bacterial surface), which determine the affinities of the amphiphilic CDs to the bacterial membranes and their modes of attachment.17–19

The new CD-labelling approach opens interesting avenues for bacterial detection applications. Fig. 4A depicts the fluorescence spectra recorded upon excitation at 350 nm using the same concentration of bacterial cells and amphiphilic CDs. Significant strain-dependent differences in spectral shifts and peak intensities apparent in Fig. 4A are ascribed to the distinct membrane compositions and molecular organization of the bacterial species tested, which affect both the affinity of the amphiphilic CDs to the cell membranes, as well as the environments of the bound nanoparticles. Interestingly, the relative intensities of the fluorescence emissions in Fig. 4A trace the abundance of phosphatidylethanolamine (PE) in the membrane of the bacteria tested (Table 1, SI), which might reflect affinity of the amphiphilic CDs to the zwitterionic phospholipid.

Fig. 4B depicts the detection sensitivities of the CD labelling assay for the four strains tested (using CD concentrations...
corresponding to the saturation values, Fig. 3). Notably, the detection threshold values recorded ($10^3 - 10^4$ cells/mL) are better than other fluorescence based techniques for bacterial detection, such as fluorescein isothiocyanate (FITC) based methods.$^{1,4}$

Fig. 5: Distinguishing between bacterial strains through carbon dots labeling. Multicolor fluorescence microscopy images of a mixture of E. coli and B. cereus recorded at different excitation/emission pairs and different fluorescence emission thresholds. A: Excitation at 365 nm, emission filter 420 LP, exposure time 0.5 sec., low fluorescence emission threshold; B: Excitation at 365 nm, emission filter 420 LP, exposure time 0.5 sec., high fluorescence emission threshold; C: Excitation at 470 nm, emission filter 510 LP, exposure time 0.05 sec.; D: excitation at 540 nm, emission filter 605 nm, exposure time 0.5 sec. high fluorescence emission threshold. Scale bar corresponds to 5 μm. The dashed ovals indicate the B. cereus cells, details in the text.

Fig. 5A depicts image showing several labeled cells, recorded using blue excitation (365 nm) and 420 nm LP emission filter, and obtained using a low fluorescence threshold and 0.5 sec exposure time. However, when a significantly higher fluorescence threshold was employed in the same microscopic image, fewer bacterial cells were observed (Fig. 5B). This result likely indicates that the bacterial cells that became “invisible” in Fig. 5B corresponded to B. cereus, as labelling of this strain with the amphillic CDs yielded much lower fluorescence emission (i.e. Fig. 3, blue curve). In comparison, the brighter remaining cells in Fig. 5B are likely E. coli as this bacterial strain emits much more intense fluorescence after attachment of amphphillic CDs (Fig. 3, black curve).

To confirm this interpretation we recorded a fluorescence microscopy image using excitation of 470 nm, 510 LP emission filter and at a very low exposure time, i.e. 0.05 sec. (Fig. 5C) – a setup optimized for imaging of GFP-labeled E. coli bacteria.$^{15}$ Indeed, the fluorescent microscopy image in Fig. 5C shows only the GFP-labeled E. coli cells (as the CD-labeled bacterial cells do not show up in such a low exposure time due to the lower quantum yield of the CDs compared to GFP), exactly coincident with the cells imaged in Fig. 5B. Optical filtering of B. cereus cells labeled with amphphillic CDs could be similarly accomplished using excitation-emission pairs in the red spectral region using excitation of 540 nm, emission filter 605 nm and 0.5 sec exposure time (Fig. 5D). Echoing the fluorescence profile in Fig. 3, CD-labeled B. cereus exhibits much lower fluorescence emission also in the red region compared to CD-labeled E. coli (Fig. 2, SI). Accordingly, by appropriate setting of the fluorescence threshold in the microscopy images one can observe only the E. coli cells, as apparent in Fig. 5D.

Fig. 4: A: Fluorescence emission spectra (excitation 350 nm) of bacterial cells labelled with the amphphillic CDs. The spectra were recorded after incubating $10^7$ bacterial cells in each case with the same concentration of amphphillic CDs (1 mg/mL). Significant differences in fluorescence shifts and intensities are apparent among the bacterial strains: E. coli (black spectrum), S. typhimurium (red), P. aeruginosa (green), and B. cereus (blue). B: Detection sensitivity of amphphillic carbon dot labeling assay. Graphs depicting the fluorescence signals (excitation at 350 nm) recorded in solutions containing different bacterial concentrations.

Fig. 5 examines the feasibility of using the carbon dot platform for distinguishing among different bacterial species in a mixture through exploiting the distinct photoluminescence profiles of the CD-labeled bacteria (i.e. Fig. 2 and 3). In the experiment shown in Fig. 5 we created a mixture of two bacterial strains which were subsequently labeled with amphphillic CDs: E. coli which was also fluorescently-labeled with green fluorescent protein (GFP),$^{13}$ and B. cereus (which was not GFP labeled). Fig. 5 depicts fluorescence microscopy images of the bacterial mixture recorded using distinct excitation/emission wavelengths (i.e. different colors), and different fluorescence thresholds in the images.
Fig. 6: Imaging bacterial cell division using carbon dot labeling. CD-labeled E. coli cells showing membrane domains associated with cell division. The arrow points to splitting bacterial cell displaying a fluorescent domain in the middle. Scale bar corresponds to 5 µm. Exposure time 0.5 sec.

Labelling bacteria with amphiphilic CDs further enabled dramatic visualization of membrane domains associated with fundamental physiological events (Fig. 6). Fig. 6 presents microscopic analysis of CD-labeled E. coli cells (excitation 365 nm and 420 nm LP emission filter) revealing high fluorescence intensities at the two "poles" of the bacterial cell. The localization of the fluorescent CDs at the poles might be ascribed to the presence of membrane domains comprising high cardiolipin (CL) concentrations,17 and migration of membrane-associated proteins to the poles during cell division.22, 23 Indeed, inspection of the fluorescence microscopy image in Fig. 6 also clearly shows E. coli cells likely in the midst of a division process – exhibiting another highly fluorescent domain in the middle of a dividing cell (i.e. cell indicated with an arrow in Fig. 6).

Conclusions

We show that amphiphilic carbon dots (CDs) can be employed as a convenient vehicle for bacterial imaging, based upon their affinity to bacterial cell surfaces. Distinct fluorescence emission profiles were recorded due to the different molecular properties of the bacterial membranes. The dependence of fluorescence emission upon bacterial species makes possible, in some cases, distinguishing among different strains. Carbon dot labeling makes possible dramatic microscopic visualization of physiological processes such as cell division, reflected in changes of cell surface morphologies.
