Accepted Manuscript

This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this *Accepted Manuscript* with the edited and formatted *Advance Article* as soon as it is available.

You can find more information about *Accepted Manuscripts* in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

**UV photodissociation spectroscopy of cryogenic cooled gas phase
host-guest complex ions of crown ethers**

Abstract:

The geometric and electronic structures of cold host-guest complex ions of crown ethers (CEs) in the gas phase have been investigated by ultraviolet (UV) fragmentation spectroscopy. As host CEs, we chose 15-crown-5 (15C5), 18-crown-6 (18C6), 24-crown-8 (24C8), and dibenzo-24-crown-8 (DB24C8), and as guests protonated-aniline ($\text{aniline}\cdot\text{H}^+$) and protonated-dibenzylamine ($\text{dBAM}\cdot\text{H}^+$) were chosen. The ions generated by an electrospray ionization (ESI) source were cooled in a quadrupole ion-trap (QIT) by cryogenic cooler, and the UV spectra were obtained by UV photodissociation (UVPD) spectroscopy. The UV spectroscopy was complemented by quantum chemical calculations of the most probable complex structures. The UV spectrum of $\text{aniline}\cdot\text{H}^+\cdot\text{CE}$ is very sensitive to the symmetry of CE; $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$ shows sharp electronic spectrum similar to $\text{aniline}\cdot\text{H}^+$, while $\text{aniline}\cdot\text{H}^+\cdot 15\text{C}5$ shows very broad structure with poor Franck-Condon factors. In addition, a remarkable cage effect in the fragmentation process after UV excitation was observed in both complex ions. In the $\text{aniline}\cdot\text{H}^+\cdot\text{CE}$ complexes, the cage effect completely removed the dissociation channels of the $\text{aniline}\cdot\text{H}^+$ moiety. A large difference in the fragmentation yield between $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C}6$ and $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C}8$ was observed due to a large barrier for releasing $\text{dBAM}\cdot\text{H}^+$ from the axis of rotaxane in the latter complex.

Introduction:

Crown ethers (CEs) are macrocyclic ethers built with oxyethylene (-CH₂-CH₂-O-) units. Pedersen synthesized the first crown ether (CE), dibenzo-18-crown-6 (DB18C6) in 1967, and investigated complexation with various metal salts^{1,2} using UV spectroscopy. Since then, CEs have been playing an important role in host-guest and supramolecular chemistry. CEs can include not only metal ions in their cavity but form various complexes with ionic and neutral species through non-covalent interactions. Applications of CEs as molecular receptors, metal cation extraction agents, fluoroionophores and phase transfer catalytic media have been described in a number of studies.³⁻¹⁴ Especially, it is well known that, in condensed phase, CEs exhibit selectivity when they include the guest species.⁹⁻¹⁴ This selectivity is described by the matching between the size of the guest species and that of the CE cavity. On the other hand, the host-guest binding energy measured in the gas phase shows different characteristics from those observed in the condensed phase.¹⁵⁻¹⁷ This discrepancy requires to search more information on the intrinsic nature of CEs, such as flexibility of the CE frame and conformation preference, as well as solvent effects on the stability of the inclusion complexes.

To investigate the difference between condensed phase and gas phase studies and to obtain information on the host-guest interaction at the microscopic level, we have been studying the structures, conformation preference, and selectivity of guests for the inclusion complexes of CEs in the gas phase.¹⁸⁻²⁷ The cold gas phase complexes are generated either in using supersonic expansion technique for neutral complexes¹⁸⁻²⁴ or with electrospray ionization (ESI)/Cold ion-trap method for ionic complexes.²⁴⁻²⁷ We apply various laser spectroscopic methods to measure conformer specific UV and IR

spectra, and the spectra are analyzed by comparing the spectra with those of possible complexes obtained by quantum chemical calculations. Based on these studies, we reported that the conformations of CEs in the inclusion complexes are generally different from the most stable conformer of bare forms, because CEs will change their structures so that they can include the different size and structure of guest species in their cavities.^{20,22,23}

In the present work, we report a study on host-guest complexes of CEs with protonated aromatic amines. CEs can be good receptors of protonated amines since stable complexes can be formed via multiple $\text{NH}\cdots\text{O}$ hydrogen bonds. First, we investigate the inclusion complexes of protonated aniline ($\text{aniline}\cdot\text{H}^+$) with 18-crown-6 (18C6) and 15-crown-5 (15C5). These complexes have the structure in which the NH_3^+ group of $\text{aniline}\cdot\text{H}^+$ (guest) is bonded to 18C6 or 15C5 (host) through $\text{N-H}\cdots\text{O}$ hydrogen bonds. In the previous study, we reported that UV photodissociation (UVPD) of $\text{aniline}\cdot\text{H}^+$ generates aniline^+ and C_6H_5^+ fragment ions.²⁸ Here we examine how the complex formation affects the electronic spectrum of $\text{aniline}\cdot\text{H}^+$ as well as the UVPD pattern. Second, we report the host-guest complexes between protonated dibenzylamine ($\text{dBAM}\cdot\text{H}^+$) with 18C6, 24-crown-8 (24C8), and dibenzo-24-crown-8 (DB24C8). $\text{dBAM}\cdot\text{H}^+$ is used as an axis molecules of rotaxane. Rotaxane molecules have attracted great interest for their potential use in molecular machines, such as molecular switches²⁹⁻³³ and molecular shuttles.³⁴⁻³⁶ In this study, we recorded the UV electronic spectra and the fragmentation yield after UV excitation for the complexes between $\text{dBAM}\cdot\text{H}^+$ and 18C6, 24C8 and DB24C8. We investigate how the complex or rotaxane formation changes the electronic structure of the constituent chromophores and UVPD

pattern by comparing the observed spectra with those of the possible structures obtained by quantum chemical calculations.

Experimental and computational:

Experimental setup

The experimental setup has been described in previous papers.^{28,37,38} The setup consists of three parts: an ESI source, a cryogenically cooled quadrupole-ion-trap (QIT) and a time-of-flight mass spectrometer (TOF-Mass).^{39,40} Protonated ions are produced in the ESI source⁴¹ and trapped in an octopole trap at the exit of the capillary. They are extracted by a negative electric pulse and are further accelerated by a second electric pulse just after the exit electrode. The ions are driven by a couple of electrostatic lenses toward the Paul trap. A mass gate at the entrance of the trap selects the parent ion. The ions are trapped in the Paul trap cooled by a cryostat (Coolpak Oerlikon) and filled with helium buffer gas injected with a pulsed valve. The ions are thermalized at around 30 K while they stay in the trap. After 60 ms, the pump UV laser is introduced to dissociate the cold ions, and after another 30 ms the fragments and remaining parent ions are extracted to the TOF spectrometer and are detected on a microchannel plates (MCP) detector. The UV spectrum is obtained by scanning the laser frequency and recording the ion fragments on the MCP detector. We use an OPO laser (EKSPLA model-NT342B) as the UV light source, and its spectral resolution is 8 cm^{-1} . The unfocused laser is shaped to a 2 mm^2 spot in the trap, corresponding to a power of c.a. 5 mW.

Computational

For the structural calculation of $\text{dBAM}\cdot\text{H}^+$, and complexes of $\text{aniline}\cdot\text{H}^+$ and $\text{dBAM}\cdot\text{H}^+$ with crown ethers, possible conformers were first searched by selecting some initial geometries optimized at the AM1 level⁴², and the obtained structures were optimized with density functional theory calculations using M05-2X/6-31+G*.

To obtain plausible structures for $\text{DB24C8}\cdot\text{H}^+$ and $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ complex, we first used a classical force field to search initial conformations. We performed a Monte Carlo simulation by mixed torsional search with low-mode sampling in MacroModel⁴³ V.9.1 with MMFF94s force field⁴⁴, and optimized the geometries by Polak-Ribiere conjugate gradient algorithm (PRCG) algorithm⁴⁵ with a convergence threshold of 0.05 kJ/mol. From this calculation, 10 isomers for the $\text{DB24C8}\cdot\text{H}^+$ complex and 3 isomers for $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ were obtained within 10 kJ/mol of the most stable one. All these isomers were geometry-optimized by DFT calculations at the M05-2X/6-31+G* level with *loose* optimization criteria. Quantum chemical calculations were performed in the Gaussian 09 program package.⁴⁶

Synthesis of materials

Dibenzylammonium hexafluorophosphate ($\text{dBAM}\cdot\text{H}^+\cdot\text{PF}_6^-$): $\text{dBAM}\cdot\text{H}^+\cdot\text{PF}_6^-$ was synthesized by a previously reported procedure by Ashton et al.⁴⁷ Aqueous hydrogen chloride (1 mol L⁻¹, 26.1 mL) was added to dibenzylamine (26.1 mmol), and the solution was stirred for 1.5 h at room temperature. The solvent was removed under vacuum and the residue was dissolved in hot deionized water (100 mL, 70 °C). Saturated aqueous ammonium hexafluorophosphate was added until no further precipitation occurred. The white solid was filtered off and dried to afford the desired

product 8.34 g (93 %).

Pseudo-rotaxanes: $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24}\cdot\text{PF}_6^-$ was prepared from DB24C8 and $\text{dBAM}\cdot\text{H}^+\cdot\text{PF}_6^-$. DB24C8 (100 mg, 0.222 mmol) was dissolved in chloroform (10 mL), and then $\text{dBAM}\cdot\text{H}^+\cdot\text{PF}_6^-$ salt (76.6 mg, 0.223 mmol) was added. After being stirred for 1h at room temperature, the mixture was concentrated in *vacuo* to afford the pseudo-rotaxane 167 mg (94 %) as a white solid.

$\text{dBAM}\cdot\text{H}^+\cdot\text{24C8}\cdot\text{PF}_6^-$ was prepared from 24C8 and $\text{dBAM}\cdot\text{H}^+\cdot\text{PF}_6^-$. 24C8 (72.0 mg, 0.204 mmol) was dissolved in chloroform (5 mL), and then $\text{dBAM}\cdot\text{H}^+\cdot\text{PF}_6^-$ salt (70.1 mg, 0.204 mmol) was added. After being stirred for 0.5 h at room temperature, the mixture was concentrated in *vacuo* to afford the pseudo-rotaxane 132 mg (93 %) as a white solid.

The rotaxane formation was confirmed using $\text{dBAM}\cdot\text{H}^+$ NMR spectroscopy. The catechol protons split two resonances, one of which was slightly upfield-shifted. Two sets of the oxymethylene protons of DB24C8 showed the up-field shifts of 0.16 and 0.05 ppm, respectively. Two benzene rings of bound $\text{dBAM}\cdot\text{H}^+\cdot\text{PF}_6^-$ face one another as found in the crystal structure. The crown moiety is placed within the cleft of the benzene rings; therefore, the aromatic shielding most likely resulted in the up-field shifts of the crown protons. The similar chemical shift change was observed in the ^1H NMR spectrum of $\text{dBAM}\cdot\text{H}^+\cdot\text{24C8}\cdot\text{PF}_6^-$. The oxyethylene protons of 24C8 showed the up-field shift of 0.19 ppm. These evidences are consistent with those reported by Ashton et al.⁴⁷

Results and discussion

1. Protonated aniline • crown ether complex ion

Left panel of Fig. 1 shows the UVPD spectra of (a) aniline•H⁺, (b) aniline•H⁺•18C6, and (c) aniline•H⁺•15C5 ions in the 35000–44000 cm⁻¹ region. The excess proton in aniline•H⁺ is attached to the amino group, forming the anilinium ion, C₆H₅NH₃⁺. The right panel of Fig. 1 shows the time of flight (TOF) spectra of aniline•H⁺ without (blue) and with UV (red) laser irradiation. As seen in the figure, the main photofragment ions for aniline•H⁺ are aniline⁺ ($m/z = 93$) and C₆H₅⁺ ($m/z = 77$), produced by H atom loss of or NH₃ loss, respectively.⁴⁵ The UVPD spectrum of the aniline•H⁺ ion shows a band origin at 38215 cm⁻¹, which is ~4200 cm⁻¹ blue-shifted as compared to the transition origin of neutral aniline (34027 cm⁻¹).⁴⁸ This blue shift between the transitions of ionic and neutral species is the largest observed for the systems investigated here. It can be assigned to the deconjugation of the nitrogen lone pair when H⁺ attaches to the amino group so that aniline•H⁺ has a toluene like electronic structure (the (0,0) band of the toluene S₁-S₀ transition is located at 37477 cm⁻¹).^{46,49} A progression on a mode of ~920 cm⁻¹ can be followed starting from the band origin, as shown with solid lines in Fig. 1a, which is assigned to the ring breathing mode (mode 1).⁵⁰ This frequency is closer to that of neutral toluene (935 cm⁻¹) than that of aniline (952 cm⁻¹).

In the case of the aniline•H⁺•18C6 complex, two sharp bands are observed at 38565 and 38640 cm⁻¹ (Fig. 1b). Since one cannot see any strong band or progression around these two bands, they may probably be ascribed to the origin band of two different isomers. The position of the origin bands is much closer to that of aniline•H⁺ than to that of neutral aniline, thus the proton is still located on the amino group of the aniline part. The UVPD spectrum of aniline•H⁺•18C6 also shows a progression with an interval

of $\sim 920\text{ cm}^{-1}$ similar to $\text{aniline}\cdot\text{H}^+$ as highlighted by solid lines in Fig. 1b, although the transitions to higher vibrational levels show broadened features. Since the frequency of the ring breathing mode is almost the same for $\text{aniline}\cdot\text{H}^+$ and $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$ ions, the benzene ring in the $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$ ion seems not to be strongly affected by the 18C6 part. The right panel of Fig. 1 shows the TOF spectra of $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$. We find the fragment pattern is quite different from that of $\text{aniline}\cdot\text{H}^+$. Three photofragment ions are observed for $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$; $18\text{C}6\cdot\text{H}^+$ ($m/z = 265$), $(\text{OCH}_2\text{CH}_2)_4\cdot\text{H}^+$ ($m/z = 177$), and $(\text{OCH}_2\text{CH}_2)_3\cdot\text{H}^+$ ($m/z = 133$); no fragment ion due to the dissociation of the $\text{aniline}\cdot\text{H}^+$ part, H loss (dissociation of an NH bond) or NH_3 loss (dissociation of the CN bond), is seen. The CN bond breaking observed in the UVPD of $\text{aniline}\cdot\text{H}^+$ could lead to formation of the $\text{CE}\cdot\text{NH}_3^+$ fragment, but is not observed either. The fragmentation pattern rather indicates that a proton transfer occurs from $\text{aniline}\cdot\text{H}^+$ to 18C6 after the UV excitation, and the excess energy initially injected in the $\text{aniline}\cdot\text{H}^+$ part efficiently flows to the 18C6 part. After UV excitation, the $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$ complex may relax to the ground state and transfer a proton and energy to the 18C6 part, leading to fragmentation in aniline and $18\text{C}6\cdot\text{H}^+$. $18\text{C}6\cdot\text{H}^+$ has enough internal energy to further fragment into $(\text{OCH}_2\text{CH}_2)_4\cdot\text{H}^+$ or $(\text{OCH}_2\text{CH}_2)_3\cdot\text{H}^+$ as observed. Thus, 18C6 has a role of reservoir of energy; the energy initially imparted by the optical excitation into electronic and vibrational energy of the aniline part is transferred to 18C6, a kind of cage effect. As shown in Fig. 1S in the Supporting Information, the intensity of the $(\text{OCH}_2\text{CH}_2)_4\cdot\text{H}^+$ fragment ion becomes stronger than that of $18\text{C}6\cdot\text{H}^+$ with increasing the UV photon energy; the formation of $(\text{OCH}_2\text{CH}_2)_4\cdot\text{H}^+$ requires more energy than that of $18\text{C}6\cdot\text{H}^+$ and the fragmentation occurs statistically after the proton and energy transfer from $\text{aniline}\cdot\text{H}^+$ to 18C6.

In contrast to aniline•H⁺ and aniline•H⁺•18C6, the UVPD spectrum of aniline•H⁺•15C5 (Fig. 1c) shows a broad absorption in the region of 39000–44000 cm⁻¹. In aniline•H⁺•15C5, the proton is attached to the NH₂ group of the aniline part as in aniline•H⁺•18C6. However, the UV spectrum of the aniline•H⁺•15C5 ion is quite different from that of aniline•H⁺•18C6, which may imply poor Franck-Condon overlap between the S₀ and S₁ states.

Fig. 2 shows the typical structures of (a) aniline•H⁺•18C6 and (b) aniline•H⁺•15C5 complexes. In the aniline•H⁺•18C6 complex, the NH₃⁺ group is bonded to 18C6 through three N–H•••O hydrogen bonds as was expected. This intermolecular bond seems to result in effective proton transfer from aniline•H⁺ to 18C6 after the UV excitation. The H•••O distances are almost the same (~1.83 Å) for all the three hydrogen bonds; the 18C6 cavity seems well fitted to the NH₃⁺ group. The 18C6 component and the aromatic ring are located apart, so that there is no strong intermolecular interaction between 18C6 and the benzene ring, which is consistent with the similar frequency observed in the UVPD spectra of aniline•H⁺ and aniline•H⁺•18C6 ions for the benzene breathing-mode. The proton transfer from aniline•H⁺ to 18C6 after UV excitation of the complex is understood in terms of larger proton affinity (PA) of the crown ether (967.0 kJ/mol) than that of aniline (882.5 kJ/mol).⁵¹ After UV excitation, the proton transfer occurs from aniline•H⁺ to 18C6 in the S₁ excited state of the complex or after the relaxation to S₀ by internal conversion (IC).

Fig. 1. (left) UVPD spectra: (a) $\text{aniline}\cdot\text{H}^+$, (b) $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$, and (c) $\text{aniline}\cdot\text{H}^+\cdot 15\text{C}5$. (right) TOF spectra of $\text{aniline}\cdot\text{H}^+$ and $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$, without UV irradiation (blue) and with UV irradiation fixed at the band origins (red). The solid black lines in figure 1a and 1b show the progression with an interval of $\sim 920 \text{ cm}^{-1}$ assigned to the ring breathing mode.

For the $\text{aniline}\cdot\text{H}^+\cdot 15\text{C}5$ complex, the proton is also initially situated on the aniline molecule, and the $\text{aniline}\cdot\text{H}^+$ ion is bonded to 15C5 through two $\text{N}\text{--}\text{H}\cdots\text{O}$ hydrogen bonds, instead of three H-bonds in $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$. The PA of 15C5 is 943.8 kJ/mol ,⁴⁸ larger than that of aniline; thus, after UV excitation, the proton of $\text{aniline}\cdot\text{H}^+$ is also transferred to 15C5. The difference in the UV spectral patterns between the $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$ and $\text{aniline}\cdot\text{H}^+\cdot 15\text{C}5$ ions can be assigned to the asymmetry of the hydrogen bond network in the $\text{aniline}\cdot\text{H}^+\cdot 15\text{C}5$ ion that distorts the structure of the complex and leads to a change in geometry between the ground and excited states, which results in poor Franck-Condon overlap in the UVPD spectrum (Fig. 2b). Another possibility to explain the broad feature of the UV spectrum of $\text{aniline}\cdot\text{H}^+\cdot 15\text{C}5$ is the

coexistence of other isomer(s) in aniline•H⁺•15C5. Pasker *et al.* investigated aniline•H⁺ and its complexes by infrared photo-dissociation (IRPD) spectroscopy and theoretical calculations,⁵² and reported that aniline•H⁺ has two almost equally stable isomers, the ammonium and carbenium isomers, and that their relative population changes with complexation. It may be possible that the asymmetrical hydrogen-bonding of the aniline•H⁺•15C5 complex induces a larger population of the carbenium isomers, which should have different vibronic structures than the ammonium type isomer. However, calculations show that the ground state carbenium complex with 15C5 is more than 1 eV higher in energy than the anilinium•15C5 complex, because in the carbenium ion the positive charge is largely delocalized whereas in the ammonium ion the charge is well localized on the ammonium group.

The UV excitation does not produce any fragment ion via the loss of H atom or NH₃ loss neither in aniline•H⁺•18C6 nor in aniline•H⁺•15C5, which differs from the UVPD of bare aniline•H⁺. The crown ether induced cage effect on the fragmentation of anilinium is surprising. While it is easy to understand that the cage will suppress the H loss channel from anilinium, the absence of the NH₃ loss channel, which is one of the major fragments in the anilinium ion, is unexpected. This is in contrast to the protonated tryptamine case in which the C-NH₃ bond breaking is observed in both the free ion⁵³ and in the complex with 18C6.⁵⁴ In the complex, this fragmentation channel was assigned to an excited state dissociation, which thus seems absent in anilinium•CE complexes.

Fig. 2. Typical stable geometries of (a) aniline•H⁺•18C6 and (b) aniline•H⁺•15C5.

2. Protonated dibenzylamine (dBAM•H⁺)

Protonated dibenzylamine (dBAM•H⁺) is used as an axis molecule in pseudo rotaxane. We investigate how the rotaxane formation affects the electronic transition of dBAM•H⁺. Fig. 3 shows the UVPD spectrum of dBAM•H⁺ obtained by monitoring the $m/z = 107$ (C₇NH₉⁺) major fragment. The spectrum is essentially the same as that reported in our previous paper,³⁸ except the spectrum is recorded in a wider energy region. A sharp (0,0) band appears at 37450 cm⁻¹ (band A) along with several sharp vibronic bands involving torsional mode (170 cm⁻¹) and skeletal modes (550, 745, 930 and 1540 cm⁻¹). The vibronic structure corresponding to skeletal modes is very similar to that of aniline•H⁺. Additionally, a weak band (band B) is observed at 70 cm⁻¹ on the lower frequency side of band A. We investigated the temperature dependence of bands A and B, and found that the relative intensity of band B with respect to band A increases

with the increase of the temperature of the trap (See Supporting Material Fig. 2S). Thus band B is due either to a hot band or to a higher energy conformer (open conformer).

Fig. 3. UVPD spectrum of cold protonated dibenzylamine ($\text{dBAM}\cdot\text{H}^+$) in the gas phase.

Possible structures of $\text{dBAM}\cdot\text{H}^+$ have been investigated by DFT calculations at the M05-2X/6-31G* level. Three stable conformers were obtained: (1) open conformer, (2) twisted conformer, and (3) stacked conformer as shown in Fig. 4. Table 1 shows their relative ground state and vertical excitation energies. Conformers (1) and (2) have very similar ground state energies; conformer (2) being 4.3 kJ/mol higher than conformer (1) without zero point energy (ZPE) correction. Conformer (3) has a higher energy (85.4 kJ/mol), and is not expected to be present in the trap. Since $\text{dBAM}\cdot\text{H}^+$ has two benzene chromophores, we expect two closely lying electronic states, S_1 and S_2 , corresponding to the excitation of each of the two chromophores. In the UVPD spectrum, a strong band A and weak band B are observed. Since they show different temperature dependence, band A can be assigned to the most stable open conformer and band B to the twisted conformer. Table 1 also lists the vertical excitation energies to S_1 and S_2 states and their oscillator strengths calculated by TD-DFT calculation at the M05-2X/6-31G* level. As seen in Table 1, S_1 and S_2 states are located at almost the

same energy for the open and twisted conformers, and the oscillator strength of the S_1 - S_0 transition of the open conformer is zero, which is due to the cancellation of the transition dipoles of the constituent two benzene chromophores. The calculated results are in accordance with the observation of a single band origin, band A, in the UVPD spectrum corresponding to the open conformer, and a weak band B corresponding to the twisted conformer.

Fig. 4 Optimized structures of $\text{dBAM}\cdot\text{H}^+$ conformers at the M05-2X/6-31G* level.

Table 1. Relative ground state stabilization energies (kJ/mol), vertical excitation energies (eV) and oscillator strength (parentheses) for the three $\text{dBAM}\cdot\text{H}^+$ conformers calculated at the M05-2X/6-31G* level.

Conformer	open	twisted	stacked
S_0 (kJ/mol)	0	4.3	85.4
S_1 (eV)	5.57(0.0)	5.56(2.0E-4)	4.93(0.0)
S_2 (eV)	5.58(9.8E-3)	5.57(8.1E-3)	5.12(3.9E-2)

3. Complexes of $\text{dBAM}\cdot\text{H}^+$ with 18C6 and 24C8

$\text{dBAM}\cdot\text{H}^+$ does not go through the 18C6 ring due to steric hindrance, but $\text{dBAM}\cdot\text{H}^+$ can go through the 24C8 ring to form a pseudo-rotaxane.⁴⁷ So, we investigated how the difference of complex structure will be reflected in the UV spectra and fragmentation yields of the two complexes.

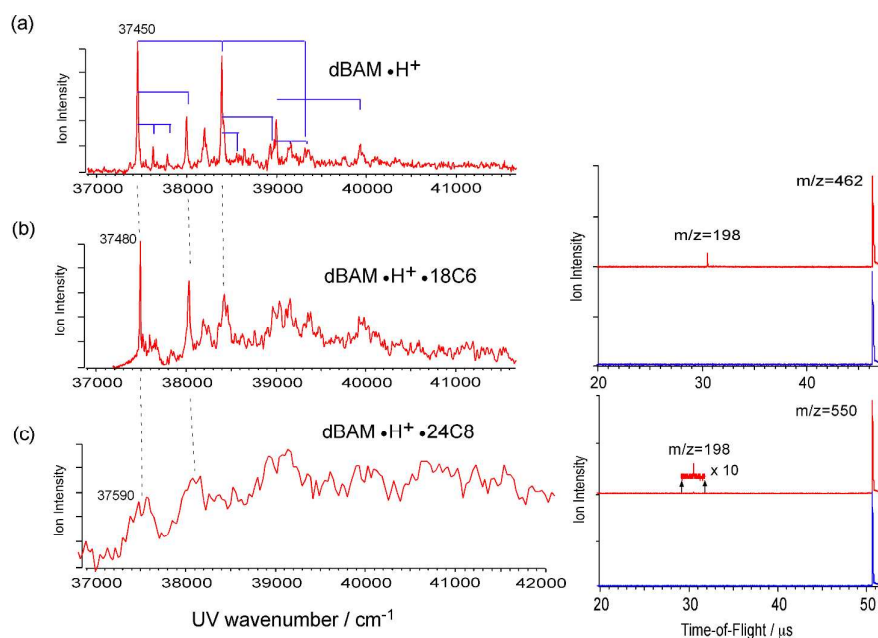

Fig. 5. (a) UVPD spectrum of $\text{dBAM}\cdot\text{H}^+$. (b) (left) UVPD spectrum of $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C}6$. (right) TOF spectrum without UV irradiation (blue) and with UV fixed at 37481 cm^{-1} (red). The ion intensity is normalized relative to that of parent ion intensity. (c) (left) UVPD spectrum of $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C}8$. (right) TOF spectrum without UV irradiation (blue) and with UV fixed at 37594 cm^{-1} (red). The ion intensity is normalized relative to that of parent ion intensity.

Figs. 5b and 5c show the UVPD spectra of $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C}6$ and $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C}8$ complex ions. At the opposite of the $\text{aniline}\cdot\text{H}^+\cdot 18\text{C}6$ UVPD, we observed $\text{dBAM}\cdot\text{H}^+$ fragment ions ($m/z = 198$) instead of $\text{CE}\cdot\text{H}^+$ in both cases (see the TOF spectra on the right panels of Fig. 5), and the UVPD spectra are recorded by monitoring the $\text{dBAM}\cdot\text{H}^+$ fragment in both cases. The PA value of dBAM is not known, but that of benzylamine is reported to be 913 kJ/mol . Since we do not observe the $18\text{C}6\cdot\text{H}^+$ fragment, the PA of

dBAM should be larger than that of 18C6 (967 kJ/mol). The UVPD spectra of $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ and $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ are compared to the UVPD spectrum of $\text{dBAM}\cdot\text{H}^+$ (Fig. 5a). The (0,0) band of $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ is located at 37481 cm^{-1} , 28 cm^{-1} blue-shifted from $\text{dBAM}\cdot\text{H}^+$ and the overall structure of the spectrum is very similar to that of $\text{dBAM}\cdot\text{H}^+$ except that higher vibronic bands are broadened. This situation is the same as between $\text{aniline}\cdot\text{H}^+$ and $\text{aniline}\cdot\text{H}^+\cdot 18\text{C6}$. The UVPD spectrum of $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ is much weaker and broader and its band origin is located at around 37590 cm^{-1} . Thus, the difference in the complex structure between $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ and $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ is not reflected in the electronic transition origins, which are almost the same, but in the width of the vibronic structures. However, the main difference is observed in the UV photo-fragmentation yield. The right panels of Figs. 5b and 5c show the TOF spectra of $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ and $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ with and without the photodissociation laser, the UV frequency being fixed on the band origin of each complex. By comparing the two TOF spectra, the relative fragmentation yield giving $\text{dBAM}\cdot\text{H}^+$ from $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ is much larger than that from $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ under the same UV laser power conditions. Since the UV absorption cross sections are similar between $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ (calculated oscillator strength of 1.4×10^{-3}) and $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ complexes (oscillator strength 2×10^{-3}), the small fragmentation yield in the latter case is assigned to a barrier for releasing $\text{dBAM}\cdot\text{H}^+$ from the 24C8 cavity in the $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ pseudo rotaxane.

It is very difficult to determine the structures of $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ and $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ from the electronic spectra. However, the number of possible isomers should be reduced because of the low temperature of the trap (30 K). Actually, as seen in Fig. 5b, the UVPD spectrum of $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ shows a single sharp band origin.

Thus, by assuming that the oscillator strengths of the conformers are not different so much from each other, only one major conformer is observed under the present conditions. Fig. 6 shows typical ground state optimized structures for (a) $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ and (b) $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$. For $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$, a twisted shaped $\text{dBAM}\cdot\text{H}^+$ is attached above 18C6 and bound to two ether oxygen atoms via $\text{NH}\cdots\text{O}$ H-bonds. In the $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ complex, on the other hand, $\text{dBAM}\cdot\text{H}^+$ goes through the 24C8 cavity forming pseudo-rotaxane. The calculated binding energy is 236 kJ/mol for $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$, and 264 kJ/mol for $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ at the M05-2X/6-31G* level with BSSE correction. Thus, though the binding energy is not so different between $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ and $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$, the low fragmentation yield of $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ may come from a larger barrier for $\text{dBAM}\cdot\text{H}^+$ to be released from the 24C8 cavity.

Fig. 6. Optimized structures of (a) $\text{dBAM}\cdot\text{H}^+\cdot 18\text{C6}$ and (b) $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C8}$ complexes at the M05-2X/6-31G* level of calculation.

4. $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ pseudo-rotaxane

Fig. 7b shows the UVPD spectrum of $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ pseudo-rotaxane measured at 30 K. The spectrum is compared with that of $\text{dBAM}\cdot\text{H}^+$ (Fig. 7a), and $\text{DB24C8}\cdot\text{H}^+$ (Fig. 7c), respectively. The spectrum of $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ shows broad

structures with a band origin at $\sim 36350\text{ cm}^{-1}$. It is not clear whether the broadness is due to the overlap of the transitions of several coexisting isomers or to spectral congestion due to low vibrational modes. The first band is more than 1000 cm^{-1} red-shifted as compared to the (0,0) transition of $\text{dBAM}\cdot\text{H}^+$, and is rather close to the (0,0) band of $\text{DB24C8}\cdot\text{H}^+$ (36050 cm^{-1}). This suggests that the electronic transition of $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ in this region is not due to $\text{dBAM}\cdot\text{H}^+$ but to DB24C8 or $\text{DB24C8}\cdot\text{H}^+$. For comparison, Fig. 7d shows the laser induced fluorescence spectrum of the S_1 - S_0 transition of jet-cooled neutral DB24C8 in the band origin region. For neutral DB24C8 , two different conformers were identified at 35195 and 35408 cm^{-1} , which were assigned to the chair and boat forms, respectively.²¹ The S_1 - S_0 electronic transition of $\text{DB24C8}\cdot\text{H}^+$ is roughly 800 cm^{-1} blue-shifted with respect to that of neutral DB24C8 . Thus, the spectrum of $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ in this region is assigned to excitation of the $\text{DB24C8}\cdot\text{H}^+$ chromophore. The intensity of the $\text{dBAM}\cdot\text{H}^+$ fragment at $m/z = 198$ from the $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ photodissociation is 10–20 times larger than from the $\text{dBAM}\cdot\text{H}^+\cdot\text{24C8}$ photodissociation although these complexes have similar pseudo-rotaxane structures. The difference is due to the larger absorption cross-section of the $\text{DB24C8}\cdot\text{H}^+$ chromophore as compared to the dBAMH^+ absorption, as will be discussed later (Table 2).

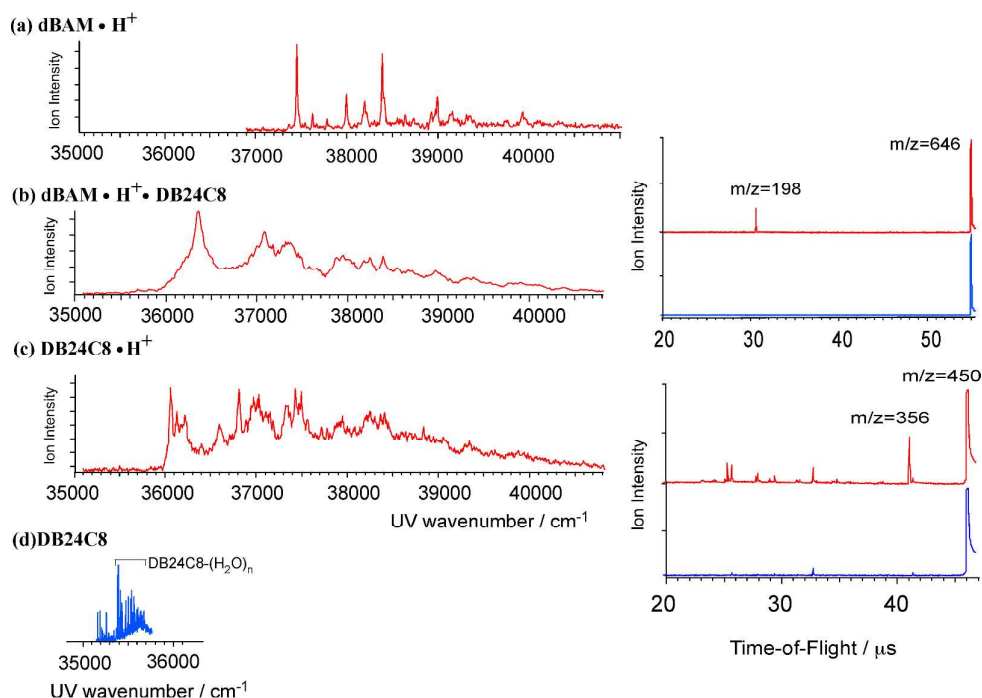

Fig. 7. (a) UVPD spectrum of $\text{dBAM}\cdot\text{H}^+$. (b) (left) UVPD spectrum of $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$. (right) TOF spectrum of $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ without UV irradiation (blue) and with UV fixed at 36350 cm^{-1} (red). The ion intensity is normalized relative to that of parent ion intensity. (c) (left) UVPD spectrum of $\text{DB24C8}\cdot\text{H}^+$ observed by monitoring $m/z = 356$ fragment ion. (right) TOF spectrum of $\text{DB24C8}\cdot\text{H}^+$ without UV irradiation (blue) and with UV fixed at 36050 cm^{-1} (red). The intensity of $\text{DB24C8}\cdot\text{H}^+$ is largely out of scale to expand the weak fragment ion signals. (d) LIF spectrum of DB24C8 in a supersonic jet.

We calculated possible initial structures of $\text{DB24C8}\cdot\text{H}^+$ and $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ by MMF calculations further optimized with DFT calculations at the M05-2X/6-31+G* level. Fig. 8 shows the two most stable structures of $\text{DB24C8}\cdot\text{H}^+$. Other conformers are more than 2.6 kJ/mol higher in energy and their structures are shown in Fig. S3. In isomer 1, a proton is bound in a bifurcated manner to two ether oxygen atoms, one of which is adjacent to a benzene ring. Isomer 2 has a covalent O-H⁺ bond and the proton is H-bonded to an opposite ether oxygen. The $\text{DB24C8}\cdot\text{H}^+$ S_1 - S_0 electronic transition is more than 800 cm^{-1} blue-shifted as compared to the neutral DB24C8 transition, which is

compatible with the structure of isomer 1, because its electronic transition should be most affected by the proton binding to the oxygen atom adjacent to one benzene ring in this structure. Fig. 9 shows the most stable structure calculated for the $\text{dBAM}\cdot\text{H}^+\cdot\text{DB24C8}$ complex. The next stable isomer is more than 5 kJ/mol higher in energy (See Fig. S4 in Supporting Information). In the most stable structure, DB24C8 has a boat-structure and the benzene rings form quasi π - π stacking structure with one of the dBAM benzene rings. In addition, one NH bond of dBAM is H-bonded to an oxygen atom adjacent to a DB24C8 benzene ring. This situation is essentially the same as in the most stable structure (Isomer 1) of $\text{DB24C8}\cdot\text{H}^+$.

Fig. 8. Two lowest energy isomers of $\text{DB24C8}\cdot\text{H}^+$ obtained at the M05-2X/6-31+G* level of calculation. Hydrogen-bonds are shown as dotted lines.

Fig. 9. Most stable structure of dBAM•H⁺•DB24C8 pseudo-rotaxane obtained at the M05-2X/6-31+G* level of calculation. Hydrogen bonds between NH and oxygen atom of CE are shown as dotted lines.

The vertical excitation energies and oscillator strengths for the most stable structures of dBAM•H⁺, neutral DB24C8, DB24C8•H⁺ and dBAM•H⁺•DB24C8 obtained at the M05-2X/ 6-31G* level are compared in Table 2. When we compare the S₁-S₀ electronic transition energies of DB24C8 and DB24C8•H⁺, and dBAM•H⁺, we see that of DB24C8•H⁺ is located between those of DB24C8 and dBAM•H⁺, which is in good agreement with the observed relationship of the UVPD spectra of Fig. 7. In addition, the S₁-S₀ and S₂-S₀ oscillator strengths of DB24C8•H⁺ are ~5 times larger than the dBAM•H⁺ oscillator strength, which also agrees with the observed larger photo-fragmentation yield of dBAM•H⁺•DB24C8 as compared to that of dBAM•H⁺•24C8.

Table 2. Vertical excitation energies (eV) and oscillator strengths (parentheses) of dBAM•H⁺, DB24C8, DB24C8•H⁺ and dBAM•H⁺•dB24C8 rotaxane calculated at the M05-2X/6-31G* level.

	dBAM•H ⁺ (Open)	DB24C8	DB24C8•H ⁺	dBAM•H ⁺ •DB24C8
S ₁	5.58 (0.0)	5.35 (6.4E-2)	5.42 (4.2E-2)	5.33 (4.7E-2)
S ₂	5.59 (9.8E-3)	5.39 (5.0E-2)	5.55 (1.3E-2)	5.40 (4.9E-2)

Conclusion

In summary, we investigated the geometrical and electronic structures of the complexes of protonated aniline (aniline•H⁺) and dibenzylamine (dBAM•H⁺) with crown ethers (CEs) of different cavity size, 15C5, 18C6, 24C8, and DB24C8. The aniline•H⁺ complexes with 15C5 and 18C6, have a structure in which the proton is located on the aniline part. After UV excitation, the complexes relax to the ground electronic state and the proton is transferred from the aniline part to the CE moiety producing the protonated CE fragments. The cage effect here completely removes the dissociation channels of the aniline•H⁺ moiety, which is different from what was observed for the tryptamine•H⁺•18C6 complex. In addition, the UV spectrum of aniline•H⁺•CE is very sensitive to the symmetry of CE; aniline•H⁺•18C6 shows sharp electronic spectrum similar to aniline•H⁺, while that of aniline•H⁺•15C5 shows very broad structure with poor Franck-Condon factors.

For the dBAM•H⁺ complexes with CE, the proton is always located on dBAM. However, CE has a role of proton acceptor, leading to the blue-shift of electronic transition. Actually, in the case of DB24C8, the transition of DB24C8 moiety of dBAM•H⁺•DB24C8 is ~ 800 cm⁻¹ blue-shifted compared to neutral DB24C8.

A large difference in the fragmentation yield between dBAM•H⁺•18C6 and dBAM•H⁺•24C8 was found due to a large barrier for releasing dBAM•H⁺ from the axis

of rotaxane. Whereas in $\text{dBAM}\cdot\text{H}^+\cdot 24\text{C}8$ the excitation is on the dBAMH^+ moiety, in $\text{dBAM}\cdot\text{H}^+\cdot\text{DB}24\text{C}8$ the initial excitation is on the $\text{DB}24\text{C}8\text{H}^+$ part and the fragmentation yield is larger in this latter case due to a larger oscillator strength. For further details on the structure of the complexes including the position of the proton, the IR spectrum in the NH and OH region should be measured, which will be the future work.
