ABSTRACT

A monolithically integrated device consisting of a tandem-junction GaAs/InGaP photoanode coated by an amorphous TiO$_2$ stabilization layer, in conjunction with Ni-based, earth-abundant active electrocatalysts for the hydrogen-evolution and oxygen-evolution reactions, was used to effect unassisted, solar-driven water splitting in 1.0 M KOH(aq). When connected to a Ni-Mo-coated counterelectrode in a two-electrode cell configuration, the TiO$_2$-protected III-V tandem device exhibited a solar-to-hydrogen conversion efficiency, $\eta_{\text{STH}}$, of 10.5% under 1 sun illumination, with stable performance for > 40 h of continuous operation at an efficiency of $\eta_{\text{STH}}$ >10%. The protected tandem device also formed the basis for a monolithically integrated, intrinsically safe solar-hydrogen prototype system (1 cm$^2$) driven by a NiMo/GaAs/InGaP/TiO$_2$/Ni structure. The intrinsically safe system exhibited a hydrogen production rate of 0.81 $\mu$L s$^{-1}$ and a solar-to-hydrogen conversion efficiency of 8.6% under 1 sun illumination in 1.0 M KOH(aq), with minimal product gas crossover while allowing for beneficial collection of separate streams of H$_2$(g) and O$_2$(g).
BROADER CONTEXT

Global climate change coupled with increasing global energy consumption drives the need for renewable and carbon-neutral alternatives to fossil fuels. Solar-driven water splitting has the potential to provide cost-effective hydrogen fuel that could provide a technological solution to both grid-scale energy storage as well as serve as a feedstock for the production of carbon-neutral transportation fuels. A widely recognized, but currently unrealized, goal for the advancement of a solar fuels technology is the demonstration of a monolithically integrated solar-driven water-splitting system that is simultaneously efficient, stable, intrinsically safe, and scalably manufacturable. We describe the development of efficient, safe water splitting systems enabled by deposition of an amorphous layer of TiO$_2$ onto a photoanode surface. The TiO$_2$ layer significantly improves the stability of III-V photoanodes in a tandem structure for water oxidation while the tandem structure produces sufficient photovoltage to sustain the efficient, unassisted production of hydrogen by water splitting in aqueous alkaline electrolytes.
One approach to solar-driven hydrogen production involves use of photovoltaic (PV) panels, modules or cells connected physically and electrically in series with an electrolyzer (E). Commercial electrolyzers typically are designed to operate at 70% efficiency.\textsuperscript{1-4} To obtain optimal impedance matching in view of hourly, daily and seasonal variability in the solar irradiance, a dynamic DC-to-DC converter, with an estimated efficiency of 85%, would be used to connect the electrolyzer to the PV unit. Hence a solar-to-hydrogen efficiency based on any specific PV+E system can be estimated by taking the peak PV efficiency and multiplying by \(~0.60.\textsuperscript{5}\) Thus, peak system efficiencies of 12.6% and 24.6%, respectively, could be obtained by use of an electrolyzer in conjunction with a high-efficiency (21%) Si PV module or a high-efficiency (41%) III-V triple junction PV operated under optical concentration.\textsuperscript{5} Such systems have been demonstrated at commercial scale, laboratory scale, and research scale.\textsuperscript{6-13} For example, Si PV mini-modules and perovskite-based solar cells, respectively, have been used recently in the PV+E configuration.\textsuperscript{7,8} At the commercial level, the high balance of systems cost and low capacity factor of stand-alone PV-electrolyzer systems results in high levelized hydrogen costs relative to hydrogen produced by steam reforming or grid electrolysis using fossil or low-carbon electricity.\textsuperscript{14}

Integrated solar-to-fuel devices provide many potential advantages relative to a discrete PV-electrolyzer system and offer a unique design space for the balance of systems.\textsuperscript{15-18} Modeling and simulation has revealed a range of integrated device architectures that can allow for efficient operation and scalable deployment of solar-driven water splitting systems that can produce renewable \(\text{H}_2(g)\) as an energy carrier.\textsuperscript{17,19-24} A compilation of reported devices\textsuperscript{16} shows a wide range of efficiency, integration, and stability. Recent advances include series interconnected CuIn\textsubscript{x}Ga\textsubscript{1-x}Se\textsubscript{2} (CIGS) absorbers in conjunction with two Pt electrodes in 3.0 M \(\text{H}_2\text{SO}_4(aq)\) with
\[ \eta_{\text{STH}} > 10\% , \] and a bismuth vanadate photoanode in combination with a thin-film silicon solar cell has produced \[ \eta_{\text{STH}} = 5.2\% . \]

Solar fuels production is subject to the constraints imposed by the minimum voltage requirements needed to sustain water-splitting and/or sustainable CO\(_2\) reduction under standard conditions. “Wireless” monolithically integrated photoelectrochemical water-splitting devices were reported in 1977 using platinized SrTiO\(_3\). However, the band gaps of SrTiO\(_3\) and related metal oxides are too large to allow for highly efficient use of the solar spectrum. Smaller band gap materials are generally unstable to photocorrosion in aqueous solutions, and need to be protected, generally with coatings of transparent, conductive oxides (TCO), to provide stable operation. TCO-coated amorphous hydrogenated Si (a-Si:H) triple junction structures have been widely explored in monolithically integrated water-splitting systems in which the photoelectrode, protection layer(s), and electrocatalytic species share a common optical path. Use of a-Si:H triple junctions in monolithically integrated structures protected by TCOs, in conjunction with either Pt or with earth-abundant electrocatalysts for the hydrogen-evolution reaction (HER) and oxygen-evolution reaction (OER), have yielded solar-to-hydrogen efficiencies of up to 5%. In monolithically integrated solar-fuels devices, tandem structures can provide significantly higher efficiencies than triple junctions. For example, a photovoltaic-biased photoelectrolysytic device based on a III-V tandem structure has exhibited 12.4% solar-to-hydrogen conversion efficiency, \[ \eta_{\text{STH}} \] under concentrated solar illumination. However, III-V semiconductors photocorrode both under hydrogen-evolution reaction (HER) and oxygen-evolution reaction (OER) operating conditions, and therefore require protection to be utilized in such applications. Operation in aqueous alkaline electrolytes allows the construction of
efficient, intrinsically safe systems and allows use of highly active, low overpotential, earth-abundant electrocatalysts based on Ni and related alloys.\textsuperscript{39} In accord with established properties of commercial electrolyzers, an intrinsically safe electrolysis or photoelectrolysis system does not produce a flammable, potentially explosive mixture of H\textsubscript{2}(g) and O\textsubscript{2}(g) in the reactor at any point in space or time. Common TCO’s, such as indium tin oxide (ITO), are not stable in alkaline electrolytes.\textsuperscript{40, 41}

Amorphous TiO\textsubscript{2} films deposited using atomic-layer deposition (ALD) have recently been shown to protect a variety of photoanode materials under OER conditions in alkaline electrolytes.\textsuperscript{42-44} The mechanism of hole conduction in TiO\textsubscript{2} has been ascribed to intrinsic conductivity through the conduction band, as well as to defect states, impurities, and other possible effects that are being evaluated in detail at present.\textsuperscript{45, 46} Exploiting the stability of the amorphous TiO\textsubscript{2} protection layer, we describe herein a photoelectrosynthetic cell consisting of a GaAs/GaInP\textsubscript{2}/TiO\textsubscript{2}/Ni photoanode connected to a Ni-Mo coated counterelectrode that effects unassisted solar-driven water-splitting for 80 h of continuous operation at 1 Sun illumination in 1.0 M KOH(aq), with $\eta_{\text{STH}} = 10.5\%$. In addition, we describe the behavior of a fully monolithically integrated, intrinsically safe, membrane-based, wireless prototype system consisting of a NiMo/GaAs/GaInP\textsubscript{2}/TiO\textsubscript{2}/Ni structure with an active area of 1 cm\textsuperscript{2} that has sustained unassisted solar-driven water-splitting with $\eta_{\text{STH}} = 8.6\%$ while producing fully separate streams of H\textsubscript{2}(g) and O\textsubscript{2}(g).

A tandem-junction photoabsorber consisting of an InGaP top cell (E\textsubscript{g} = 1.84 eV) and GaAs bottom cell (E\textsubscript{g} = 1.42 eV) was designed and modeled using a 1-D numerical simulator for operation under the Air Mass (AM) 1.5 solar spectrum.\textsuperscript{47} Fig. 1 shows the structure of the InGaP/GaAs tandem cell. The GaAs bottom cell consisted of an n\textsuperscript{+}-InGaP back surface field
The InGaP/InP tandem device consisted of two sub-cells: a top cell and a bottom cell. The InGaP top cell consisted of an n⁺-AlInP BSF layer, an n-InGaP base layer, a p⁺-InGaP emitter, an p⁺-AlInP window, and a p⁺-GaAs contact layer. The InGaP top cell and GaAs bottom cell were connected electrically by the AlGaAs/GaAs tunnel junction. Fig. 1b shows the solid-state current density vs voltage (J-V) performance of the tandem cell. Under 1 sun illumination, the short-circuit current density (Jₛₑ), the open-circuit voltage (Vₒ₂) and the fill factor (FF) were 7.6 mA cm⁻², 2.4 V and 0.76, respectively. Fig. 1c shows the spectral response behavior of the tandem device. The integrated short-circuit current density under AM 1.5 illumination for the top cell and the bottom cell were Jₜₒᵖₜ,ᵢⁿᵗ = 7.6 mA cm⁻² and Jₜₒₜᵦ,ᵢⁿᵗ = 9.3 mA cm⁻², respectively. The large band gap InGaP top cell was current limiting, and the calculated Jₜₒᵖₜ,ᵢⁿᵗ matched the measured Jₛₑ in Fig. 1b.

For water oxidation, the photoanode surface was protected from corrosion by a 62.5 nm layer of amorphous, hole-conducting TiO₂ that was grown by atomic-layer deposition (ALD). Fig. 2a shows a cross-sectional scanning-electron microscopy (SEM) image of the cell structure. The thickness of the TiO₂ layer was chosen to minimize reflection as a single-layer anti-reflection coating (see Supporting Information for a discussion of further improvements to this non-optimized cell design). A 2 nm layer of Ni metal provided an ohmic contact to the TiO₂ surfaces and, upon activation, formed a highly active, stable, OER catalyst. Fig. 2b shows the cyclic voltammetry of the photoelectrode at 1 sun illumination in 1.0 M KOH. The cyclic voltammetric behavior closely matched the solid-state J-V performance of the device structure, with a light-limited photocurrent density of 8.6 mA cm⁻². Fig. 2b shows the dark electrochemical behavior of the TiO₂/Ni protection layer on highly-doped p⁺-GaAs anodes. A load-line analysis using an equivalent-circuit model that consisted of a photodiode connected in series with the
dark electrolysis cell indicated that a photodiode with a $V_{oc} = 2.25$ V, FF = 0.82 and $J_{sc} = 8.5$ mA cm$^{-2}$ (i.e. $\eta = 15.7\%$) would be required to produce the same shift in $J$-$E$ properties as was produced by use of the TiO$_2$-coated InGaP/GaAs photoelectrode. Fig. 2c shows the spectral response of the photoanode. The integrated light-limiting current densities under AM 1.5 illumination were calculated to be $J_{\text{top, int}} = 8.5$ mA cm$^{-2}$ and $J_{\text{bot, int}} = 10.0$ mA cm$^{-2}$, respectively. The slightly larger light-limited photocurrent density for the photoelectrode relative to the solid-state device is ascribable to decreased reflection losses in the PEC cell configuration.

Unassisted solar-driven water-splitting was performed in 1.0 M KOH(aq) by wiring the 0.031 cm$^2$ photoanode to a ~1 cm$^2$ Ni-Mo cathode, to form a full photoelectrosynthetic cell (Fig. 3a). The photoanode and the cathode were separated by an anion-exchange membrane (AHA-type, NEOSEPTA membrane). The compression cells were covered using high-performance black masking tape to prevent illumination of electrochemically inactive surfaces outside of the O-ring area. Two-electrode chronoamperometry of the device (Fig. 3b) was measured under 1 sun illumination in 1.0 M KOH(aq) through two quartz windows and without an external voltage bias. Initially, a short-circuit photocurrent density, $J_{\text{photo, short}} = 8.6$ mA cm$^{-2}$, which corresponds to $\eta_{\text{STH}} = 10.5\%$, was observed. $J_{\text{photo, short}}$ decreased to 7.3 mA cm$^{-2}$ after 80 hours of operation, maintaining $\eta_{\text{STH}} > 10\%$ for 40 h of continuous operation. At these current densities, dissolution of the entire epilayer at 100% faradaic efficiency would require only 3% of the total charge passed. The sudden decrease in the $J_{\text{photo, short}}$ during the chronoamperometric measurements was caused by transient blocking of the photoelectrodes by the evolved oxygen bubbles. The use of a round and thick fluorosilicone O-ring caused occasional bubble accumulation inside the O-ring compartment. The transient blocking of the photoelectrodes from the electrolyte due to bubble accumulation caused a sudden decrease in $J_{\text{photo, short}}$ during the chronoamperometric
measurements. However, the dislodging of bubbles did not noticeably affect the device performance. The gradual decrease in current density can be attributed to pathways in the TiO$_2$ film that lead to minimal corrosion, possibly due to cell processing in a non-cleanroom environment.

A membrane-based, wireless prototype was constructed to demonstrate operation of a full, intrinsically safe, solar-driven water-splitting system. The system was based on a monolithically integrated device that included the tandem light absorbers and protection layers, as well as the HER and OER electrocatalysts (Fig. 4a). The dimensions of the chassis were designed using a multi-physics model to minimize the transport losses in the electrolyte and in the membrane, and a thicker 150 nm layer of ALD-TiO$_2$ served as a protection layer. The prototype exhibited an average hydrogen and oxygen production rate of 0.81 $\mu$L s$^{-1}$ and 0.41 $\mu$L s$^{-1}$ as measured by two eudiometers (Fig. 4b). The gas evolved from the cathode chamber and from the anode chamber showed minimal (<0.5%) product gas crossover. The near 2:1 ratio of the product gas and the minimal product crossover also indicated that minimal photocorrosion of the III-V materials occurred during the testing period. The gas production rate decreased by ~10% after 4 h of operation of the monolithically integrated device, due to pinhole formation around the dust particles that were present on photoanode surface before the protection coating process.

The performance attributes exhibited by the fully operational system resulted from adherence to the optoelectronic and electrochemical engineering design principles that have been developed to guide the fabrication of efficient, intrinsically safe, solar-fuels generators. The system geometry and sample dimensions produced maximal light absorption while minimizing the ohmic losses in the electrolyte. In the absence of product separation, co-evolved, stoichiometric mixtures of H$_2$(g) and O$_2$(g) would be produced, and this explosive
mixture would prevent safe operation of the device. The membrane allowed for robust product separation, and low gas crossover rates through the membrane ensured intrinsically safe operation of the system. The pressure differential between the anolyte and catholyte allowed for beneficial collection of the H$_2$(g) into a pipeline without fluid flow across the membrane, resulting from Darcy’s law, which would produce catastrophic failure of the system. The alkaline electrolyte insured a transference number of essentially unity for flow of hydroxide ions across the anion exchange membrane, to allow for neutralization of the pH gradient that would otherwise occur between the surface of the anode and cathode in the system. The band gaps and photovoltages of the light absorbers were optimized to produce a photovoltage at the maximum power point of the system that would be sufficient to drive the electrolysis reactions as facilitated by earth-abundant, active, stable, HER and OER electrocatalysts in conjunction with the residual ohmic losses in the device. Further improvements in efficiency are possible by minimizing reflection losses and by optimization of the subcell current densities for current matching. Note that the electrolyte need not be a liquid, and polymeric electrolytes in conjunction with a pure water feed are generally used in analogous systems such as PEM-based electrolyzers.

Monolithically integrated solar-driven water-splitting devices based on tandem structures or triple junctions have been described previously. Some of those devices are compatible with operation in an efficient, intrinsically safe system of the type depicted in Fig. 3a. a-Si:H triple junction devices, with RuO$_2$ on a Ti substrate used for the OER and Pt islands deposited directly onto the a-Si:H as the HER catalyst, have been used to split water in 1 M H$_2$SO$_4$(aq). Those devices exhibited steady-state $\eta_{\text{STH}} = 5\%$ over $> 4$ h of operation. a-Si:H triple-junction and quadruple-junction devices, coated with Pt as a HER catalyst and RuO$_2$ as an OER catalyst, have
yielded $\eta_{\text{STH}} = 2.6\%$ in 5 M H$_2$SO$_4$.\textsuperscript{33,34} Such structures would benefit by the use of more advanced a-Si:H triple junction structures\textsuperscript{54} that could produce higher current densities at the $\sim$1.7 V optimal operating voltage that results from the relatively low combined HER and OER overpotentials of Pt in 1.0 M H$_2$SO$_4$ at 10 mA cm$^{-2}$ of current density.\textsuperscript{39} Such devices have the capability of being incorporated into intrinsically safe systems because the transference number of protons in acidic media is essentially unity across gas blocking, cation-exchange membranes such as Nafion.\textsuperscript{55} Monolithically integrated a-Si:H devices, protected on one side by ZnO in conjunction with a Co-Mo HER catalyst, and protected on the other side by SnO$_2$ in conjunction with an Fe-NiO$_x$ OER catalyst, have yielded $\eta_{\text{STH}} = 2.5$-3.0\% in 1.0 M KOH(aq), with stability for $> 18$ h of operation.\textsuperscript{56} Such devices also have the capability of operating in intrinsically safe systems, due to the essentially unity transference numbers of hydroxide ions across anion exchange membranes in alkaline media. In 1.0 M KOH(aq), the combined HER and OER Ni-based catalyst overpotentials are $< 0.5$ V at 10 mA cm$^{-2}$ of current density.\textsuperscript{39} Hence relatively high efficiency systems can potentially be achieved through improvements in the performance of the light absorber, especially in conjunction with the Ni islands on protective TiO$_2$ films deposited by ALD. Indeed, prior attempts to fabricate monolithically integrated solar-driven water-splitting devices and systems based on a-Si:H triple junctions in 1.0 M KOH(aq) failed due to the lack of a suitable, stable protective anode coating.\textsuperscript{40,41,57} Triple junction a-Si:H devices, protected by ITO on one side in conjunction with phosphate-containing Co oxide as an OER electrocatalyst\textsuperscript{41,58-60} and on the other side by stainless steel in conjunction with a Ni-Mo-Zn HER catalyst, yielded $\eta_{\text{STH}} = 1.75$-2.5\% for 10 h in aqueous solutions buffered to pH = 9 with borate.\textsuperscript{41} The combined HER and OER overpotentials of the electrocatalysts at 10 mA cm$^{-2}$ of current density exceeded 1 V,\textsuperscript{61} and the OER catalyst delaminated from the electrode at current
densities of $< 10 \text{ mA cm}^{-2}$,\textsuperscript{62,63} precluding construction of robust, efficient monolithically integrated devices. Moreover, such devices co-evolve stoichiometric mixtures of $\text{H}_2$ and $\text{O}_2$,\textsuperscript{41} precluding intrinsically safe operation. When a cation-exchange or anion exchange membrane is included in the system, severe pH gradients and electrodialysis of the solution occurs. These effects are a consequence of the low transference number\textsuperscript{64} at near-neutral pH of protons or hydroxide ions across the membrane, relative to the transference number of other, higher concentration, charge-carrying ions in the buffered solution.\textsuperscript{49,65} In the absence of a membrane and with adequate convection of the electrolyte, the losses due to electrodialysis and ohmic resistance can be minimized, but potentially explosive mixtures of $\text{H}_2(\text{g})$ and $\text{O}_2(\text{g})$ are produced over active catalysts for recombination of the gases, in the presence of light and heat. Hence, electrolysis or photoelectrolysis systems that are operated in buffered or unbuffered bulk near-neutral pH electrolytes are inefficient and/or not intrinsically safe.\textsuperscript{19,49,52,65}

Tandem structures based on III-V materials related to those described herein, based on GaInP\textsubscript{2}/GaAs structures, but where the GaInP\textsubscript{2} is exposed to the electrolyte as a photocathode, in conjunction with Pt/Ru and Pt as HER and OER electrocatalysts, respectively, have been used to produce monolithically integrated solar-driven water-splitting devices in 1.0 M $\text{H}_2\text{SO}_4(\text{aq})$ or in $>1$ M KOH(\text{aq}).\textsuperscript{66} Such devices yielded $\eta_{\text{STH}} = 4\text{-}6\%$ under $\sim 11$ Sun illumination,\textsuperscript{66} whereas related structures based on a two-electrode photoelectrosynthetic cell configuration have yielded $\eta_{\text{STH}} = 12.4\%$ under 11 Suns of concentrated illumination for $<20$ h of operation in 1 M $\text{H}_2\text{SO}_4(\text{aq})$.\textsuperscript{36} The stability of both systems is limited due to cathodic decomposition processes characteristic of III-V materials in aqueous electrolytes.\textsuperscript{37} Protection of these III-V materials as photoanodes has been a valuable and unrealized objective. Such devices are well-suited for use in efficient, intrinsically safe water-splitting systems, and increases in the stability of such
devices will require the development of robust protective coatings that are compatible with operation in aqueous acidic media, and/or the use of the protection schemes such as those described herein for operation under aqueous alkaline conditions.

The 1 cm$^2$ protected III-V photoelectrodes used in the functioning prototype system were less photochemically stable than the smaller area protected tandem III-V photoelectrochemical devices. This behavior is expected because GaAs, and most III-V materials, undergo active corrosion by dissolution under anodic conditions in alkaline electrolytes.\textsuperscript{27,37,38} Hence, for such materials, the presence of macroscale defects or pinholes in the protective film, due to the presence of dust particles on the semiconductor surface prior to and during film deposition, led to etching and undercutting of the TiO$_2$ that eventually resulted in catastrophic failure of the device. One approach to mitigate this issue is to mutually electrochemically isolate the defects, such as by use of microwire or nanowire arrays, so that only those wires that possess a defect will be etched, leaving the other parts of the device protected and operational. Another benefit of high-aspect-ratio structures is that the lower photocurrent density over the internal surface area favors fuel production relative to corrosion, and thus enhances the functional device lifetime relative to planar structures operated under the same incident light intensities.\textsuperscript{43} Results on such systems will be reported separately both for devices and fully operational systems.

In summary, a tandem junction GaAs/InGaP photoanode coated with a TiO$_2$ protection layer has provided efficient ($\eta_{STH}>10\%$) and sustained (> 40 h) unassisted solar-driven water-splitting. A fully integrated, membrane-based, intrinsically safe, monolithically integrated prototype (1 cm$^2$) system comprised of earth-abundant electrocatalysts for the HER and OER exhibited $\eta_{STH} = 8.6\%$ at 1 sun illumination in 1.0 M KOH(aq) while producing physically separate streams of the H$_2$(g) and O$_2$(g) product gases.
