This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Herein we demonstrate redox switchable emission from a sensitized, europium-ferrocene containing, molecular film assembled by a novel nitrene-based strategy. Electrochemical modulation of europium emission upon switching the ferrocene moiety redox state is ascribed to the reversible generation of a quenching ferrocenium species.

The preparation of functional molecular architectures capable of exhibiting well-defined responses under specific conditions requires careful design, and offers significant new opportunities for the further development of molecular electronics, molecular machines and advanced sensory platforms. For many applications, not least those facilitating device integration, it is desirable that such constructs should be effectively immobilised on a solid support. Consequently, the immobilisation of transducing species at interfaces for sensing/switching applications is attracting ever-increasing interest. While signal transduction within such systems may be achieved by a wide range of mechanisms, the incorporation of luminescent species offers a particularly convenient and non-destructive means to report on coordinative, electronic and conformational changes within these architectures. Accordingly, a number of sensing and switching platforms have been developed where a film’s optical response is induced by changes in local conformation, surface potential, or the presence of analytes. Redox modulation of emission affords considerable opportunities for applications in molecular electronic constructs, novel display technologies and even for incorporation as modular components in molecular machines. While there have been a number of examples of redox modulation of absorption at well-defined organic molecular monolayers, examples of luminescence switching in such systems are extremely rare. Luminescent lanthanide species are particularly attractive in this context, offering sharp, well-defined, characteristic fingerprint emission bands, as well as long lifetimes allowing for noise and radiative scattering effects to be reduced by time gating. There have, however, been surprisingly few examples of the incorporation of lanthanide luminescent species into surface bound constructs.

In the current work we demonstrate the electrochemical modulation of emission from lanthanide-containing thin films on gold substrates through redox-mediated switching of a tethered ferrocene/ferrocenium moiety. After assembly of a ferrocene europium dyad at gold interfaces, electrochemical oxidation specifically leads to a reversible reduction in lanthanide phosphorescence. This constitutes, to the best of our knowledge, the first report of redox switching of lanthanide luminescence in a molecular film.

Scheme 1. Summary of the interfaces utilised in this work, showing a schematic representation of photografting of the europium 4-azidophenacyl DO3A (Eu.1), followed by nitrene insertion into ferrocene and benzene terminated monolayers.
The preparation of europium cyclen incorporating surface architectures (SAM,R,Eu) is outlined in Scheme 1. Initially, ferrocene, benzene and trifluorobenzene-terminated interfaces were prepared and characterized as summarized in the supporting information (SI 1 and SI 2). Subsequent photografting of Eu.1, via photogeneration of a reactive nitrene species from the aryl azide, onto the primer layers was carried out. Reactive nitrenes, generated from the photolysis of aryl azides, are well known to insert into aromatic C/H or inert C/F bonds.10 The construction of ferrocene-europium interfaces (SAM,Fc.Eu) was observed and studied by fluorometry, ellipsometry, X-ray photoelectron spectroscopy (XPS) and electrochemistry. After photografting of Eu.1 to the SAM,Fc primer layer the characteristic europium luminescence emission fingerprint was observed upon excitation through the aryl ketone antenna at 350 nm11 (Figure 1 a) with a lifetime of 0.32 ± 0.02 ms; a value markedly lower than that of 0.60 ms determined previously11 for the azide precursor in aqueous solution, and consistent with the proximity of a quenching gold interface.9 No europium emission was seen for controls prepared in the same manner in the absence of irradiation, indicating that generation of the reactive nitrene species is vital for the formation of a stable europium cyclen film. Similarly, the europium 3d XPS signature was only observed after photografting of Eu.1 (SI 3). Voltametrically determined surface concentrations of 3.8 x 10^{-10} mol cm^{-2} for ferrocene at the SAM,Fc.Eu interfaces compare well to the theoretical value of 4.6 x 10^{-10} mol cm^{-2} previously suggested for a close packed monolayer of ferrocene thiol at the interface12 indicating densely packed thiol layers are formed with little loss of electroactivity upon photografting.

Subsequent to assembly and characterisation, spectroelectrochemical analyses were undertaken where europium luminescence emission intensity (at 616 nm, λex = 350 nm) was monitored upon alteration of the potential between a value negative (0 V) of the Ferrocene/Ferrocenium (Fc/Fc+) redox potential (seen at 0.3 V, see Figure 2 insert) and one positive (0.7 V) of that potential. Upon electrochemical oxidation of the surface bound ferrocene to the ferrocenium, a significant decrease (~ 35 %) of the europium emission intensity is observed. Subsequent reduction back to the ferrocene species results in a return of emission intensity (Figure 2, •). To further investigate the origins of reversible quenching, SAM,Ar.Fe.Eu control interfaces were analysed. These interfaces are analogous to the SAM,Fc.Eu surface constructs, incorporating the

[a] controls prepared in the same way as the photografted interfaces but in the absence of irradiation.
same europium-containing moiety at a comparable distance from the surface; crucially, however, this architecture does not incorporate a ferrocene group. The slightly lower emission intensity observed for SAM.Fc.Eu in comparison to the SAM.Ar.Eu interfaces we attribute to the weak quenching effect of the ferrocene in its reduced state\(^\text{15}\) (an effect much less pronounced than that associated with ferrocenium).

\[\text{SAM.Fc.Eu} \quad \begin{array}{c} \text{Sensitization} \\ \text{Energy Loss} \end{array} \quad \begin{array}{c} \text{Oxidation} \\ \text{Reduction} \end{array} \quad \text{SAM.Ar.Eu} \]

Figure 2. Intensity of europium emission (at 616 nm, \(\lambda_{ex} = 350\) nm) upon alternation of potential between 0 V and +0.7 V for the ferrocene-europium dyad interface (SAM.Fc.Eu, ●) and (non-ferrocene incorporating) a europium control interface (SAM.Ar.Eu, ○). For the SAM.Fc.Eu interfaces oxidation of ferrocene to ferrocenium brings about a large (up to 35 %) drop in europium emission intensity. Subsequent reduction back to the ferrocene state brings about a return of emission intensity. A comparable modulation is not seen for the SAM.Ar.Eu control interfaces.

\[\text{SAM.Fc.Eu} \quad \begin{array}{c} \text{Sensitization} \\ \text{Energy Loss} \end{array} \quad \begin{array}{c} \text{Oxidation} \\ \text{Reduction} \end{array} \quad \text{SAM.Ar.Eu} \]

Figure 3. Electrochemical modulation of europium emission proceeds via interconversion between the ferrocene and ferrocenium redox state for the SAM.Fc.Eu surface bound architectures. This is assigned to the quenching of sensitized emission by the ferrocenium moiety.\(^\text{16}\)

† The baseline progressive decrease in emission intensity, for SAM.Fc.Eu interfaces, upon cycling is attributed to a growing and incomplete electrochemical reduction back to the ferrocene state upon cycling (likely to be the result of anion association with the ferrocenium\(^\text{15}\)) and not to photobleaching, a proposal strongly supported by voltammetric analyses (SI 5.) Note that the emission intensity associated with the ferrocenium state is constant and there is no physical film loss from the interface.

# The much smaller modulation observed at SAM.Ar.Eu interfaces could be ascribed to a field induced perturbation of molecular conformation and thus europium – gold optical coupling.
