This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
A series of novel metal-free organic sensitizers based on N-annulated perylene derivatives have been designed and synthesized, and exhibit broad absorption spectra in the visible region. The dye-sensitized solar cells exhibit overall conversion efficiencies ranging from 4.90% to 8.28% under AM 1.5 solar conditions.

Dye-sensitized solar cells (DSCs) have attracted significant attention due to their clean and pollution-free nature, low-cost fabrication and high power conversion efficiency.\(^1\) Since the first demonstration in 1991,\(^2\) DSCs have gained great improvements in the stability and efficiency, especially ruthenium sensitizer-based DSCs having shown very impressive solar-to-electricity power conversion efficiency (PCE) of over 11%.\(^3\) However, owing to the high cost and a resource restriction of the noble metal ruthenium, more efforts have been devoted to the development of metal-free organic sensitizers in recent years for the wide availability of the raw materials.\(^4\) Generally, donor-π-acceptor (D-π-A) configuration is the typical structure of organic sensitizers because of the efficient intramolecular charge transfer properties. Through changing the three elements of donor moiety, π-linker and acceptor moiety, it could obtain novel sensitizers with wide absorption spectra, appropriate energy levels and improved carrier transporting ability.\(^5\) Among the common organic donor moieties of indole, triarylamines, coumarin, and carbazole,\(^6\) triphenylamine is one of the most popular donor units due to its powerful electron-donating ability and steric structure.\(^7\)

We are particularly interested in the design and synthesis of heteroatom-annulated rylene dyes.\(^8\) In the past few years, we have demonstrated the efficient synthesis of N-annulated perylene (NP) on gram scale and longer N-annulated perylene derivatives (bis-N-annulated quaterylene and tri-N-annulated hexarylene), which have received considerable interest due to their excellent optical and physical properties such as high molar extinction coefficient, high fluorescence quantum and tunable energy band gap.\(^9\) Meanwhile they have strong electron-donating character owing to the introduction of nitrogen atoms to the bay region, and have been proved to be excellent candidates as donor segments of organic dyes. For example, Wu and co-worker introduced the NP unit to the porphyrin-based dyes and the power conversion efficiencies of the DSCs exceeded 10% under simulated AM 1.5 global sunlight.\(^10\)

Quite recently, Wang reported a new metal-free NP-based D-A dye C261 showing a PCE as high as 8.8%.\(^11\)

In order to further explore the relationship between the structure and properties of organic sensitizers, herein, we designed and synthesized a series of pure organic dyes based on NP. In which triphenylamine derivatives were introduced into NP donor as an additional electron donor and steric unit to prevent the molecular π-π aggregation, and 2-cyanoacetic acid as an electron acceptor. A different number of thiophene units were chosen to serve as π spacer that may cause certain difference in electrons injected on the TiO$_2$ film. Meanwhile, the introduction of branched alkyl chain to NP unit would improve the solubility and decrease the dye aggregation in the solid film. The structures of the dyes NPS-1--NPS-4 are shown in Figure 1 and their synthetic routes are shown in Scheme 1. The sterical unit of triphenylamine derivatives and the conjugated linker of different number of thiophene units were introduced to the donor NP segment via Suzuki reaction. The acceptor of 2-cyanoacetic acid was obtained via Knoevenagel condensation reaction of the aldehydes with cyanoacetic acid in the presence of piperidine. It should be noted that in order to avoid the bromination of triphenylamine, 2Br-NP 1 instead of 1Br-NP 5 was chosen as the starting material for the synthesis of NPS-1 and NPS-4.

![Fig. 1 Molecular structures of the dyes NPS-1–NPS-4.](image)
The electrochemical properties of the dyes were investigated by cyclic voltammetry (CV) in CH$_2$Cl$_2$ solutions. The CV curves are shown in Figure S1 and the relevant data are summarized in Table 1. The HOMOs of NPS-1–NPS-4 corresponding to their first oxidation potentials are 0.71, 0.56, 0.54 and 0.76 V vs. NHE, respectively. It is clear that the dye NPS-2 is oxidized at lower potentials than NPS-1 because the introduction of methoxy groups to triphenylamine improves the electron-donating ability of the dye. Meanwhile, the oxidation potential of NPS-3 is almost the same to NPS-2 implying that the longer thiophene linkers have no obvious influence on the redox properties of the dyes. The estimated excited state potentials corresponding to the LUMO levels, calculated from $E_{HOMO} - E_{0.0}$ were -1.29, -1.43, -1.44 and -1.26 V vs. NHE, respectively. Consequently, we found the LUMO levels of NPS-1–NPS-4 were more negative than the conduction band (CB) of the TiO$_2$ electrode (~0.5 V vs. NHE), indicating that electron injection from the LUMO orbital into the CB of TiO$_2$ is energetically permitted.

To gain an insight into the molecular structure and electron distribution, density functional theory (DFT) calculations were performed at the B3LYP/6-31G* level. The electron distributions of the HOMOs and LUMOs of dyes NPS-1–NPS-4 are shown in Figure S2. The calculation indicates that the HOMOs of four dyes are delocalized over the π-conjugated system of planar NP and triphenylamine. The LUMOs of NPS-1–NPS-3 are delocalized over the cyanoacetic acid and thiophene spacer, whereas the LUMO of NPS-4 is delocalized over the cyanoacetic acid and NP. Accordingly, these observations can facilitate charge migration from the donor to acceptor and efficient electron injection from the dye to the conduction band of TiO$_2$.

The UV-vis absorption spectra of the four organic dyes in CH$_2$Cl$_2$ solution and on TiO$_2$ transparent film are shown in Figure 2 and the corresponding data are summarized in Table 1. All of these dyes exhibit broad and strong absorption bands in the range of 350-700 nm both in solution and on film, which suggests a good electronic delocalization throughout the whole molecular system. $^{12,13}$ Remarkably, the maximum absorption peak of the dyes NPS-1 and NPS-2 are somewhat bathochromic-shifted by 6 and 10 nm from 472 nm in CH$_2$Cl$_2$ solution to 478 and 482 nm on TiO$_2$ film caused by J-aggregates. By contrast, the maximum absorption peak of the dyes NPS-4 is hypsochromic-shifted by 28 from 512 nm in CH$_2$Cl$_2$ solution to 484 on TiO$_2$ film, which could be attributed to either the formation of H-aggregates$^{14}$ or deprotonation of the carboxylic acid.$^{15}$ There is no obvious change between in solution and on solid film for NPS-3, and the maximum absorption peaks are both at 472 nm. Therefore, the incorporation of methoxy groups to triphenylamine has no effect on the absorption spectra. The dye NPS-4 was red-shifted by 40 nm relative to NPS-1–NPS-3 in solution, which can be explained that NP unit directly attached to the cyanoacetic acid brings forth a strengthened intramolecular charge transfer interactions. It should be noted that the molar extinction coefficient of NPS-4 on TiO$_2$ film becomes much higher than others probably due to that the amount of dye NPS-4 loading on TiO$_2$ is higher than other dyes at the same conditions. Comparing the absorption onset of these dyes, there is not a significant bathochromic-shift of absorption thresholds despite the introduction of two methoxy groups and thiophene-conjugated bridge. The band gap energies ($E_{\text{g}}$) of the dyes NPS-1–NPS-4 were 2.00, 1.99, 1.98 and 2.02 eV, respectively, which were calculated from their absorption thresholds of dyes in CH$_2$Cl$_2$ solution.

The DSC devices were fabricated to test the photovoltaic performance of NPSs according to the literature procedure (The method for the cell fabrication is described in the SI). The action spectrum of incident photo-to-current conversion efficiency (IPCE) and the photocurrent density-$V$ curves for the DSCs based on the dyes are illustrated in Figure 3 and the detailed performance parameters are displayed in Table 2. The IPCE for DSCs based on NPS-2$-$NPS-4 exceeds 70% over the spectral region ranging from 400 to 580 nm, and reaches a wide maximum of approximately 71%, 70% and 76% in the 430$-$550 nm range, respectively. The IPCE value of NPS-2 was higher than that of NPS-1 which attributed to the reduced charger combination at the TiO$_2$/dye/electrolyte interface by tailoring two methoxy groups. However, the IPCE of NPS-4 are higher relative to those of NPS-1$-$NPS-3 which maybe be due to the relatively higher molar extinction coefficient in films. Under standard global AM 1.5 solar condition (100 mW cm$^{-2}$), the dye NPS-3 bearing thiophene $\pi$-spacer shows lower $\eta$ values compared to the NPS-2 containing thiophene $\pi$-space. Under the same conditions, the NPS-4 sensitized cell having no thiophene $\pi$-space gave a short-circuit photocurrent density ($J_{sc}$) of 16.50 mA cm$^{-2}$, an open-circuit photovoltage ($V_{oc}$) of 0.734 V, and a fill factor (FF) of 0.684, corresponding to an overall conversion efficiency ($\eta$) of 8.28%. These results imply that NP unit directly attached to the cyanoacetic acid is beneficial to electrons injection into the conduction band ($E_c$) of TiO$_2$ film. Compared to NPS-1, NPS-2 has a larger $J_{sc}$, which originates from the broader IPCE spectra. On the other hand, the $V_{oc}$ of DSCs is relevant to the electronic density of $E_c$ of TiO$_2$. The introduction of methoxy substituents into the structure of NPS-2 could reduce the charge recombination between excited electrons in the $E_c$ and holes located on the redox I$_3^{-}$ and the oxidized state dye, thus improving the $V_{oc}$.

Figure 4 illustrates electron lifetime ($\tau_e$) at different bias potentials for the four sensitizers, and the $\tau_e$ values show a significant gap among the sensitizers, resulting in the decreasing order NPS-4 > NPS-2 > NPS-3 > NPS-1. The influence of dyes on $V_{oc}$ has mostly been attributed to electron lifetime, which is related to factors such as molecular size, and dye adsorption behavior. In our results, the trend of the $\tau_e$ values is well consistent with that of the $V_{oc}$ values.

To summarize, a series of novel metal-free organic sensitizers based on N-annulated perylene derivatives, in which triphenylamine derivatives were introduced as additional electron donor and steric structures, different number of thiophenes as conjugated linkers, and 2-cyanoacetic acid as an electron acceptor, have been designed and synthesized. The methoxy groups introduced to triphenylamine could efficiently reduce charge recombination. Meanwhile, the NP unit directly attached to the acceptor unit of cyanoacetic acid without thiophene $\pi$-space is beneficial to electrons injection into the TiO$_2$ film. The DSCs fabricated with these organic dyes displayed remarkable overall conversion efficiency in a range of 4.90% - 8.28% with the best performance of solar cells based on NPS-4 ($\eta = 8.28\%$, $J_{sc} = 16.50$ mA cm$^{-2}$, $V_{oc} = 0.734$ V, and $ff = 0.684$). We believe that the photovoltaic performance will be greatly improved with further
structure modifications and DSC device optimizations which are ongoing in our laboratory.
