This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Low-temperature fabrication of brown TiO\textsubscript{2} with enhanced photocatalytic activities under visible light

Mingzheng Wang\textsuperscript{a,b,\#}, Biao Nie\textsuperscript{b,\#}, Ka-Kit Yee\textsuperscript{c}, Haidong Bian\textsuperscript{b,c}, Chris Lee\textsuperscript{b}, Hung Kay Lee\textsuperscript{d}, Bo Zheng\textsuperscript{f}, Jian Lu\textsuperscript{e,f}, Linbao Luo\textsuperscript{a}, Yang Yang Li\textsuperscript{b,e,\*}

Here we report a facile one-step low-temperature solution-based method to treat native TiO\textsubscript{2} with NaH. The NaH treatment effectively induces the Ti(III) species and oxygen vacancies into the TiO\textsubscript{2} host lattice, and enables the absorption edge of TiO\textsubscript{2} to be conveniently adjusted from the UV region to the red end of the visible spectrum.

Titanium oxide (TiO\textsubscript{2}), as a type of widely studied photocatalyst, offers attractive technological advantages, but presents outstanding limitations at the same time. The former includes high stability, low toxicity and wide commercial availability—advantages that are crucial for large-scale applications in energy and environment areas (e.g., electrode material, hydrogen production and water decontamination).\textsuperscript{1} Native forms of TiO\textsubscript{2}, however, have a wide electronic bandgap (e.g., 3.0 and 3.2 eV for rutile and anatase); as a result, only UV or higher-energy photons can be effectively absorbed by native TiO\textsubscript{2}, while the visible light and longer-wavelength photons cannot. As UV light only covers a small fraction (3-5%) of the solar spectrum (the visible/infrared region is dominant), TiO\textsubscript{2} in the native forms is generally not efficient in harnessing solar energy for photocatalytic applications.

Intensive efforts are therefore being made to modify the absorption behaviours of TiO\textsubscript{2}, in order to achieve higher responsiveness to the abundant visible light in the solar spectrum. Several strategies have been reported. One common strategy is to mix in additives or reductants with the titanium compound precursors in the preparative process so that the resultant TiO\textsubscript{2} is doped with Ti\textsuperscript{3+} or other impurity centers.\textsuperscript{2} This can be accomplished using various approaches, e.g., the sol-gel\textsuperscript{2b, 2f, 3} or hydrothermal methods.\textsuperscript{4} Another modification approach that is being intensively investigated is to directly modify native TiO\textsubscript{2}. This is usually done by heating native TiO\textsubscript{2} in a particular atmosphere (e.g., H\textsubscript{2}, NH\textsubscript{3} or N\textsubscript{2}).\textsuperscript{5} By means of thermal treatments, TiO\textsubscript{2} products doped with various impurity atoms (e.g., N),\textsuperscript{5e} self-doped with Ti\textsuperscript{3+} centers\textsuperscript{5a} have been successfully made. Among these, H\textsubscript{2}-thermal treatment\textsuperscript{5a, 5c, 5d, 6a} has lately attracted much attention as a particularly effective method to generate TiO\textsubscript{2} with broader light absorption and outstanding photocatalytic properties in solar or visible light. Mechanisms accounting for absorption edge extension have been suggested to involve the emergence of the Ti\textsuperscript{3+} ions or oxygen vacancies in the H\textsubscript{2}-treated TiO\textsubscript{2} samples.\textsuperscript{5a, 5c, 5d, 6a} In addition, a recent breakthrough reported by Chen et al.\textsuperscript{5b, 5c} pointed to a novel modification mechanism: through the introduction of surface disorders.\textsuperscript{5b, 5c, 6a, 7} In spite of these encouraging progress achieved, the reported hydrogenation procedures generally involve high safety risk due to the application of high-temperature (e.g., 500 °C) or high-pressure (e.g., 20 bar) H\textsubscript{2}.

Here we report a facile solution-based method (the experimental details are shown in ESI) to modify native TiO\textsubscript{2} via treatment with a NaH solution under the mild condition of low temperature (e.g., 150 °C) and atmospheric pressure, thus lowering the safety hazard associated with the reported...
hydrogenation methods that entail high-temperature/pressure H\textsubscript{2}. Using this solution protocol, doped TiO\textsubscript{2} solid samples featuring adjustable absorption edges (from UV to the red light\textsuperscript{4}) and largely enhanced photo-activities in visible light, can be conveniently prepared. In particular, brown-colored (Fig. 1, Fig. S1) TiO\textsubscript{2} solids can be fabricated, adding another hue to the color selection\textsuperscript{2e, 5b, 5c, 6a, 9} of modified TiO\textsubscript{2} products.

Distinct color change from white to brown was readily observed in the above treatment of TiO\textsubscript{2} by NaH (i.e., Sample D; see Fig. 1). The TEM study (Fig. 2a-c) revealed that the particle sizes of native (P-25) and treated (Sample D, shown in Table S1) TiO\textsubscript{2} particles were in the range of 20 \textendash{} 50 nm, whereas the elemental analysis of both samples by EDS (Fig. 2c) suggested a chemical formula consistent with TiO\textsubscript{2} (i.e., the degree of doping was not detectable by EDS).

The commercial native TiO\textsubscript{2} nanoparticles (P-25) possess mixed crystal phases of anatase and rutile with a weight ratio of approximately 4/1. The XRD patterns (Fig. 2d) of P-25 and NaH-treated TiO\textsubscript{2} (Samples A-D) indicated that the crystallinity of the TiO\textsubscript{2} solid was maintained before and after the treatment, with no impurity peaks observed. However, the diffraction peaks of Samples A-D shifted to the larger diffraction angles compared to P-25 (the shift was particularly more apparent for the higher-order peaks), indicating a smaller lattice spacing in the NaH-treated samples. Furthermore, lower peak intensities were observed on the treated TiO\textsubscript{2} (particularly Sample D), suggesting an increased level of defects resulted from the treatment. This observation is in good agreement with the TiO\textsubscript{2} samples doped using other methods.\textsuperscript{5b}

To investigate the chemical environment and states of Ti and O in the treated TiO\textsubscript{2}, XPS measurements were performed. The XPS spectra of native TiO\textsubscript{2} (P-25) (Fig. 3a) and treated (Sample D) TiO\textsubscript{2} (Fig. 3b) indicated that Ti, O elements and a trace amount of C and Na were present in the samples. The high-resolution Ti2p spectra (Fig. 3c) indicated an apparent shift towards the lower energy end for the peaks of NaH-treated TiO\textsubscript{2} (457.2 eV), relative to native TiO\textsubscript{2} (458.6 eV). This observation is thus in line with the presence of Ti\textsuperscript{3+} in the NaH-treated TiO\textsubscript{2} samples, for the major Ti2p peak for Ti\textsuperscript{4+} is normally found at lower energy (around 457.7 eV) than that of Ti\textsuperscript{3+} (459.5 eV).\textsuperscript{5a} Moreover, the XPS study also suggested the formation of oxygen vacancies resulted from the NaH treatment. The O1s spectra (Fig. 3d) distinctly showed a new peak emerging at 531.2 eV, which can be ascribed to the existence of oxygen-vacancy sites nearby Ti\textsuperscript{3+}.\textsuperscript{7} One weak peak located at 1072.7 eV corresponding to the Na1s core levels was observed in the high-resolution Na1s spectrum (inset of Fig. 3b), indicating the presence of Na\textsuperscript{+} in the treated TiO\textsubscript{2} samples.

The UV-Vis diffuse reflectance spectra (Fig. 4a) showed that, comparing to native TiO\textsubscript{2}, the absorption edges of NaH-treated TiO\textsubscript{2} shifted to longer wavelengths in the visible region. The spectrum of native TiO\textsubscript{2} showed a single steep absorption edge around 400 nm corresponding to its bandgap. Clearly, NaH-treated TiO\textsubscript{2} exhibited different optical responses (Fig. 4a, Fig. S2). In particular, Sample D displayed considerable absorption in the visible region between 400 and 700 nm, consistent with its brown-colored appearance.

The Kubelka-Munk function, \( F(R) \), as a function wavelength was derived from the measured diffuse reflectance spectra, based on the Kubelka-Munk equation:\textsuperscript{10}

\[
F(R) = \frac{(1 - R)^2}{2R}
\]

where \( R \) is the ratio of the sample reflectance to the reference reflectance. A Tauc plot [(\( F(R) \cdot h\nu \))\textsuperscript{2/3} vs. \( h\nu \), where \( h\nu \) is the photon energy] was then obtained (Fig. 4b). The absorption edge was determined from the extrapolation of the linear fit for the Tauc plot onto the energy axis. Note that the Tauc plot is commonly used for determining the absorption edge of TiO\textsubscript{2} in literature.\textsuperscript{11} It was estimated that absorption edge is 3.04 eV for native TiO\textsubscript{2} and 2.69, 2.32, 2.11 and 1.82 eV for Samples A-D, respectively (Table S1). Previous studies show that, as the concentration of the Ti\textsuperscript{3+} ions/oxygen vacancies increase, the band tailing becomes more evident and lowered absorption edge is resulted.\textsuperscript{5a, 6a} The gradual lowering of the absorption edge from Samples A to D indicates the gradual increasing concentration of the Ti\textsuperscript{3+} ions/oxygen vacancies in these samples. The finding that P-25 (native TiO\textsubscript{2}) showed a lower absorption edge than the bulk anatase (\( E_g = 3.2 \) eV) is in good agreement with previous studies, and can be ascribed to the fact that that P-25 is mix-phased nanoparticles containing \(~ 25\% \) rutile phase and \( 75\% \) anatase phase.\textsuperscript{12}

A possible reaction mechanism leading to the formation of the Ti\textsuperscript{3+} ions and the oxygen vacancies by the NaH treatment are shown in eqs. 1-3. First, the H\textsuperscript{+} ions supplied by NaH bond
with $\text{Ti}^{4+}$ to form a titanium hydride species $[\text{TiH}]^{3+}$; the $[\text{TiH}]^{3+}$ species then disintegrate to give the $\text{Ti}^{3+}$ centers and H-radicals that readily combine to form $\text{H}_2$ gas. The charge balance is likely maintained by intercalation of Na$^+$ ions into the host lattice of TiO$_2$, generating confined defects featuring local stoichiometry of NaTiO$_2$.

$$\text{Ti}^{4+} + \text{H} \rightarrow [\text{TiH}]^{3+} \quad \text{(1)}$$

$$[\text{TiH}]^{3+} \rightarrow \text{Ti}^{3+} + \cdot\text{H} \quad \text{(2)}$$

$$2 \cdot\text{H} \rightarrow \text{H}_2\text{I} \quad \text{(3)}$$

A comparison between Samples A and D (0.9 eV difference in absorption edge) indicates that the UV irradiation applied during the NaH treatment can result in a markedly lower absorption edge in the treated TiO$_2$ product. Previous studies have shown that trace amount of the Ti(III) species can be produced transiently in irradiated TiO$_2$. The significant impact of UV irradiation observed here could be attributed to the UV-photon generated electrons and holes in TiO$_2$. The photogenerated electron-hole pairs may facilitate the doping process (see eqs. 4-6), e.g., the positive holes generated in the valence band of TiO$_2$ is highly oxidizing, and therefore more readily accepts electrons from the $\cdot\text{H}$ ions compared with the TiO$_2$ system without excitation by UV light. Furthermore, because the electron-hole pairs can be UV-excited not only at the surface layer but also inside the TiO$_2$ lattice, Ti$^{3+}$ can be produced (eq. 5) deeper inside the TiO$_2$ lattice. Comparing to those on the surface, the Ti$^{3+}$ ions inside the TiO$_2$ are likely much less susceptible to oxidation by oxygen, leading to a higher stability of the treated TiO$_2$ when placed in the ambient environment.

$$\text{TiO}_2 + h\nu \rightarrow \text{TiO}_2 + e^-\text{CB} + h^+\text{VB} \quad \text{(4)}$$

$$\text{Ti}^{4+} + e^-\text{CB} \rightarrow \text{Ti}^{3+} \quad \text{(5)}$$

$$h^+\text{VB} + \cdot\text{H} \rightarrow \cdot\text{H} \quad \text{(6)}$$

Comparison between Samples B and D shows that a higher reaction temperature (e.g., by 30 °C) can lead to a substantial reduction of the absorption edge (e.g., by ~0.5 eV). In general, the reductive doping of the very stable TiO$_2$ solid is a slow process. The great effects of higher temperature and UV treatment in lowering the absorption edge of the doped TiO$_2$ product help to highlight the underlying reasons for the success of the current strategy for self-doping TiO$_2$.

To examine the presence and distribution of Ti(III) in the samples, the ESR measurements were carried out. No signal due to the paramagnetic Ti(III) species were observed in the NaH-treated samples (Fig. S3). This can be possibly due to the formation of a di-Ti(III) species, in which the two Ti(III) centers anti-ferromagnetically couple with each other forming a diamagnetic binuclear compound that is EPR silent. For Sample A, a weak signal occurring around 1600 Gauss was observed, which can be attributed to some residual Fe(III) impurities introduced to the system during the sample handling (e.g., from the steel spatula).

Compared with native TiO$_2$, the NaH-treated TiO$_2$ samples all displayed higher ability to photo-degrade phenol, with the degradation rates gradually increasing from Sample A to Sample D (Fig. 4). It is noted that no significant adsorption of the organic molecules onto the samples was observed in darkness (Fig. S4). To explain the higher photo-degradation rate observed on NaH-treated TiO$_2$, a discussion on the photodegradation mechanism is helpful. TiO$_2$ is an n-type semiconductor. For native TiO$_2$ when illuminated with UV photons with energy higher than its bandgap, the photogenerated electrons in the conduction band (CB) can be transferred to the O$_2$ molecules absorbed on the surface of TiO$_2$ and form oxygen radicals, $\cdot\text{O}_2^-$, that can degrade the absorbed organic molecules. For treated TiO$_2$, previous studies indicate that the Ti$^{3+}$ ions/oxygen vacancies induce donor levels in the bandgap (a higher concentration of the Ti$^{3+}$ ions/oxygen vacancies leads to more donor levels in the band gap).
Notably, the enhancement effect on photodegradation under UV irradiation is not as dramatic as under visible illumination (Fig. 4c-d). This is because the photon energies of visible light are insufficient to excite native TiO$_2$ but high enough to excite NaH-treated TiO$_2$. It was found that TiO$_2$ with a lower absorption edge displayed higher photodegrading efficiency, possibly because they utilized a larger portion of the visible spectrum and possessed more donor levels to trap more photo-excited electrons which in turn generate more $\cdot$O$_2^-$. A closer look at Fig. 4d reveals that, under visible illumination, the degradation rate for native TiO$_2$ is very low but slightly higher than when no catalyst was used. It is well known that native TiO$_2$ cannot be excited by visible light because of its wide bandgap. This observed slight photodegradation ability of native TiO$_2$ under the visible light irradiation is possibly caused by the photo-sensitizing capability of the dye molecules which can be excited by the visible light and inject electrons to the conduction band of TiO$_2$.\textsuperscript{14}

The NaH-treated TiO$_2$ samples did not change color after stored in dark in air at room temperature for 6 months. The photocatalytic properties and the performance stability (Fig. S5) of the NaH-treated TiO$_2$ can be potentially further improved by increasing the temperature, time, and UV light intensity used for the NaH treatment. In the second photodegradation test, NaH-treated TiO$_2$ showed reduced activity, although still better than P-25. This activity reduction observed is possibly due to the decreased concentrations of Ti$^{4+}$ and the oxygen vacancies in the samples. Oxygen vacancies and Ti$^{4+}$ are not very stable and can be susceptible to oxidation by the dissolved oxygen molecules in solution.\textsuperscript{13}

In summary, brown-color TiO$_2$ with the absorption edge in red light has been conveniently fabricated using a facile one-step treatment in a NaH solution. The dramatic absorption edge lowering is attributed to the Ti$^{4+}$ ions/oxygen vacancies created by the NaH treatment. The fabricated brown TiO$_2$ showed significantly higher photocatalytic activity than untreated commercial TiO$_2$. The outstanding photocatalytic performance and the great fabrication convenience enabled by the novel method presented in this study open a new route to practical applications of TiO$_2$ under visible light. Besides photodegradation of organic molecules presented here, the NaH-treated TiO$_2$ is potentially promising for solar water splitting applications as well. Furthermore, the method reported here can be potentially applied for modifying other metal oxide semiconductor systems, based on the fact that metal oxide semiconductors generally share similar modification mechanisms.
