ABSTRACT

We study the correlation of wetting properties and corrosion rates on hydrophobized cast iron. Samples of different surface roughness (abraded by sandpaper) are studied without coating and with two types of hydrophobic coatings (acetic acid and a liquid repelling spray). The contact angles and contact angle hysteresis are measured with a goniometer while corrosion rates are measured by a potentiodynamic polarization test. The data shows a decrease in corrosion current density and an increase in corrosion potential after superhydrophobization. A similar trend is found also in the recent literature data. We conclude that the decrease in the corrosion rate can be attributed to the changing open circuit potential of a coated surface and increased surface area.
making the non-homogeneous (Cassie-Baxter) state possible. We interpret these results in light of the idea that the inherent surface energy is coupled with the electric potential in accordance with the Lippmann law of electrowetting and Le Châtelier’s principle and, therefore, hydrophobization leads to a decrease in the corrosion potential. The approach can be used for novel anti-corrosive coatings.

**KEYWORDS.** Superhydrophobicity, corrosion resistant, wetting, roughness, corrosion current, corrosion potential.

**Table of contents entry**

The decrease in the corrosion rate is interpreted in light of Le Châtelier’s principle. Hydrophobization leads to decrease in the corrosion potential.
INTRODUCTION

Corrosion of metals is a highly undesirable process since it damages metallic materials used for various components leading to their gradual destruction. Consequently, various types of anti-corrosive coatings have been developed, including ones which prevents the contact of the material with corrosive environment, such as aqueous solutions. A relatively new type of coating which repel water and aqueous solutions is the superhydrophobic coating which modifies wetting properties of a material.¹

Contact angle (CA) is the main parameter characterizing wetting of a solid surface by a liquid, usually, water. Hydrophilic surfaces have water CA less than 90° while hydrophobic surfaces have water CA greater than 90°. For an ideally smooth homogenous surface, the equilibrium CA ($\theta_0$) of a liquid droplet (say, of water) is given by the Young equation $\cos \theta_0 = \frac{\gamma_{SA} - \gamma_{SW}}{\gamma_{WA}}$ where $\gamma_{SA}$, $\gamma_{SW}$, and $\gamma_{WA}$ are the surface free energies of the solid-air, solid-water, and water-air interfaces.² However on real surfaces, which are rough and heterogeneous, the contact angle is different from the equilibrium value.³ The effect of roughness and chemically heterogeneity on CA is incorporated into two well-known models of wetting, namely the Wenzel⁴ and Cassie-Baxter⁵ models. According to the Wenzel model, the effective contact angle of a rough surface is given by

$$\cos \theta_w = R_f \cos \theta_0$$  (1)

where the so-called roughness factor $R_f \geq 1$ is the ratio of the solid surface area to the projected area. In the Wenzel wetting state, the surface below the droplet is completely wetted by the liquid, creating a homogenous solid-liquid interface. The Cassie-Baxter model explains how
interfacial heterogeneities affect wetting. If cavities on the surface harbor pockets of air, then the contact angle is given by the Cassie-Baxter equation as

$$\cos \theta_{CB} = r_f f_{SL} \cos \theta_0 - 1 + f_{SL}$$

(2)

where \(r_f\) is the roughness factor of the wet area, and \(0 \leq f_{SL} \leq 1\) is the fractional solid-liquid interfacial area. Note that Eq. 2 applies only when cavities on the surface harbor pockets of air and there is no liquid penetration into the cavities, as it was recently discussed in the literature,\(^6\) which is the case for most metallic samples. In the Cassie-Baxter state, the interface below the droplet is non-homogenous involving solid, water, and air pockets. The highest possible contact angle on any smooth solid is believed to be 119°,\(^7\) therefore, only a rough surface may have larger contact angles. Non-homogenous wetting occurs only when the CA is greater than \(\cos^{-1}\left(\frac{f_{SL} - 1}{R_f - f_{SL}}\right)\).\(^8\)

Contact angle hysteresis (CAH), which is the difference between the maximum CA (advancing CA, e.g., in front of a moving droplet) and minimum CA (receding CA, e.g., at the rear of a moving droplet) is a parameter used to characterize the adhesion between a liquid and a surface. Surfaces that exhibit water CA greater than 150° and very low CAH (<10°) are said to be superhydrophobic. But there are a number of important exceptions, and sometimes called the “petal effect”.\(^9,10\) While CA characterizes wetting during normal loading, CAH characterizes wetting during shear loading at the solid-liquid interface. Adhesion under both these types of loadings can be measured separately using the centrifugal adhesion balance.\(^11,12\)

Besides water-repellency, the superhydrophobic surfaces have many emerging applications such as self-cleaning, drag reduction in water flow, antifouling,\(^13\) icephobicity,\(^14-16\)
oleophobicity,\textsuperscript{17} water filtering,\textsuperscript{18} etc. One newly emerging area of application for hydrophobic and superhydrophobic surfaces is corrosion inhibition. There are a number of recent experimental studies of how superhydrophobicity can reduce corrosion, although there are few studies of the fundamental physicochemical mechanisms involved or potential applications to fresh water materials. Typically, electrochemical corrosion occurs when a metallic surface is oxidized while in contact with an electrically conducting solution called electrolyte. A typical electrolyte used in corrosion studies is 3.5 wt. % aqueous solution of sodium chloride in water, with an electrical conductivity of 5.3 $\Omega^{-1}$ m$^{-1}$ due to solvated ions. A hydrophobic/superhydrophobic surface with a non-homogeneous interface would have a reduced interfacial contact area between the electrolyte and the metallic surface.

Making a metallic surface superhydrophobic is a challenging task. Typically, a stable combination of a low-energy surface coating with a hierarchical roughness having roughness details of characteristic length scales from microns down to nanometers is needed. Several attempts to create corrosion-resistant superhydrophobic coatings have been reported in the literature.\textsuperscript{1} To operate in an aggressive corrosive environment, a superhydrophobic surface needs to resist chemical etching as well as degradation due to prolonged exposure. Also the surfaces roughness features and coatings need to withstand mechanical wear. Mechanical abrasion,\textsuperscript{19-21} etching,\textsuperscript{22, 23} oxidation,\textsuperscript{24, 25} galvanic replacement,\textsuperscript{26} and templating,\textsuperscript{27-30} are some of the methods used to create roughness on these surfaces. Several methods such as immersion coating,\textsuperscript{19, 21, 23-25, 31-34} spin coating,\textsuperscript{35} chemical vapor deposition,\textsuperscript{26} spray coating,\textsuperscript{20, 36} etc. are used to reduce surface energy. Such surfaces exhibit reduction in corrosion current and maintain superhydrophobicity on prolonged exposure to corrosive environments.
Superhydrophobicity as a means of corrosion inhibition has been studied on several metallic materials such as stainless steel,\textsuperscript{20} cold rolled steel,\textsuperscript{27-30} copper,\textsuperscript{21, 22, 36-39} zinc,\textsuperscript{26, 40} aluminum,\textsuperscript{19, 23, 31, 41} titanium,\textsuperscript{24, 25, 34} and magnesium alloys.\textsuperscript{32, 33, 42} The results from literature of corrosion tests on some of the aforementioned materials are summarized in table 1. The general trend observed in these results is that the corrosion current decreases several folds when the surface is rendered superhydrophobic. Also the corrosion potential tends to become more positive. These two tendencies are interpreted as the signs of reduced corrosion rates for superhydrophobic surfaces. Most of the methods to produce superhydrophobic surfaces involved polymer coatings which might act as diffusion barriers, oxide formation which resulted in passivation of materials, or fillers which reduced the coating permeability. Each of these factors contributed to corrosion inhibition. Therefore, the superior corrosion resistance was not the result of the superhydrophobicity alone, but a synergistic effect of several factors listed above. The influence of the superhydrophobicity alone in reducing corrosion current can be determined by comparing the entries of columns pertaining to flat-coated and rough-coated samples in table 1.

Error! Reference source not found. Figure 1 shows the corrosion current density as a function of the contact angle based on the same data. In Figure 1(a) this dependency is shown for materials with the tendency of low corrosion in their native state, whereas Figure 1(b) shows the data for materials with high tendency of corrosion in their native state. In all these cases, the corrosion current density decreased significantly as soon as the contact angle became greater than 90° indicating that hydrophobicity leads to corrosion inhibition. Further decrease in corrosion current density is seen as stable air pockets are established in the Cassie-Baxter state. Feng et al.\textsuperscript{19} reported superhydrophobic aluminum alloy surfaces with $f_{SL} \sim 0.05$, which showed 87% reduction in corrosion current density compared to uncoated alloy. Similarly, Xu et al.\textsuperscript{32} reported superhydrophobic magnesium alloy surfaces with $f_{SL} \sim 0.046$ with a 90% reduction in corrosion current density. Effective corrosion resistant surfaces require not only large contact...
angles, but also minimal fractional solid-liquid interfacial area. It can be concluded that the mechanisms which correlate the superhydrophobicity to the corrosion rates, such as the formation of Cassie heterogeneous interface, may explain the experimental data reported in the literature.

![Figure 1](image)

**Figure 1.** (a) and (b) Corrosion current density as a function of contact angle from published literature. The trend clearly shows a significant decrease in corrosion current densities with increase in contact angle. The lowest corrosion current densities occur in the Cassie-Baxter domain, where contact angle is much greater than 90°.

**Electrochemical foundations of corrosion and wetting**

Corrosion current is the main characteristic of the rate of the electrochemical corrosion. This type of corrosion happens when a metal (electrode) comes in contact with an electrolyte. During corrosion, a metal ($M$) transform from its pure state to more stable oxidized states. This involves an anodic oxidation reaction
where \( e^- \) denotes electrons, and \( z \) is the number of electrons involved in the reaction. These excess electrons in the electrode should be consumed by a reduction reaction to prevent charge accumulation on the metal (Figure 2a). The common cathodic reduction reactions are hydrogen evolution

\[
2H^+ + 2e^- \rightarrow H_2
\]

or reduction of dissolved oxygen in the electrolyte

\[
O_2 + 4H^+ + 4e^- \rightarrow 2H_2O
\]

Figure 2. (a) A typical electrochemical corrosion process in the presence of an electrolyte. Material is removed from anodic sites and then deposited as corrosion products (rust) at cathodic sites. (b) The dynamic equilibrium current is zero.

When a metal comes in contact with an electrolyte, an ionic double layer is formed at the electrode surface. Due to that the electrode attains an electrochemical potential referred to as
corrosion or open circuit potential, $E_{corr}$ or $E_{oc}$. This potential is essentially the difference of the potentials between the electrode and electrolyte or a “reference electrode” immersed in the electrolyte next to the working electrode. At the corrosion potential, the anodic and cathodic reactions are in dynamic equilibrium, so that no charge transfer between the electrode and electrolyte occurs (Figure 2b). The anodic current density of oxidation of metal, $i_{anode}$, is exactly balanced by the cathodic current density of reduction, $i_{cathode}$, and it is also equal by absolute value to the corrosion current density, $i_{corr}$, associated with the transfer of the electrons in the electrode from the anodic to cathodic spots ($|i_{corr}| = |i_{anode}| = |i_{cathode}| \neq 0$).

While the total current between the electrode and electrolyte is zero, the transfer of ions (such as $M^{2+}$ or $H^+$) occurs in both directions, and the transfer rate is proportional to the anodic / cathodic / corrosion current. The ion transfer effectively results in corrosion of the metal (e.g., rusting). Therefore, the corrosion current can be used as a measure of the corrosion rate. However, the corrosion current cannot be measured directly. Various corrosion tests have been developed to evaluate the corrosion current.

One such corrosion test that is commonly used is the potentiodynamic polarization test (PPT). During the PPT, the potential of the sample electrode is changed above and below $E_{oc}$, and corresponding changes in the current are measured as a function of the potential. The value of the potential above or below $E_{oc}$ is called the overpotential, overvoltage, or polarization, $\eta$. During an anodic polarization, the potential is increased with respect to $E_{oc}$ resulting in oxidation of the electrode, while during a cathodic polarization the potential is decreased resulting in reduction of the electrode. The electric current density $i$ as a function of the overpotential is given by the Butler-Volmer equation involving both the anodic and cathodic exponential terms.
\[ i = i_{corr} \left[ \exp \left( \frac{\alpha_a \eta z F}{RT} \right) - \exp \left( -\frac{\alpha_c \eta z F}{RT} \right) \right] \]  \hspace{1cm} (6)

where \( \alpha_a \) and \( \alpha_c \) are the anodic and cathodic charge transfer coefficients, \( F=96,485 \text{ C mol}^{-1} \) is the Faraday constant, \( R=8.31 \text{ J K}^{-1} \text{ mol}^{-1} \) is the universal gas constant, \( T \) is the absolute temperature, and \( z \) is the number of electrons involved in the reaction per molecule. Note that zero overpotential \( \eta = 0 \) corresponds to the dynamic equilibrium \( |i_{anode}| = |i_{cathode}| \) as it has been explained above. Therefore, in order to find \( i_{corr} \) from the experimental data plot of \( i \) vs \( \eta \), one should subtract the exponential term, either anodic or cathodic, from the net dependency and consider the difference at \( \eta = 0 \) (Figure 3a).

Since the current changes over several orders of magnitude during a typical corrosion test, a plot of \( \eta \) vs \( \log i \) called the Tafel plot is usually made (Figure 3b). The linear regions of the anodic and cathodic plots correspond to the exponential terms of the Butler-Volmer equation, and tangential straight lines can be extrapolated as to intersect at \( i_{corr} \).

The typical set-up used in a PPT test is shown in Figure 3c. It employs a three electrode electrochemical cell. In a three electrode system, one electrode is the working electrode which undergoes corrosion, the second is a reference electrode to measure potential difference between the working electrode and the electrolyte, and the third is a counter electrode (usually of an electrochemically inert material, such as gold, platinum, or carbon), which completes the circuit by allowing the current flow. There is negligible current flow through the reference electrode due to high resistance of the voltmeter. The electrode potential of the reference electrode is known and highly stable (saturated calomel is often used as the reference electrode material). A potentiostat is used to sweep across a range of voltages, and measure the corresponding currents.
Figure 3. (a) A typical $i$ vs $\eta$ dependency based on the Butler-Volmer equation (b) Red curves show the Tafel plot of the net (anodic and cathodic) current. Corrosion current can be obtained by extrapolating along the tangential lines corresponding to the exponential polarization curves. (c) A typical three electrode set-up for the PPT corrosion measurement. The red arrows show current flow during anodic polarization, and the broken green arrows show current flow during cathodic polarization.

Wetting and electric properties of an interface are related to each other by the so-called Lippmann equation of electrowetting, which states that the contact angle at a solid-liquid interface subjected to the applied voltage $\eta$ is given by

$$\cos \theta^* = \cos \theta_0 + \frac{C \eta^2}{2 Y W A}$$

(7)

where $C$ is the specific capacitance per unit area of the double layer at the interface. A more general form of the Lippmann equation appropriate for the heterogeneous has been recently suggested by Bormashenko & Gendelman.$^{43}$ While normally changing potential is used to
control wetting properties \textsuperscript{44}, it has been demonstrated that a reverse process (controlling the electrode potential by changing the wetting properties) is feasible as well \textsuperscript{45}.

Note that the effect of the electric potential applied to the interface on the surface energy and equilibrium contact angle (Eq. 7) is similar to the effects of roughness (Eq. 1) and heterogeneity (Eq. 2). In accordance with Le Châtelier’s principle, one could expect that changing the wetting properties would result in a certain compensatory change of the corrosion potential, which, in turn, could lead to a change of the corrosion current and, finally, of the rate of corrosion.

In this paper we correlate two surface phenomenon namely, wetting and corrosion. Surface wettability is determined by parameters like surface energy, roughness and homogeneity of the interface. We study theoretically, how each of these affect corrosion current and rate of corrosion. Then we describe experiments to correlate wetting properties with corrosion rate, followed by discussion and comparison to theoretical predictions.

**THEORETICAL MODEL**

In this section, we discuss how changing the wetting properties by modifying the surface roughness in the Wenzel and Cassie-Baxter states affects the corrosion rate. First, we establish how the solid-liquid contact area and surface roughness affect the electric current in the Cassie-Baxter state in accordance with the Ohm’s law. Then, we relate the corrosion rate to the current using the Faraday’s law of electrolysis. Finally, we apply the Nernst equation to relate the corrosion rate to the surface energy due to the decrease of the chemical potential.

**Ohm’s law and the wetting states**
Ohm’s law $E = IR$ provides the relationship between the interfacial potential $E$ and current $I$ with the interfacial resistance $R$. The resistance is inversely proportional to the interfacial solid-liquid contact area $A_{SL}$. We can write,

$$I \propto A_{SL} \propto r_{f}f_{SL}$$  

(8)

Figure 4 shows variation of the current with contact angle ($\theta$) for a substrate whose equilibrium contact angle is 75°. Here we consider non-homogeneity (Cassie-Baxter state) created by pockets of trapped air. The corrosion current decreases with increasing apparent contact angle ($\theta$). As the value of $f_{SL}$ decreases, the current across the interface also decreases. The air pockets serve to increase the interfacial electrical resistance.

![Figure 4](image)

**Figure 4.** Variation of the current ($I$) with contact angle ($\theta$) and fractional solid-liquid interfacial area ($f_{SL}$).

The theory predicts a large reduction in corrosion current with a decrease in solid-liquid interfacial area. Generating a stable hydrophobic surface can significantly decrease corrosion. The main factor affecting corrosion current in Cassie-Baxter state is $f_{SL}$.

*Faraday’s law of electrolysis and wetting properties*
Mass of material removed in corrosion reaction is given by Faraday’s law of electrolysis,

\[ m = \frac{A \ i_{\text{corr}} \ t}{zF} \] (9)

where \( A \) is the atomic (or equivalent) weight of the corroding substance, \( t \) is the corrosion time, \( z \) is the number of electrons transferred in the corrosion reaction and \( F = 9.648533 \times 10^4 \text{C mol}^{-1} \) is Faraday’s constant.

**Rate of corrosion and the surface free energy**

From absolute reaction theory, the rate at which the metal molecules are oxidized can be written as \( r = \frac{kT}{h} \exp\left(-\frac{\Delta G}{RT}\right) \), where \( r \) is in s\(^{-1}\), \( k \) is Boltzmann’s constant, \( T \) is absolute temperature, \( h \) is Planck’s constant, \( \Delta G \) is the activation energy, and \( R \) is universal gas constant.

The activation energy for a corrosion reaction of a metal can be written as \( \Delta G^0 = G_O^0 - G_R^0 \), where \( G_O^0 \) and \( G_R^0 \) are free energies associated with the oxidized state and the metal respectively.

If the metal surface is not ideally smooth, but is instead composed of surface asperities, assuming complete oxidation of the surface

\[ \Delta G^* = (G_O^0 + \gamma Ar_f) - (G_R^0 + \gamma Ar_f f_{SL}) \] (10)

Then the rate of corrosion reaction is

\[ r = r_0 \exp\left(-\frac{\gamma Ar_f (1-f_{SL})}{RT}\right) \] (11)

where \( r_0 \) is the rate of corrosion reaction at ideal surface conditions. Figure 5 shows the rate of reaction as a function of apparent contact angle in Cassie-Baxter state. The rate of reaction
decreases with increase in contact angle. Increasing the surface roughness decreases the rate of reaction in Cassie-Baxter state.

![Graph showing rate of corrosion reaction (r) as a function of contact angle (θ) for different values of roughness factor (r_f). The equilibrium contact angle of the surface was assumed to be 50°.](image)

**Figure 5.** Rate of corrosion reaction \( (r) \) as a function of contact angle \( (θ) \) for different values of roughness factor \( (r_f) \). The equilibrium contact angle of the surface was assumed to be 50°.

The main conclusion of this section is that rendering the electrode surface rough and the interface with the electrolyte non-homogeneous provides a coupling mechanism for the wetting and corrosion properties. In other words, both increased surface roughness \( r_f \) and decreased solid-liquid (electrode-electrolyte) contact area, \( f_{SL} \), simultaneously affect the effective surface energy and the rate of corrosion.

**EXPERIMENTAL**

To further investigate the relationship of the corrosion rate and wetting, we conducted several experiments on metallic materials typically used for fresh water industry applications (e.g., water pipes and other similar components) including steel and cast iron. Out of these two, cast iron turned out to be a material of interest which can relatively easily be hydrophobized and also subjected to corrosion at a significant rate. For that end, a procedure was developed which is outlined in this section, and followed by PPT tests on ADI90 Cast iron (CI) samples.
Surface roughening

CI samples were cut into 25 mm squares of approximately 6 mm thickness. The sample set identifiers are given in parenthesis, the number 1 denotes uncoated, while 2 and 3 denote two types of hydrophobic coatings. The surfaces were roughened as described below, and then the samples were ultrasonically cleaned in water, then in ethanol, and then air dried. One set of samples were mechanically abraded by successively using 320, 400, 600, 800, 1200 grit silicon carbide papers, followed by polishing with a soft cloth impregnated with 3 μm alumina particles to obtain a smooth surface (Samples P1). Another set was abraded by using 320 grit silicon carbide paper to obtain a rough surface (Samples R1). A third set was roughened by sandblasting for 30 s to obtain an extremely rough surface (Samples S1).

Hydrophobic coating

Following the procedure of hydrophobization suggested by Yuan with some modifications, the samples (P2, R2, and S2) were immersed in acetic acid (CH$_3$COOH) solution (36%) for two hours, followed by hydrogen peroxide solution (15%) for three hours. After that, the samples were immersed in a 0.01 M solution of stearic acid (CH$_3$(CH$_2$)$_{16}$COOH) in ethanol for 24 hours. Then the samples were taken out of the solution and air dried. Stearic acid coating was used to study if hydrophobization by monolayers can inhibit corrosion.

Another set of samples (P3, R3, and S3) were spray coated with a commercial liquid repelling treatment (Rust-Oleum® NeverWet®). First the samples were spray coated with a base coat and allowed to dry for 30 min. Then four top coats were applied with 2 minutes between each coat. The top coat was allowed to dry for 3 hours.

Contact angle and surface roughness measurements
The as-placed water contact angles (CA) were measured using a ramé-hart goniometer (model 250) by placing three pure water droplets of 10 μl at different locations on the surface. The contact angle hysteresis (CAH) were calculated by the tilting plate method. The samples were observed at 20X with an Olympus Lext OLS4100 microscope and average surface roughness ($S_a$) of an area 0.625 μm x 0.625 μm was measured.

**Potentiodynamic polarization test**

The corrosion behavior of samples was studied using the PPT procedure. A standard three electrode system with the sample as the working electrode, saturated calomel as the reference electrode, and platinum as the counter electrode was used. A potentiostat (Biologic SP-200) with EC-Lab software was used for voltage sweep and data acquisition. The electrolyte was 3.5 wt % NaCl solution. The exposed area of the working electrode was circular with the diameter of 1 cm or approximately 0.79 cm$^2$. The samples were kept in contact with the electrolyte for 30 min to reach the open circuit potential. The potential was varied at the rate of 0.116 mV/s during the tests. The results from the experiments are discussed in the following section.

**RESULTS AND DISCUSSION**

The polished sample P1 had the lowest CA of 50.5° among uncoated samples, while P2 had the lowest CA of 95.4° among stearic acid-coated ones. Roughening of the samples led to increase in CA in uncoated samples. All the uncoated samples showed significant CAH. Once the stearic acid coating was applied, all the samples became hydrophobic with CA>90°. The sample P2 was only slightly hydrophobic with the CA of 95.4°. The sample R2 had a CA of 110.0°. The sand blasted sample S2 had the highest CA of 124.4° among stearic acid coated
ones. The stearic acid-coated samples also showed large CAH values. Water droplet was placed on each of the samples P1, R1, S1, P2, R2, and S2 and then the samples were tilted to a vertical position. The water droplet clung to the surface in all the cases, showing strong adhesion with the surface. This also suggested that most of the surface cavities were filled with water, than air. The CAH of the samples also reveal high adhesion with water. The adhesive forces can be quantified using a centrifugal adhesion balance.11 All the samples coated with NeverWet were superhydrophobic. It was extremely difficult to place water droplets on the surface for CA measurement. They rolled off at the slightest disturbance, making CAH measurement extremely difficult. Sample P3, R3, and S3 had contact angles of 160.3°, 158.5°, and 150.7° respectively, with negligible CAH. The results of the CA measurements are presented in Table 2.

It is difficult to conclude from direct observations whether the wetting state for the samples P2, R2, and S2 were Wenzel or Cassie-Baxter; however, it was found that surfaces immersed in water tended to reflect light indicating possible presence of air pockets. Due to the extreme water repellency observed for P3, R3, and S3, it can be concluded that they were in the Cassie-Baxter state.

*Figure 6.* Optical images of surfaces of the samples (a) P1, (b) P2, and (c) P3. The coating on P3 is visibly different with cracks and bubbles on the surface.
Figure 7. (a) to (i) shows the surface topographies of P1, P2, P3, R1, R2, R3, S1, S2, and S3 respectively. Coating with the liquid repellent spray results in drastic change in surface roughness as seen in the case of P3, R3, and S3. All scales are in μm.
The average surface roughness for samples P1 and R1 were 0.042 and 0.144 μm. For S1 the roughness was on the micron scale with a value of 2.335 μm. The samples P2, R2 and S2 had average surface roughness values of 0.086, 0.216, and 2.843 μm respectively. These roughness values are higher than those for corresponding hydrophilic samples. The average surface roughness values for P3, R3, and S3 were substantially higher than those for corresponding hydrophilic and hydrophobic samples. The optical images of samples P1, P2, and P3 are shown in Figure 6, while the surface topographies of all the samples are shown in Figure 7.

The Tafel plots were obtained from the EC-Lab software (Figure 8). For the samples P2 and R2 the PPT did not produce any characteristic Tafel plots, which might be caused by poor stability of the stearic acid coating on the samples with low roughness. Consequently, no corrosion current and potential was measured on these samples.

Corrosion current densities, corrosion potentials, and corrosion rates were obtained from these plots using the software. These values are presented in table 2. The polished sample P1 had an \( i_{\text{corr}} \) of 5.81 μA/cm\(^2\). After rendering it superhydrophobic, the resulting sample P3 had an \( i_{\text{corr}} \) of 6.33x10\(^{-6}\) μA/cm\(^2\). The sample R1 had an \( i_{\text{corr}} \) of 5.22 μA/cm\(^2\). Rendering it superhydrophobic resulted in sample R3 with \( i_{\text{corr}} \) 3.16 x10\(^{-8}\) μA/cm\(^2\). The samples S1, S2 and S3 had an \( i_{\text{corr}} \) of 18.01, 11.98, and 7.10x10\(^{-4}\) μA/cm\(^2\) respectively. The corrosion potentials also showed significant change with the wettability of the surface. The absolute values of the corrosion potentials decreased by more than 50% for the superhydrophobic samples. Consequently, the corrosion rates of the superhydrophobic samples were several orders smaller than those of the hydrophilic and hydrophobic samples. Repeated PPT on samples give corrosion current values of similar magnitudes.
Figure 8. Potentiodynamic polarization curves for the samples. Rendering the surface superhydrophobic is seen to shift decrease the corrosion current density as well as shift the corrosion potential closer to the reference electrode potential.

The hydrophilic samples P1, R1, and S1 showed significant rusting on their surfaces after PPT. The hydrophobic samples P2, R2, and S2 also showed rusting on their surfaces, with a loss of hydrophobicity after PPT. The loss of hydrophobicity on P2, R2, and S2 is due to the combined effect of corrosion as well as destruction of trapped air pockets under hydrostatic pressure. The superhydrophobic samples P3, R3, and S3 however had no visible rusting on their surfaces following the PPT. These samples were robust, retaining their superhydrophobicity and ability to trap pockets of air at the surface.
The trends observed in the experimental data were that the corrosion current density decreased and the corrosion potential increased as a result of rendering a surface superhydrophobic. The corrosion potentials of most metals and alloys in their native state are negative. Therefore, these metals and alloys have the tendency to get oxidized into corrosion products. The corrosion potential of a hydrophobic surface typically shifts to a value closer to that of the reference electrode. This means a lower thermodynamic tendency to oxidize. Also, the reduction in the solid-liquid interfacial contact area by formation of trapped air pockets results in excellent corrosion resistance.

The experimental results obtained with CI samples showed a similar trend to the results from published literature. Corrosion current densities decreased by several magnitudes and corrosion potentials shifted in the positive direction once the surfaces were made superhydrophobic. These were signs of corrosion inhibition.

The samples P1 and R1 had sub-micron scale surface roughness. As the roughness of the samples increased from P1 to R1, the corrosion current density decreased and the corrosion potential increased, but only slightly. Interestingly, when the roughness increased to the scale of microns for S1, the corrosion current density increased three folds. This can be explained by the formation of homogenous solid-liquid interfacial contact. Roughness at such an interface can amplify the effects of corrosion similar to what is observed in Wenzel model. Increase in surface roughness leads to increase in surface area exposed to the electrolyte. Therefore more reaction sites are available for corrosion to proceed and hence the increased corrosion current density. Having a homogenous solid-liquid interface is detrimental to the metal or alloy.
When the samples were hydrophobized with stearic acid, the surface roughness changed. This is due to the reaction of cast iron with acetic acid, as well as hydrogen peroxide. The stearic acid coating as well as the surface roughness is seen to impart hydrophobicity to the samples. The corrosion current density decreases in the case of S2 when compared with S1. The difference between S1 and S2 is in the type of interface formed when in contact with the electrolyte. The sample S1, as seen before, has an amplified corrosion tendency due to its very rough surface and hydrophilicity. The sample S2 is hydrophobic and can sustain some trapped pockets of air compared to S1 as observed when S2 was dipped in water. These air pockets result in reduced electrode-electrolyte contact. Hence the decrease in corrosion current density from S1 to S2. But hydrophobic S2 has higher corrosion current densities than hydrophilic P1 and R1. Even though S2 has a non-homogenous interface, its effective solid-liquid contact is more than P1 and R1 due to its high surface roughness. This suggests that as long as the wetting regime on a surface is not purely Cassie-Baxter, the effect of roughness is more pronounced than contact angle on corrosion.

In case of samples P3, R3, and S3, the roughness of the cast iron itself was not of particular importance. After applying the spray coating, the surface roughness of all three samples increased drastically. The coating itself was visible to the naked eye, and felt rough to touch. Under the microscope, the coating was seen have cracks and bubbles on the surface (Figure 6c). These surface features resulted in the extremely high surface roughness values. The surfaces of P3, R3, and S3 looked unaffected to the naked eye after the PPT.

For the samples P2, R2, and S2, the stearic acid coating was not visible to the naked eye. These surfaces showed signs of corrosion after the PPT. Stearic acid usually form a monolayer on the surface that renders the surface hydrophobic. This layer is not robust like the spray
coating. Such a fragile layer may also undergo a Cassie-Baxter to Wenzel wetting transition due to the hydrostatic pressure in the corrosion cell. This may be a reason for the relatively feeble performance of S2.

In most of the published literature, epoxy or similar coatings were employed. These coatings themselves act as diffusion barriers to ionic species or are less permeable to air. Such coatings were far superior offering 85% or higher drop in corrosion current densities compared to uncoated metals or alloys. In the case of our experiments, we employed both thick coatings as well as monolayers. Therefore, the effects of surface roughness and non-homogenous hydrophobic interface on corrosion inhibition were isolated in this study. The thickness of coating on P3, R3 and S3 was much larger than the stearic acid monolayer on S2. This suggests that thickness of coating has a significant part to play in corrosion inhibition. Thicker coatings provide a tortuous path for the corrosive agents. In the case of a Cassie-Baxter to Wenzel transition, a relatively thick coating can act as a second line of defense against the corrosive agents.

This general principle of chemical equilibrium (Le Châtelier’s principle) states that when many factors affect equilibrium of a system, any change in status quo prompts an opposing reaction in the responding system. While further studies of fundamental mechanisms of corrosion on non-wetting surfaces may be required to understand the underlying mechanisms, we note that the observed trends are consistent with this principle. In the case of an electrode immersed in electrolyte, the equilibrium surface energy depends both on the inherent surface energy of the material and on the potential of the electrode. By rendering the electrode surface hydrophobic we decrease the inherent surface energy. This shift in equilibrium of the system is compensated by a change in the potential difference between the surface and the wetting liquid.
A positive change in potential was observed in all the cases discussed here. However, the absolute value of the potential decreased, which, in accordance with the electrowetting laws, such as the Lippmann equation (Eq. 7) corresponds to increasing surface energy. This change in corrosion potential can lead to a decrease in the corrosion current density for the surface, and thus the rate of corrosion. This trend is also universally observed in the cases discussed here.

CONCLUSIONS

We discussed the principles of corrosion and electrowetting as well as mechanisms which lead to their correlation with the superhydrophobicity. The mechanism of electrochemical corrosion was discussed and the technique for measuring corrosion parameters was introduced. Corrosion test data were compiled from recent literature to highlight the trends observed in critical parameters related to corrosion. A facile, scalable hydrophobic coating using stearic acid was developed on cast iron. A commercial liquid repelling spray was used to render cast iron superhydrophobic. Corrosion tests were performed on cast iron in hydrophilic, hydrophobic and superhydrophobic states. Both the compiled data as well as our experimental results showed a decrease in corrosion current density and an increase in corrosion potential after superhydrophobization. This can be explained in light of Le Châtelier’s principle. A stable non-homogenous solid-electrolyte-air interface was essential for superior corrosion resistance. A theoretical model was developed and validated with the experimental data. This will provide a fundamental understanding of wetting phenomena in corrosion inhibition.

We studied here a relatively new area of corrosion inhibition employing hydrophobic/superhydrophobic surfaces. Existence of a stable non-homogenous interface and the significant reduction in corrosion current density meant that similar coating will find applications
in the water industry like water pipelines, gauges, probes, etc. An ideal superhydrophobic coating for corrosion inhibition should satisfy two requirements: it should be able to withstand Cassie-Baxter to Wenzel transition under duress, and it should provide a tortuous path for the corrosive agents trying to attack the metallic surface.

ACKNOWLEDGEMENT

We would like to acknowledge NSF IUCRC FRP award 1331532 support and thank Prof. Pradeep Rohatgi for discussions and Mr. Emad Omrani for help with sample preparation and PPT training.
