This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this *Accepted Manuscript* with the edited and formatted *Advance Article* as soon as it is available.

You can find more information about *Accepted Manuscripts* in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

Using hematite for photoelectrochemical water splitting: a review of current progresses and challenges

Abstract

Photoelectrochemical (PEC) water splitting is a promising technology for solar hydrogen production to build a sustainable, renewable and clean energy economy. Hematite ($\alpha\text{-Fe}_2\text{O}_3$) based photoanodes offer promise for such applications, due to their high chemical stability, great abundance and low cost. Despite these promising properties, progress towards the manufacture of practical water splitting device has been limited. This review is intended to highlight recent advancements and the limitations that still hamper the full utilization of hematite electrodes in PEC water splitting systems. We review recent progress in manipulating hematite for PEC water splitting through various approaches, focused on *e.g.* enhancing light absorption, water oxidation kinetics, and charge carrier collection efficiency. As the morphology affects various properties, progress in morphological characterization from thicker planar films to up-to-date ultrathin nanophotonic morphologies are also examined. Special emphasis has been given to various ultrathin films and nanophotonic structures which have not been given much attention in previous review articles.

1. Introduction

Photoelectrochemical (PEC) water splitting using semiconductor electrodes has received much attention and is considered to be the "holy grail" of the solar energy conversion and storage revolution. Despite these promises, most PEC water splitting systems that have been exploited so far have faced numerous challenges. Hematite ($\alpha\text{-Fe}_2\text{O}_3$) based photoelectrodes have been intensively studied on account of hematite's abundance, non-toxicity, high photochemical stability, and narrow bandgap (1.9–2.2 eV). With a band gap of 2.1 eV hematite can achieve a theoretical maximum solar-to-hydrogen (STH) efficiency of 15%, which exceeds the STH benchmark efficiency of 10% required for practical applications. However, the practical maximum efficiency is still far from both the benchmark and theoretical maximum STH efficiencies. Several reviews have been published highlighting significant achievements in hematite photoanode performance using various approaches. For example in 2011 Grätzel's group presented a review focusing on new insights into its basic properties, attractive aspects, and the challenges in using it for photoelectrochemical (PEC) water splitting.¹ A year later, Wheeler *et al.* provided another review dealing with progress towards the synthesis and characterization of nanostructured hematite, with an emphasis on charge carrier dynamics and photoelectrochemical properties.² In this review, we aim to present the research effort made in recent years, with a view to providing up-to-date approaches and inspiring new ideas for tackling the remaining challenges. Starting with a brief introduction, first, we briefly discuss important recent progresses in morphology determination and its relationship with the material's resulting properties, *e.g.* light absorption, water oxidation kinetics, and charge carrier collection, progress in morphology from the late thicker planar films to recent ultrathin nanophotonic morphologies are examined. Special emphasis is given to ultrathin film approaches which offer the promise of improving the tradeoff between poor carrier collection and the poor light absorption of hematite. The poor oxygen evolution reaction kinetics (charge injection efficiency) of hematite electrode; are a major challenge limiting solar conversion efficiency, *i.e.* they require a large applied potential to drive water oxidation. We discuss three different approaches to minimize the oxygen evolution overpotential *e.g.* using earth abundant catalysts, surface passivation layers and surface chemical corrosion techniques. The discussion finishes with another issue that limits the PEC efficiency of hematite; namely, the low charge separation efficiency, which results from its very

short excited-state lifetime (3-10 ps) and small hole diffusion length (2-4 nm). Extreme doping, the formation of heterojunctions, incorporation of charge separating scaffolds are some approaches that are considered to improve poor charge separation efficiency.

2. Towards sunlight-driven photocatalyst

The mismatch between increasing world population, growing energy demand and declining fossil fuel reserves all highlight the need for sustainable energy sources. To date, much effort has been put into the search for renewable and environmentally friendly energy sources. It has been established that the efficient utilization of solar energy would have the potential to alleviate many energy and environmental issues, as the solar energy that irradiates earth's surface (1.3×10^5 TW) exceeds current global human energy consumption (1.6×10^1 TW in 2010) by roughly four orders of magnitude.³ However, the intermittency of solar energy together with the temporal and geographical divergence between production and demand mean that solar energy harvesting and storage must be made more efficient and cost effective. PEC water splitting using earth abundant semiconductor electrodes, long considered to be the "holy grail" of the solar energy conversion and storage revolution, has received much attention.⁴ Such a quest if successful could pave the way for the broad use of hydrogen as a clean, green fuel. PEC water splitting dates back to the early 1970s, when pioneering research on catalysts, triggered by the work of Fujishima and Honda, demonstrated overall water splitting using a PEC cell consisting of a single crystalline TiO_2 (rutile) anode and a Pt cathode under ultraviolet (UV) irradiation and an applied external bias.⁵ Since then various metal oxide photoelectrode materials, such as $\alpha\text{-Fe}_2\text{O}_3$, WO_3 , BiVO_4 , Cu_2O , ZnO , CdS , TaON , GaP , MoS_2 , Ta_3N_5 have been extensively used for PEC water splitting. Despite these promises and many significant achievements, most of the PEC water splitting systems that have been exploited so far still face numerous challenges – meaning that the search for efficient water splitting photoelectrode materials is still in progress.

C_{BE}: Conduction band edgeV_{BE}: Valence band edge

For a semiconductor electrode to be employed as a PEC water splitting device, it should meet some critical requirements such as: suitable band gap and appropriate valence and conduction band positions relative to water oxidation and reduction potential, high visible light absorption, chemical stability in dark and illumination, commercial viability *etc.* The band gap and band edge positions of various semiconductor photocatalysts are shown in Table 1. For an ideal overall water splitting semiconductor, the valence band and conduction band edge positions must straddle the water oxidation and reduction potentials (*i. e.* $E_c > E_{\text{red, water}}$ and $E_v < E_{\text{ox, water}}$), Fig. 1 shows the band edge positions of some photoelectrodes relative to water redox potentials. Although most PEC water splitting devices reported to date have suffered from low solar-to-hydrogen (STH) efficiencies, a single ideal semiconductor light absorber with a band gap of 1.6 eV can reach as high as 30% STH. However, due to several stringent requirements, it is very difficult to find an ideal semiconductor material for PEC water splitting. As a result, most of these semiconductor electrodes still suffer from low solar-to-hydrogen conversion efficiencies. There are some factors that lower STH efficiency, *e.g.* limited photon absorption, lower charge separation efficiency (η_{sep}), low charge injection efficiency (η_{inj}), and the back reaction of photoelectrons. The most challenging issue is to improve efficiency by collectively alleviating these limitations.

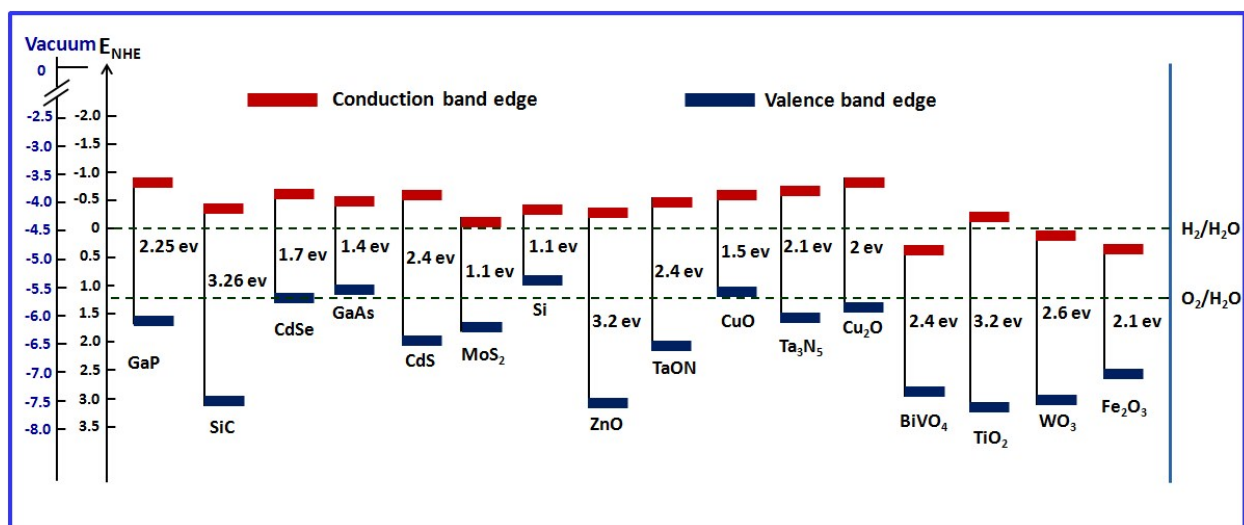

Figure 1. Band edge positions of semiconductors in contact with aqueous electrolyte at pH = 0 relative to NHE and the vacuum level. For comparison the HER and OER redox potentials are also presented.

As visible-light-driven photoelectrode materials, much attention has been given to the development of oxides, especially Fe_2O_3 , BiVO_4 , and WO_3 , because they are generally inexpensive, stable, and easily prepared on a large scale. Fe_2O_3 (α is omitted henceforth) based photoelectrodes have been studied most intensively on account of several promising properties. Fe_2O_3 is earth abundant, non-toxic, photochemically stable with a narrow bandgap (1.9–2.2 eV);²⁹ thus, with an average band gap of 2.1 eV it can achieve a theoretical maximum STH of 15%, which exceeds the STH benchmark efficiency of 10% required for practical applications.³⁰ All these properties make it a potential candidate as a water splitting photoanode for the main proof-of-concept demonstrations. However, several limitations such as relatively low absorption coefficient (due to an indirect band gap), very short excited-state lifetime ($\sim 10^{-12}$ s), poor oxygen evolution reaction kinetics, a short hole diffusion length, and poor electrical conductivity still hinder the PEC activity of hematite. To overcome these shortcomings various efforts have been made, *e.g.* nanostructuring; passivating surface localized electron trap states using co-catalysts and thin overlayer coatings; using more than one absorber (heterostructures); using localized surface plasmons; quantum dot sensitization; reduction of film thickness; doping; and introducing electron collecting scaffolds.

3. Scope of the review

This review comprises four main sections, organized as follows: the first part gives details about electronic structure, morphology, photoelectric properties and the photocatalytic reaction mechanisms of hematite. The second part presents a detailed review of the mismatch between hole diffusion length and light harvesting efficiency in ultrathin hematite nanostructures. Significant emphasis has been given to recent experimental approaches, such as superior light harvesting photonic structures that simultaneously enhance photon absorption and hole diffusion lengths. In the third part great emphasis is paid to the recent emerging strategies employed to improve the water oxidation reaction kinetics that promise to split water at low applied potentials. The outcome of surface passivation layers on charge transfer processes across semiconductor–liquid interfaces will be also discussed in accordance with different approaches. One of the main factors that limit lowering of the practical water oxidation photocurrent ($J_{\text{H}_2\text{O}}$) is charge separation efficiency (j_{sep}). Therefore, strategies such as doping, the formation of

heterojunctions and the application of electron conductive scaffolds to improve the j_{sep} are studied in the fourth part of this review.

4. Hematite ($\alpha\text{-Fe}_2\text{O}_3$)

4.1. Magnetic, optical and electronic properties of hematite

In this section we discuss the crystal structure, magnetic, optical and electronic properties of hematite and band bending in hematite/electrolyte interfaces. In keeping with the theme and motivation of this article, we restrict our discussion to matters relevant to solar energy conversion devices. According to literature reports, polycrystalline n-type iron oxide electrode films were first investigated by Hardee and Bardl using chemical vapor deposition (CVD) onto Ti and Pt substrates.³¹ Hematite, which is iso-structural with corundum ($\alpha\text{-Al}_2\text{O}_3$),³² is the most thermodynamically stable form of iron oxide under ambient conditions and also the most common form of crystalline iron oxide. The hematite structure has two formula units per unit cell, the trigonal-hexagonal and the primitive rhombohedral unit cells (Fig. 2).³³ It contains iron and oxygen atoms arranged in a trigonal-hexagonal unit cell structure with space group R-3c and lattice parameters $a=b=0.5034$ nm, $c=1.375$ nm, with six formula units per unit cell. For rhombohedra unit cell, $a_{\text{rh}}=0.5427$ nm and $\alpha=55.3^\circ$.

It is easy to understand the hematite structure based on the packing of the anions, O^{2-} , which are arranged in a hexagonal closed-packed lattice (hcp) along the [001] direction with the cations (Fe^{3+}). Two thirds of the sites are filled with Fe^{3+} ions which are arranged regularly with two filled sites being followed by one vacant site in the (001) plane thereby forming six fold rings.³²³⁴ The arrangement of the cations produces pairs of FeO_6 octahedra that share edges with three neighboring octahedra in the same plane with one face in an adjacent plane in the [001] direction (Fig. 2(b)).³³ Octahedral face sharing, which occurs along the c-axis, is responsible for the distortion, from ideal packing, of the cation sub-lattice; Fe atoms in the octahedra which share faces are repelled along the direction normal to the [001], causing the cations to shift closer to the unshared faces.^{32, 35}

Figure 2. Schematic illustration of the crystal structure of hematite: (a) hexagonal unit cell and (c) rhombohedral primitive cell. The face-sharing octahedra in (a) and (c) are shown in (b) and (d) respectively. The Fe^{3+} ion is along the c -axis. Color scheme: Fe = grey and O = red. Adapted from *J. Phys.: Condens. Matter* 2012, 24, 325504 and *Dzade et al. Minerals* 2014, 4, 89-115.

Even though the magnetic properties of hematite are not pertinent to its photoelectrochemical performance, the iron spin configuration does influence its optoelectronic and carrier transport properties. These attributes should be properly understood prior to its use as a solar water splitting semiconductor.¹ Various studies have shown that the magnetic features of hematite depend on two factors, i.e. temperature^{1, 33, 36, 37} and particle size.³⁶⁻³⁸ At room temperature hematite is weakly ferromagnetic, while above 956 K (T_c) it is paramagnetic. At 263 K it undergoes a magnetic phase transition to an antiferromagnetic state.³⁶⁻³⁸ This lower temperature transition is called the Morin temperature (T_M), below which the two magnetic sub-lattices are oriented along the rhombohedral $[111]$ axis and are exactly antiparallel.^{37, 38} Above T_M the magnetic moments lie in the basal (111) plane with a slight canting away from the antiferromagnetic axis resulting in a small net magnetization in the plane.³⁸ Above T_M , the Fe^{3+} ions are antiferromagnetically coupled across the shared faces along the c -axis. The antiferromagnetic (AFM) structure is shown in Fig. 3 where iron atoms are coupled ferromagnetically within a single octahedral layer, and alternating layers are coupled anti-parallel along the $[0001]$ direction.³⁹ However, as all iron atoms have an equivalent octahedral environment, the electronic and magnetic properties will be the same at each iron site. A study

by M. Chirita *et al* observed strong dependence of the Morin temperature on the size of the particles, generally decreasing with it and tending to disappear below a diameter of ~ 8 nm for spherical particles.³⁷ They showed that hematite nanoparticles below 8 nm in diameter have superparamagnetic properties. Another similar study by F. Bødker and coworkers also found that for particles smaller than 8–20 nm, the transition temperature is below 4 K.³⁸ This effect has been explained by a lattice expansion in the small particles, but strain and defects may also be important. In particular, it is known that the spin reorientations in hematite are determined to a large extent by the presence of impurities or substitutions and by the particle's size and morphology.³⁶ Therefore, the magnetic features of hematite are influenced by the method of preparing the sample, which in turn influences the particle size and morphology.

Figure 3. Magnetic order around iron atoms in the hematite hexagonal cell below and above the Morin temperature. Color scheme: Fe = grey and O = red. Adapted from *J. Phys. Chem. C*, 2013, 117, 3779-3784.

The optoelectronic properties of hematite must be understood to optimize its performance as a solar energy conversion material. The optical absorption bands of hematite begin in the near-infrared spectral region and extend into the UV region.^{30, 40} The optical spectrum of Fe^{3+} in hematite results from three types of electronic transitions.^{41, 42} (1) ligand field transitions (i.e. d–d transitions), (2) ligand-to-metal charge transfer transitions (LMCT) from the O (2p) non-bonding

valence bands to the Fe (3d) ligand field orbitals and (3) pair excitations resulting from the simultaneous excitation of two adjacent Fe^{3+} cations which occupy adjacent sites.

4.2. Photoelectrochemical water splitting on hematite photocatalyst

When a semiconductor absorbs photons with energy equal to or greater than its band gap, electrons will be excited from valence band (VB) to conduction band (CB), leaving the holes in the VB. Then the electrons and holes migrate to the photoelectrode's surface and are injected into the electrolyte through the co-catalyst to generate hydrogen and oxygen respectively. This electron-hole pair generation process in Fe_2O_3 can be expressed as follows:

The possible photoinduced chemical and physical processes involved inside and on the surface of a semiconductor electrode during solar water splitting are shown in Fig. 4. The reaction entails several critical steps such as: (i) light absorption (ii) charge separation; (iii) charge transfer (injection); (iv) surface chemical reactions; (v) bulk and surface recombination; (vi) water oxidation and reduction reactions. The water oxidation efficiency on a semiconductor photoanode such as hematite is determined by three processes: light harvesting; the transport of photogenerated holes to the solution interface and photoelectrons to the current collector (charge separation efficiency); and hole collection *via* water oxidation at the electrode's surface (charge injection efficiency). Understanding charge transfer at the electrode/electrolyte junction is therefore of paramount importance to enhancing efficiency. When hematite is brought in contact with an electrolyte solution, charge will flow between the electrode and the electrolyte solution. This charge transfer results in an interfacial electric field whose electrostatic potential balances the initial electrochemical potential difference between the solution and semiconductor. Due to this equilibration a band-bending, which depends on the difference of the Fermi levels of semiconductor and electrolyte, is created within the semiconductor phase. The region where there is bending is called the space charge layer (SCL) and is characterized by the accumulation of electrons or holes at the surface. Fig. 5 shows the behavior of charges in the semiconductor before and after equilibration when it comes in contact with an electrolyte. The electric field developed inside the space charge region (depletion layer) plays a role in assisting the spatial

separation of the charge carriers, since holes (h^+) are attracted to the surface, where the negative field is stronger; for the same reasons electrons (e^-) are repelled from the surface to the bulk of the solid, where they diffuse through the external circuit to the counter electrode. For a hematite photoanode in equilibrium with redox species in solution (O_2/H_2O), the electrode will have an excess positive charge over the depletion width and the solution will have an excess negative charge in the Helmholtz layer close to the electrode.⁴³ When an external bias is applied the Fermi level will vary depending on the amount of bias and thereby the band will bend.⁴⁴ At a certain applied bias the potential drops between the surface and the bulk of the electrode to zero; in other words, there is no space charge layer. This potential is called flat-band potential, V_{fb} (Fig. 5). The application of any potential greater than the flat band potential will increase band-bending at the electrode. In this case electrons are depleted and holes will reach the electrode's surface.

Figure 4. Schematic illustration of an ideal photocatalyst loaded with water oxidation and reduction co-catalysts with possible photoelectrochemical processes.

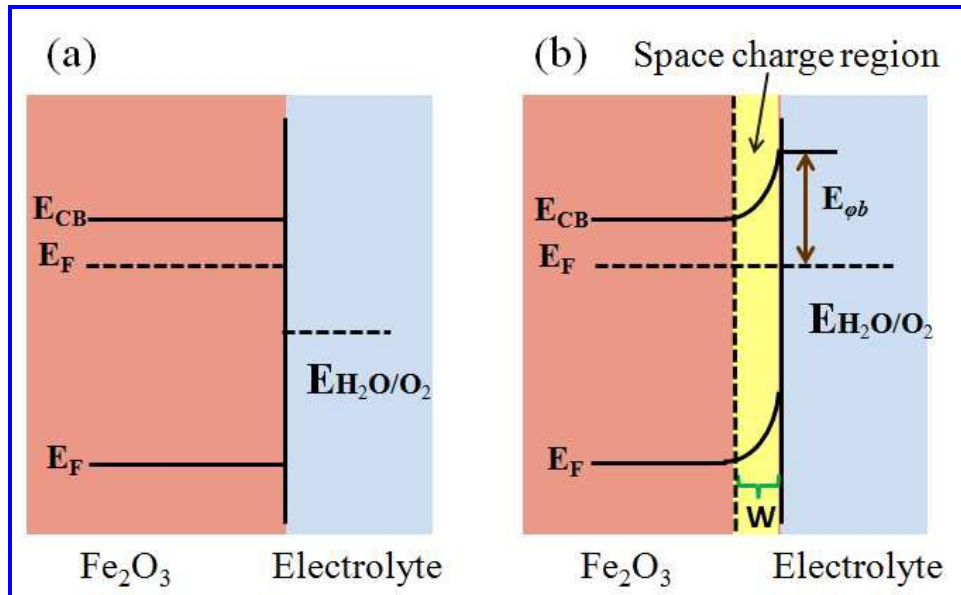

Figure 5. Dark equilibration of hematite (n-type semiconductor) with an electrolyte containing a redox couple potential E . (a) before equilibration; (b) departure from equilibration. The potential barrier height Φ_b sets the upper limit to the energy that can be extracted from the junction.

Theoretically, the maximum water oxidation photocurrent (J_{\max}) for a Fe_2O_3 photoanode, at a band gap of 2.1 eV under Air-Mass 1.5 Global (AM 1.5G) solar illumination, is 12.5 mA cm^{-2} , which is equivalent to 15.4% STH. However, the practical water oxidation photocurrent ($J_{\text{H}_2\text{O}}$) is lower due to the limited light absorption (J_{abs}), charge separation (η_{sep}), and surface charge injection efficiency (η_{inj}) of the material, according to $J_{\text{H}_2\text{O}} = J_{\text{abs}} \times \eta_{\text{sep}} \times \eta_{\text{inj}}$.^{44, 45} Hematite has a light penetration depth of 118 nm at 550 nm which is longer than its hole diffusion length (2-4 nm).⁴⁶⁻⁵⁰ Hence, effective charge generation and separation cannot be achieved in a flat geometry of hematite because increasing the film thickness would lead to more charge carrier accumulation and decreasing the film thickness would lead to less light absorption. The practical consequence is that only holes generated within a few nanometers of the semiconductor liquid junction (SLJ) can reach the interface and be used for water oxidation. The rest recombines with electrons and generates only heat. Charge separation efficiency is limited by both the short hole diffusion length and the very short excited state lifetime (1 ps).⁵¹⁻⁵³ An ultrafast transient absorption measurement showed that the very fast decay of charge carriers in hematite is possibly due to a high density of intrinsic mid-band gap electronic states, internal defect induced trap states, and, to a lesser extent, surface defects.⁵² Moreover, the poor electrical conductivity of

hematite (in the order of 10^{-2} cm²/V.s at room temperature), which is associated with the Fe³⁺/Fe²⁺ valence alternation on spatially localized 3d orbitals, also affects the charge separation efficiency greatly. A third limiting factor is the sluggish oxygen evolution reaction (OER) at the electrode/solution interface. This might be due to the rapid capture of holes by Fe³⁺ e_g level, which lie above the top of the O 2p⁶ band, instead of the O 2p⁶ band itself.⁵⁴ It has been also shown that surface trap states preferentially trap holes before they reach to the electrolyte interface and oxidize water.⁵⁵ Using transient absorption measurements, Barroso *et al* also showed that the existence of interband states can trap holes at the surface.⁶ Indeed, in the absence of an applied bias, or under a cathodic bias close to flatband potential, these intraband states are largely occupied by electrons and therefore photoholes can rapidly become trapped in these sites. Various strategies have been developed to overcome these limitations. To improve light absorption and photon-to-current conversion efficiency, nanophotonic structures, using more than one absorber, with reflective coatings, plasmonic structures, *etc* have been employed. Different approaches have been used to enhance the charge separation efficiency such as nanostructuring, doping, using heterojunctions, incorporating conducting scaffolds. Co-catalysts, surface passivation layers and surface chemical corruptions have been used to facilitate charge injection at the SLJ and reduce the required overpotential.

5. Progresses in morphological design

Despite having several advantages, the small carrier harvesting depth of hematite greatly limits its photoelectrochemical performance. Several studies have demonstrated various highly photoactive Fe₂O₃ morphologies to offset this limitation. In the case of thicker planar Fe₂O₃ films a majority of the photogenerated carriers vanish due to recombination. Therefore, most of the carriers generated far away from the semiconductor-electrolyte interface cannot be collected, resulting in a negligible photocurrent. In addition to this, Souza *et al.* argued that in thicker films the strong interaction between film and substrate induces stress which generates defects in the crystal lattice of the hematite film, increasing the e⁻-h⁺ recombination process.⁵⁶ On the other hand, stacked thin films are considered to be effective approaches to extend the hole transport distance. However, the surface area and photon absorption of this type of photoanode is not high enough.⁵⁷ A means of resolving this problem is to construct nanostructured electrodes, such as

nanoparticles, nanoflowers, nanowires (NWs), nanotubes, or nanocones. For PEC water splitting, the nanostructured materials can offer a large interfacial area between the photocatalyst and the electrolyte, which is favorable for the transportation and separation of charge carriers.⁵⁸⁻⁶¹ Nanoparticles, dendrites and mesoporous hematite films often suffer from recombination and poor transport across grain boundaries between particles.⁶² In this regard, one dimensional (1D) nanostructures such as nanowires, nanotubes, and nanorods with high aspect ratios and large surface areas can improve charge carrier collection by minimizing hopping transport and thus reduce recombination losses at grain boundaries.⁶³ Moreover, 1D hematite nanostructures with smaller diameters can minimize the distance needed for the holes to diffuse to electrolyte-semiconductor interface, thereby avoiding the poor charge transport limitation. Beermann and co-workers recently reported the use of hematite nanorod arrays as photoanodes in a PEC cell and demonstrated that 1D nanostructures could potentially address some of the fundamental PEC issues and increase the device's efficiency.⁶⁴ Cauliflower nanostructures grown *via* atmosphere pressure chemical vapor deposition (APCVD) in combination with doping and surface modification with more efficient oxygen evolution catalysts have shown significantly improved performances and made nanostructured hematite a more promising photoanode material. For example Andreas *et al* reported cauliflower-like structured hematite with an incident photon current efficiency (IPCE) of 42% at 370 nm at 1.23 VRHE.⁵⁹ The detailed comparison of nanofilm and 1D nanostructures for water splitting application was reported by Warren's group, in which the better photo-response was obtained by 1D nanostructured electrode.⁶⁵ Most recently, an ultrathin hematite photoanode grown on a 3D nanophotonic structures was considered to be an ideal promising morphology.^{66, 67} It has been reported that, the 3D nanophotonic structures provided excellent light-trapping capability, ensuring sufficient light absorption with thin hematite film and short carrier transport distance. (A detailed account of nanophotonic hematite structures is given in the next section). Fig. 6 and Table 2 summarize the progress of the morphological evolution of hematite nanostructures for photoelectrochemical water splitting.

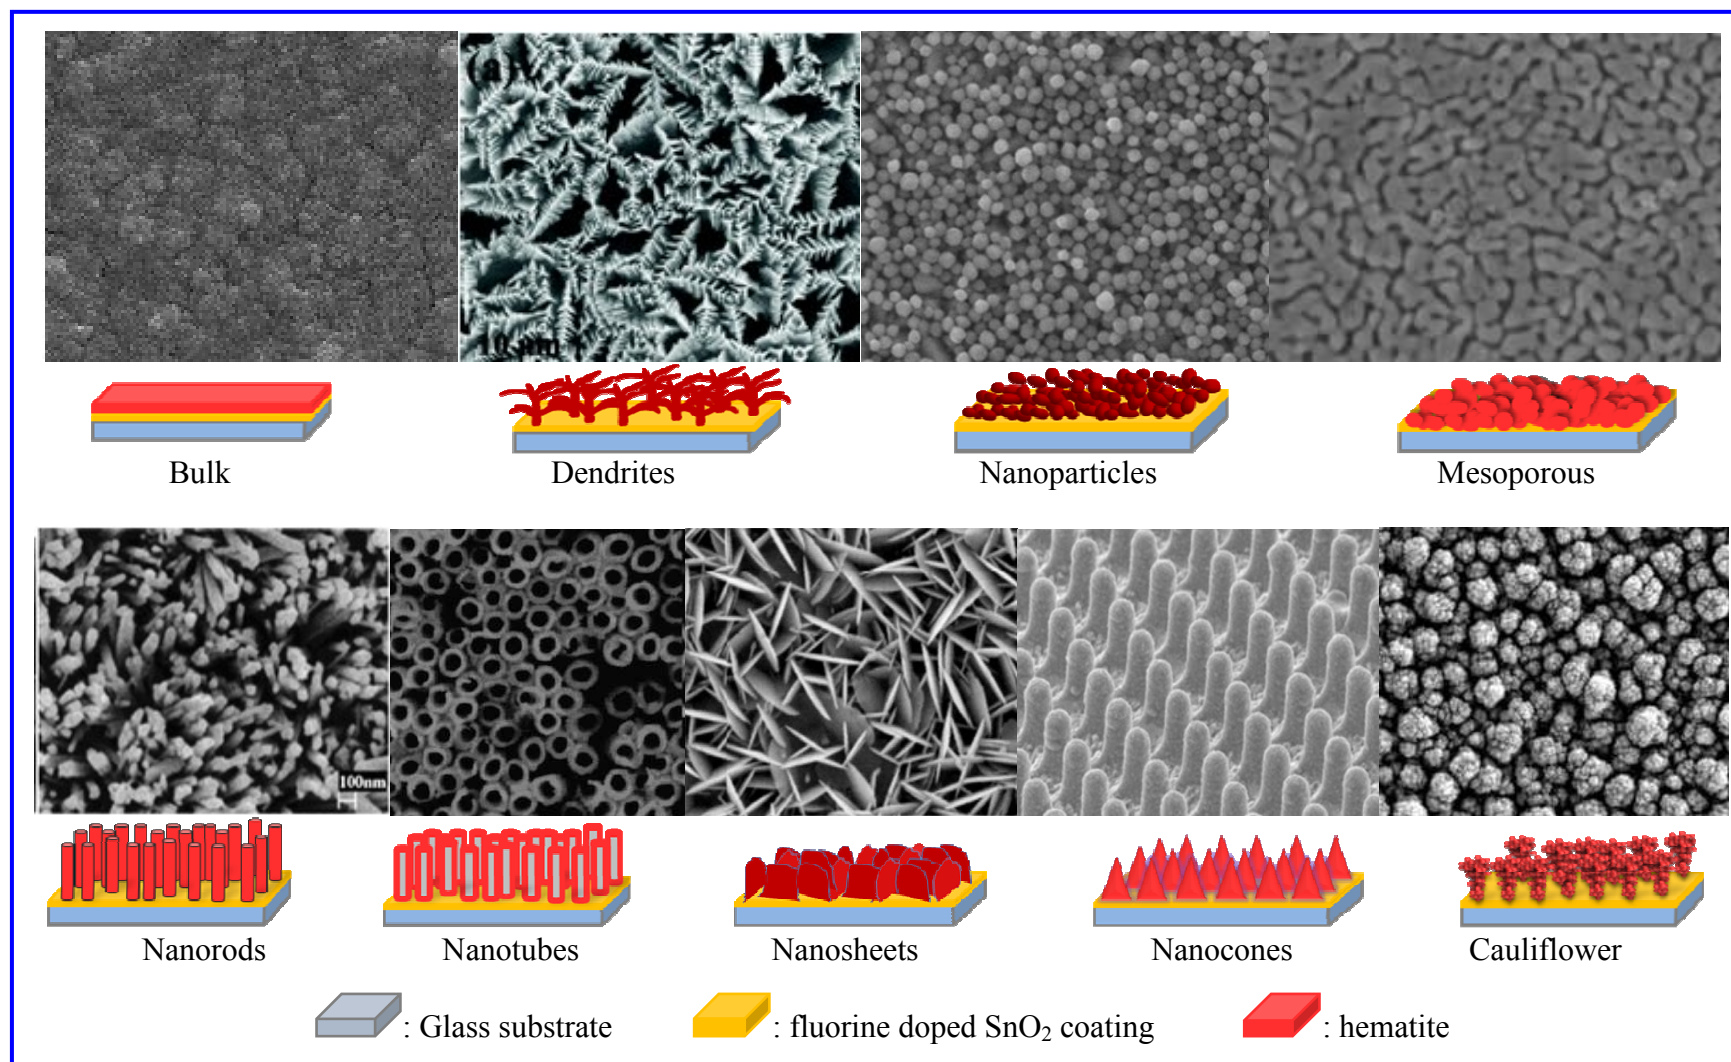

Figure 6. SEM images and representative schemes of different hematite nanostructures grown on FTO coated glass substrate showing the progress in morphology for photoelectrochemical water splitting.

Table 2. Major advances in the morphological evolution of hematite nanostructures for photoelectrochemical water splitting. (NB: The synthesis methods and the photocurrent values for each nanostructure are taken from a single reference)

Type of Nanostructure	Features	Synthesis methods	J at 1.23 V vs. RHE (mA cm ⁻²)	Reference
Bulk	Dense, high e-h recombination, high photon absorption	Electrodeposition	No photocurrent response*	Chou <i>et al.</i> ⁶⁸
Dendrites	Dense, poor light absorption, long electron path, high e-h recombination	Electrodeposition	~0.018	Zheng <i>et al.</i> ⁶⁹
Nanoparticles	More surface area than bulk, long electron path, low electrode/electrolyte interaction	Anodization	0.05	Fu <i>et al.</i> ⁷⁰
Mesoporous	More surface area than bulk, higher electrode / electrolyte interaction than nanoparticles	Colloidal synthesis	1.1	Gonçalves <i>et al.</i> ⁷¹
Nanorods/ Nanowires	strong anisotropic conductivity, low grain boundaries	Hydrothermal	1.24 (Sn doped)	Ling <i>et al.</i> ⁷²
Nanosheets	Ultrathin film thickness (< 10 nm), highly dense film (430 nm)	Hydrothermal	1.4 (Ge doped)	Liu <i>et al.</i> ⁷³

6. The trade-off between absorption and carrier collection efficiency

Many candidate photocatalyst materials suffer from highly reduced charge transport as the minority carrier diffusion lengths are significantly shorter than the absorption depth of light (micrometer scale near the band edge). In this section we will briefly discuss some of the latest advances with respect to the fabrication of ultrathin film hematite photocatalysts giving maximum possible photon absorption. A particular emphasis will be given to light trapping strategies specially nanophotonic structures which are promising solutions to the dilemma of low charge separation and low photon absorption efficiencies. Hematite has very short hole diffusion length (20 nm⁷⁶, 2–4 nm^{49,72}) compared to the light penetration depth ($\alpha^{-1} = 118$ nm at $\lambda = 550$ nm)⁷⁷ and it results in rapid non-radiative electron-hole recombination inside the semiconductor and thereby greatly limits its PEC performance.⁷⁸ In general, for an active material with a short carrier diffusion length, thinning down the material can lead to improved carrier collection. However, ultrathin hematite films suffer from low photon absorption due to the mismatch between the photon penetration depth and the film's thickness.

Recent studies on thick layers^{79,80} as well as ultrathin films⁸¹ confirm that the efficiency of Fe₂O₃ photoanodes is mainly limited by the collection of photogenerated holes at the surface. Thus, reducing bulk recombination is the key to improving the internal quantum efficiency (IQE) of Fe₂O₃ photoanodes, an important step towards efficient, sustainable, durable and potentially inexpensive solar hydrogen production. To start our discussion of ultrathin planar films we begin with a promising approach by Dotan and co-workers.⁸² They use reflecting coatings and take advantage of resonant light trapping using multiple reflections in a flat hematite film deposited on a reflective surface (Fig. 7 (a)). The authors claimed that interference between forward- and backward-propagating waves enhances the light absorption in quarter-wave or, in some cases, deeper sub-wavelength films. This enables maximization of absorption in regions where the photogenerated minority charge carriers (holes) can reach the surface, while minimizing of the wasted absorption in regions where they are lost to recombination. Combining this effect with photon re-trapping schemes, such as using V-shaped cells (Fig. 7 (b)), provides efficient light harvesting in ultrathin films, overcoming the trade-off between light absorption and charge collection. A water photo-oxidation current density of 4 mA cm⁻² was achieved using a V-shaped

cell comprising 26-nm-thick Ti-doped Fe_2O_3 films grown a substrate coated with silver–gold alloy back-reflector.⁸²

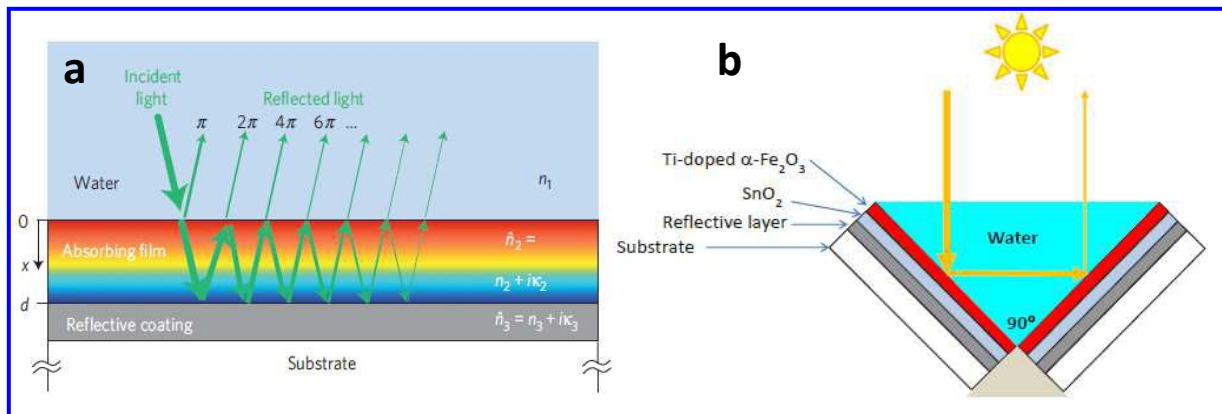

Figure 7. (a) Schematic illustration of the light propagation in a quarter-wave ($d=\lambda/4$, for normal incidence) absorbing film on a back-reflector substrate. The different colors represent the light intensity distribution across the film (red, high; blue, low). (b) Schematic illustration of photon re-trapping using a 90° V-shaped cell. Adapted from *Nature Materials*, 2013, 12, 158-164.

Even though such ultrathin planar films are advantageous for carrier collection they still suffer from severe light absorption (unless a proper light trapping configuration is designed as discussed above) and a low PEC surface area. In this regard 1D nanostructured morphologies with controlled film thickness are beneficial. Besides the smaller feature size and film thickness, the preferential growth orientation of 1D nanostructures also plays a crucial role in improving PEC performance. Iordanova *et al.* have concluded that a strong anisotropic conductivity in the hematite lattice, where the conductivity within the (001) basal plane is four times higher than the conductivity along the [001] direction because of a hopping mechanism related to $\text{Fe}^{2+}/\text{Fe}^{3+}$ mixed valence states within the iron bilayers.⁸³ Thus arrays of 1D single crystal hematite nanostructures, such as nanoscaled rods, tubes, or wires, attached and oriented vertically to the conducting substrate are important to facilitate the collection of photogenerated electrons, and further enhance PEC efficiency. They provide a direct path that facilitates electron transport, and allows photogenerated holes to efficiently reach the electrolyte interface, while also exposing as many active facets as possible to the electrolyte for water oxidation.

Many studies have demonstrated efficient nanostructured hematite morphologies, while at the same time controlling the size of the nanostructure down to the ultrathin level. The first attempt to synthesize ultrathin hematite nanostructure was made by Duret and coworkers.⁸⁴ They synthesized vertically aligned mesoscopic Fe₂O₃ platelets having a thickness of 5-10 nm and size of 100 nm using ultrasonic spray pyrolysis technique. The mesoscopic leaflet structure has the advantage that it allows for efficient harvesting of visible light, while offering at the same time a very short hole diffusion length to reach the electrolyte interface before recombining with electrons. Recently Lui *et al* synthesized highly oriented Ge-doped Fe₂O₃ nanosheet arrays grown in the (001) basal plane and vertically aligned on FTO coated glass substrates using a hydrothermal method (Fig. 8 (a)).⁷³ These nanosheets display ultrathin nanostructures with thicknesses of no more than 10 nm and construct a highly dense film with the average overall thickness of 430 nm. Perpendicularly aligned Fe₂O₃ sheets having a thickness between 15 and 25 nm have also been synthesized by Cesar *et al.* using ultrasonic spray pyrolysis of their iron precursor solutions. The authors argued that this particular grain size, orientation and morphology (leaf shaped sheets) afford facile transfer of holes to the electrolyte, before the recombination occurs, while still shuttling electrons to the back contact. The addition of silicon produced further improvements in the photo-response that was attributed to morphology changes rather than to electronic effects.⁵⁸ An innovative work by Mohapatra *et al.*, who synthesized smooth Fe₂O₃ nanotubes on Fe foil, using a sonoelectrochemical anodization method, targeted the short hole diffusion length of hematite, while simultaneously enhancing photon absorption by controlling the thickness of the nanowalls to 5-6 nm and the overall film thickness to 3-4 μm (Fig. 8 (b), (c)). They found that the charge transport properties of the nanotubes to be 40-50 times higher than those of the nanoparticles, leading to better photoactivity of the nanotubes compared to the nanoparticles.⁷⁴ Recently, design guidelines for efficient light harvesting nanostructures for applications such as photovoltaics and photodetection were demonstrated using finite difference time domain (FDTD) simulations with Ge as the model material.⁸⁵ They showed that properly designed nanopillar and nanocone arrays are the most efficient light harvesting morphologies with high broad band solar spectrum absorption capabilities (Fig. 8 (d1) to (d4)).

Adapted from *Nano Ener.*, 2013, 2, 951-957.

The creation of rationally designed multi-diameter nanopillar or nanocone structured hematite is not as simple as for other monoatomic semiconductors *e.g.* Si and Ge, due to problems encountered in synthesis. Kim *et al.* fabricated judiciously nanopatterned multi-walled nanobeam arrays of hematite photocatalyst from lithographically defined Fe nanobeam-arrays and

subsequently transforming to iron oxide beams simply by calcination in air at 600 °C for 4–5 min. Such nanostructuring allows sunlight to drive optical resonances that can both enhance the light intensity inside the photoelectrode and favorably redistribute the highest fields to the near surface region from which carriers can effectively be collected without significant recombination.⁸⁶

An alternative efficient approach that offsets the trade-off between smaller film thickness and low photon absorption of hematite is the design and construction of three-dimensional (3D) nanostructures. 3D nanostructured arrays not only enhance carrier collection efficiency (due to shortened diffusion length) but also improve photon harvesting capability at smaller film thickness. Recently, great attention has been given to ultrathin hematite nanocone/nanospike arrays. Their anti-reflective and light trapping properties enable them to absorb the majority of the incident light.⁸⁷

It has been shown using first-principles full-field electromagnetic simulations that near total above-band-gap solar absorption can be achieved in ultra-thin nanocone iron oxide film photoanodes for water splitting applications. Assuming a hole diffusion length of 20 nm, which is within the experimental range, a photocurrent density of 12.5 mA cm⁻² can be obtained, which is comparable to the ideal photocurrent limit.⁸⁸ Fig. 9 (a) shows a schematic diagram of a 20 nm hematite film on a 3D photonic substrate, where any region of hematite is within of the nearest hematite-water interface which is favorable for efficient carrier extraction. Although charge transport is very complex in real hematite electrodes, the authors assumed that all photogenerated carriers in such a design can contribute to the photocurrent. Similar near-unity absorption characteristics are also shown by thinner structures; a simplification that allows us to focus on the optical aspects of such structures. Fig. 9 (b) shows the performance of the photonic structures at different total height (H) relative to the photocurrent (J) generated from single-pass absorption. The authors assumed perfect antireflection at the water-hematite interface for the planar structure with single-pass absorption; however, due to the extremely short hole diffusion length of 20 nm, only the photons absorbed in the first 20 nm region in the hematite can effectively contribute to the photocurrent. On the other hand, in the nanocone structure, all absorption in hematite occurs within 20 nm of the water-hematite interface, and hence all photons can, in principle, contribute, resulting in a much higher photocurrent. In fact, no single material can meet all the requirements

of an ideal PEC photoelectrode. Qiu *et al* fabricated ultrathin hematite coated on pre-synthesized regular arrays of 3D conductive nanospikes (NSPs).⁶⁶ Figs. 9 (c) and (d) show ultrathin hematite film deposited on a 3D nanophotonic Al₂O₃ structure after deposition of several protective coating layers, including a ~100 nm thick Ti/Pt metal layer and a ~200 nm thick FTO layer. It has been stated that the nanophotonic structures can significantly improve light absorption in the ultrathin hematite active material, where the large surface area accommodates the slow surface water oxidation process and act as an efficient carrier collection path. As a result, a high current density of 3.05 mA cm⁻² at 1.23 V *vs.* RHE has been achieved on such nanophotonic structures (Fig. 9 (e)), which is about three times higher than that of the planar photoelectrode. Finite-difference-time-domain (FDTD) simulations carried out in the wavelength range 300 to 600 nm on planar and NSP showed much greater photon absorption on NSP substrate than on a planar substrate, which shows the light trapping enhancement when the 3D NSP photoelectrode is used. More recently the same research group demonstrated Ti doped hematite with a film thickness of 90–100 nm deposited on a novel 3D hexagonal nanocone array of fluorine-doped tin oxide (FTO) supporting electrodes that showed an 86 % increment in current density at 1.23 V *vs.* RHE compared to its planar counterpart (Fig. 9 (f) and (g)).⁶⁷ The authors claimed that the specially designed 3D FTO layer provides a larger electrode surface area and/or stronger light-trapping compared with the commonly used planar FTO glass substrate. To fully utilize the special light harvesting property of the 3D FTO structure, a gold layer was deposited under the Fe₂O₃ film to concentrate the incident light into the near surface region. Finite different-time-domain (FDTD) simulations have also been performed to confirm the strong light trapping property of the 3D FTO substrate and the surface light absorption enhancement brought about by the gold layer (Fig.9 (h)). The authors argued that as the distance between neighboring cones is close to the incident light wavelength, the incident light becomes diffracted and the electromagnetic wave will re-distribute in the nanocone area, leading to a significant electric field enhancement around the 3D structure. In other words, the incident light has been “trapped”. In addition to this, the electric field at the surface of the Fe₂O₃ layer has been significantly enhanced in the 3D structure, resulting in more efficient absorption by the active material.

The recent and rapid development of surface plasmon resonance (SPR) combined with thin films has also offered a new opportunity to overcome the limited efficiency of hematite photoanodes.⁸⁹⁻⁹² SPR improves the solar-energy-conversion efficiency by (i) extending light absorption to longer wave lengths, (ii) increasing light scattering, and (iii) exciting electron–hole pairs in the semiconductor by transferring the plasmonic energy from the metal to the semiconductor.⁹³ In 2011, Gao *et al.* published a report on the synthesis of ultrathin hematite nanopillars patterned on pre-synthesized Au nanopillars⁹² (Fig. 10 (a)). The gold nanopillars were first fabricated by nanoimprinting. Then they deposited the photoanode material (Fe_2O_3) on the Au surface using electron-beam-evaporated metallic Fe followed by annealing in pure oxygen at 450 °C for about 1 hour. It was stated that the enhanced saturated photocurrent density of iron oxide thin-film photoanode coated on arrays of Au nanopillars (Fig. 10 (b)) was attributed primarily to the increased optical absorption originating from both SPR and photonic-mode light trapping in the nanostructured topography. The resonances can also be tuned to a desirable wavelength by varying the thickness of the iron oxide layer. A similar approach was reported by Li and co-workers on the use of photonic and plasmonic energy-transfer enhancement techniques to enhance the PEC performance of hematite.⁸⁹ They reported a unique heterostructure which consists of a hematite nanorod array grown on a plasmonic gold nanohole array pattern (Fig. 10 (c)). As the nanohole array is filled with the hematite nanorods, the extraordinary optical transmission launches a guided wave mode inside the nanorod similar to an ‘optical fibre’, creating the confined modes, which trapped the incident light and enhanced the light absorption further. The authors argued that this heterostructure not only reduces the charge recombination rate but also enables both photonic and plasmonic energy-transfer enhancement in a wide ultraviolet–near-infrared spectral region. Using this configuration, a tenfold enhancement in

photocurrent density was achieved at 0.23 V vs. Ag/AgCl (Fig. 10 (d)) by taking the whole geometric area of the photoanode instead of the effective electro-active area.

7. Enhancing water oxidation kinetics

The poor oxygen evolution reaction kinetics of the hematite electrode is one of the major challenges that limits its solar conversion efficiency and thereby imposes the requirement of a large applied potential to drive water oxidation. This is due to insufficient transfer of photogenerated holes from the electrode's surface to the electrolyte solution (hole injection) which occurs only under high applied potentials. This is typically attributed to the large amount of recombination between electrons in the conduction band and oxidized surface states at low applied potentials.^{50, 94, 95} Even though the nature and role of these surface states remain a topic of debate, as highlighted in several recent perspectives, all of them showed that surface states greatly affect the intrinsic onset potential of hematite.^{50, 94-96} To date, the preparation of hematite with intrinsically low onset potential has remained a great challenge. Various studies reported that the intrinsic onset potential of hematite ranges between 0.7 to 1.1 V vs. RHE in 1M NaOH electrolyte.⁹⁷⁻¹⁰⁰ In August 2014 Han *et al* published a communication article reporting on the preparation of a unique gradient structure photoanodes directly oxidizing Fe foil in a H₂/O₂ flame at *ca.* 1700 K that shows the lowest intrinsic onset potential of 0.58 V vs. RHE for the PEC water oxidation. This extremely low onset potential observed is mainly ascribed to the passivation of surface trap states by high temperature heating treatment and the facile charge migration facilitated by the gradient structure of the photoanode.¹⁰¹ The higher overpotential of hematite can be improved either by lowering potential-dependent rate constants for surface-mediated charge recombination or by increasing the rate constant for hole transfer from the photoelectrode to the molecular reactant.¹⁰² The former can be accomplished by passivating surface localized electron trap states-for example, *e.g.* by deposition of surface trapping overlayers, chemical treatment techniques.^{60, 99, 103} The latter can be overcome by deposition of oxygen evolution reaction (OER) catalysts. In this section we will focus on recent strategies employed to lower the overpotential of hematite for PEC water oxidation.

7.1. Cocatalyst

One of the biggest challenges in water splitting is to overcome the thermodynamically 'uphill' hydrogen and oxygen evolution half reactions which involve four-electron transfer reactions.¹⁰⁴ Cocatalysts loaded on the surface of semiconductors have been proven to be able to facilitate

photocatalytic reactions by accommodating excited electrons/holes and promoting redox reaction kinetics. They facilitate water oxidation reactions usually through the oxidation of the metallic element of the co-catalyst itself which assists hole transport from the hematite surface to the electrolyte. For example the electrochemical, XANES, and EPR analyses have indicated that the electrocatalytic function of the famous cocatalyst, Co-Pi, is associated with oxidation from Co(II) to Co(III) and Co(IV), leading to the formation of high-valence Co(IV)-O intermediates.¹⁰⁵⁻¹⁰⁷ Fig. 11 schematically describes the role cocatalysts play in photocatalytic and PEC water oxidation. Overpotential is always necessary to drive the water oxidation reaction due to the activation energy barrier. The presence of cocatalysts on photoanodes can improve the photocurrent and negatively shift the overpotential (Fig. 11 (a)) by decreasing the activation energy (Fig. 11(b)) and improving the solar and electric energy utilization efficiency.^{98, 104} The negative shift of onset potential corresponds to the lowering of the overpotential.

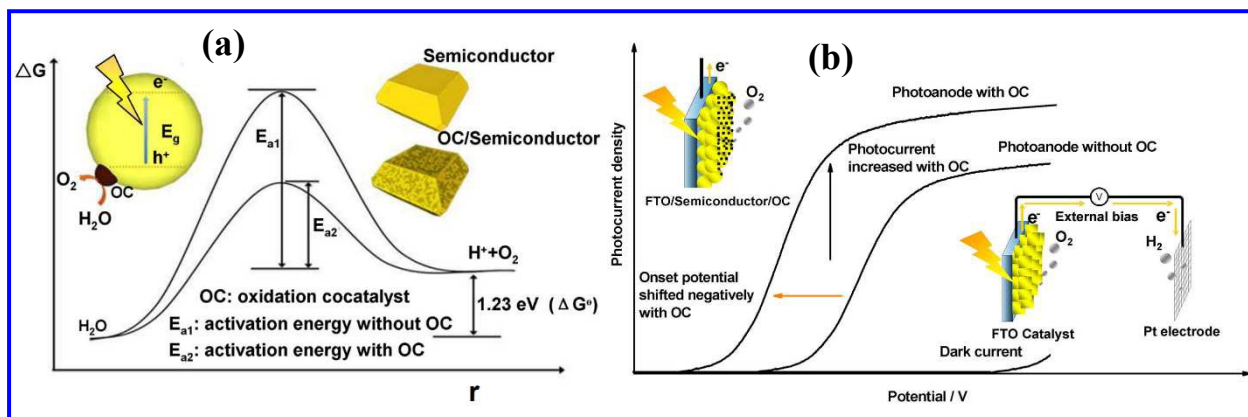

Figure 11. Schematic description of the role of oxidation cocatalysts in (a) photocatalytic and (b) photoelectrochemical water splitting systems. Adapted from *Acc. Chem. Res.*, 2013, 46 (8), 1900–1909

Noble metal oxides such as IrO_x ^{108, 109} and RuO_x ¹¹⁰ have been investigated as conventional water oxidation cocatalysts. It has been reported that the surface modification of nanostructured hematite photoanodes by IrO_2 nanoparticles (*ca.* 2 nm diameter) resulted in a 200 mV shift in the photocurrent onset potential and an increase in the plateau photocurrent from 3.45 to 3.75 mA cm^{-2} vs V_{RHE} under standard testing conditions.¹⁰⁹ A stoichiometric IrO_x , with $x \approx 2.1$ also showed a 300 mV cathodic shift in photocurrent onset potential with the highest surface

concentrations of IrO_x tested.¹⁰⁸ Even though Iridium oxide is one of the best water oxidation catalysts, Iridium is an expensive non-abundant element. In this context, recent developments have been made on earth abundant Co and Ni based catalysts which could achieve the target of a high turnover frequency (TOF) and are stable inorganic based oxide catalysts which could be used on a large scale. Cobalt-based cocatalysts *e.g.* cobalt oxide,¹¹¹ cobalt hydroxides¹¹² and cobalt phosphate^{75, 106, 113-116} have been investigated for PEC water oxidation on hematite. Zhong *et al.* demonstrated the deposition of Co^{2+} cocatalyst on hematite photoanode using different approaches; photo-assisted electrodeposition of Co-Pi, electrodeposition of Co-Pi, and Co^{2+} wet impregnation (Fig. 12 (a) to (c)).⁷⁵ The authors argued that by allowing deposition only where visible light generates oxidizing equivalents, photo-assisted electrodeposition provides a more uniform distribution of Co-Pi onto Fe_2O_3 than is obtained by electrodeposition. A stable -170 mV cathodic shift was observed with photo-assisted electrodeposition of Co-Pi, while electrodeposition of Co-Pi and Co^{2+} impregnation gave cathodic shifts of 100 mV and 80 mV respectively. Very recently, Han *et al* reported PEC water oxidation on a hematite photoanode at low applied potential.¹⁰¹ First, they lowered the intrinsic onset potential of a hematite photoanode to 0.58 V *vs.* RHE by the passivation of surface states using $\text{H}_2\text{-O}_2$ flame treatment at a high temperature to suppress surface charge recombination. Then, the onset potential further shifted to 0.50 V after Co-Pi cocatalyst has been deposited. These impressive results represent the most favorable photocurrent onset potential reported to date for a hematite-based photoanode. It has also been reported that in spite of some additional light absorption losses,¹¹⁵ the Co-Pi cocatalyst can cause a pronounced cathodic shift in the onset potential of Fe_2O_3 photoanodes.^{48, 105-107, 115} In some reports, the decrease in onset potential was accompanied by increased saturated photocurrent densities. For instance, Kim *et al* showed that modifying Pt doped Fe_2O_3 photoanodes with the Co-Pi cocatalyst increases the generated photocurrent by 170% to 4.32 mA cm^{-2} , which is the highest stable PEC water oxidation current for hematite photoanode reported.⁴⁸ Another efficient Co-based cocatalysts are Co_3O_4 and $\text{Co}(\text{OH})_2$. Previously an hematite photoanode has been coated with an ultrathin cobalt oxide layer by atomic layer deposition (ALD).¹⁰⁰ 1 ALD cycle, depositing <1 monolayer of $\text{Co}(\text{OH})_2/\text{Co}_3\text{O}_4$; resulted in a 100 to 200 mV cathodic shift in the photocurrent onset potential. Furthermore, the optical transparency of the ultrathin $\text{Co}(\text{OH})_2/\text{Co}_3\text{O}_4$ coating establishes it as a particularly advantageous treatment for nanostructured water oxidation photoanodes. In a similar report, a 40

mV cathodic shift of water oxidation overpotential with hematite nanorods has been observed upon decoration with Co_3O_4 nanoparticles.¹¹¹ Although the advantages of coupling cobalt-based species with hematite photoanodes have been widely confirmed, it has to be born in mind that the reasons remain unclear. The controversy centers mainly on whether the photogenerated holes are transferred to and stored by the cobalt oxide layer, or the enhancement is largely due to the formation of a heterojunction between photoanode and Co overlayer which contributes to enhance electron depletion in the Fe_2O_3 . In the latter case CoO_x is playing a noncatalytic role.^{113,} 114, 117, 118

Recently, Ni based OER catalysts such as nickel hydroxide,^{47, 119} nickel oxide¹¹⁹ and nickel borate¹²⁰⁻¹²² have attracted a lot of interest, due to their efficient catalytic performance, low cost and low toxicity. Ni–Bi OEC discovered soon after the development of the Co–Pi OEC showed

promising oxygen evolution properties under mild conditions similar to that of a Co–Pi OEC.¹²⁰ Hong *et al.* showed that photodeposition of a Ni–Bi OEC on hematite nanorods led to a >200 mV cathodic shift in the onset potential for water oxidation and a 9.5 fold enhancement in the photocurrent density at 0.86 V *vs.* RHE compared to the parent hematite photoanode.¹²² Recently our group has also demonstrated a NiOOH modified codoped (Sn, Zr) α -Fe₂O₃ photoanode with a significantly lower onset potential (0.58 V, Fig. 13 (a) and (b)). Interestingly, in contrast to an unmodified codoped photoanode, a 160 mV cathodic shift in the photocurrent onset potential and a 1.6 to 9.5 fold enhancement in the charge injection efficiency (η_{inj}) in the kinetic control region, i.e. 0.7 to 0.9 V, were also observed. We employed a photo-assisted electrodeposition technique which helps to deposit more uniform and compact NiOOH layer with the optimal loading amount. Ni(OH)₂ has also been reported as an efficient water oxidation catalyst on hematite electrodes. Kelley and co-workers used atomic layer deposition to deposit NiO onto thin-film Fe₂O₃ electrodes for photocatalytic water splitting.¹¹⁹ The authors claimed that photoelectrochemical conditioning of the deposited NiO converts it to Ni(OH)₂, which results in a stable reduction of the photocurrent onset potential for water oxidation by -300 mV and improves photocurrent density by two-fold at 1.23 V *vs.* RHE as compared to untreated Fe₂O₃. It has been proposed that the catalytic mechanism of the Ni(II) catalyst for water oxidation is a two-step process that involves the fast initial oxidation of Ni²⁺ to Ni³⁺, followed by the slow oxidation of Ni³⁺ to Ni⁴⁺, which is believed to be the active catalytic species for water oxidation.⁴⁷ The catalytic action of Ni(OH)₂ on the hematite photoelectrode is thought to result from the suppression of the photoinduced charging effect.⁴⁷

7.2. Surface passivation layers

Photogenerated holes that successfully navigate through the bulk of the hematite electrode and reach the electrode/electrolyte interface are still susceptible to loss by recombination with photoelectrons at surface sites (Fig. 14(a)).^{50, 55, 60, 123, 124} It has been found that the hole-transfer step leading to water oxidation takes place predominantly from surface trapped holes, and not directly from valence band holes. Therefore the photocurrent onset appears only after holes start to accumulate in these surface sites.⁵⁰ As highlighted in several recent perspectives, the nature and role of surface states remain a topic of debate.^{55, 125} For example, it has been suggested that the surface states are iron-based intermediates that are directly involved in the water oxidation mechanism.^{95, 125, 126} In contrast with this, Le Formal *et al.* have portrayed surface states as more of an electronic state.¹²⁷ In this case, the surface states are not chemically involved in water oxidation; rather, they are only a source of deleterious recombination.¹⁰³ Bard *et al* mentioned that these electronic states on the surface of an oxide photoanode, due to oxygen vacancies or crystal defects, could cause a degree of the so-called Fermi level pinning.¹²⁸ The sluggish hole transfer (injection) from the electrode to electrolyte interface can be improved by employing co-catalysts (Fig. 14 (b)) or non-catalytic passivation layers (Fig. 14 (c)). These two phenomena have fundamentally different mechanisms in assisting hole transport. Surface passivation (a non-

catalytic process) implies the reduction of hematite surface defects which reduces the hole–electron recombination rate, while a co-catalyst usually implies the oxidation of the metallic element of the co-catalyst which assists hole transport from the hematite surface to the electrolyte.¹²³ In this section, passivation layers which have been recently formed on Fe_2O_3 that effectively accelerate solar water oxidation by passivating surface states, will be reviewed.

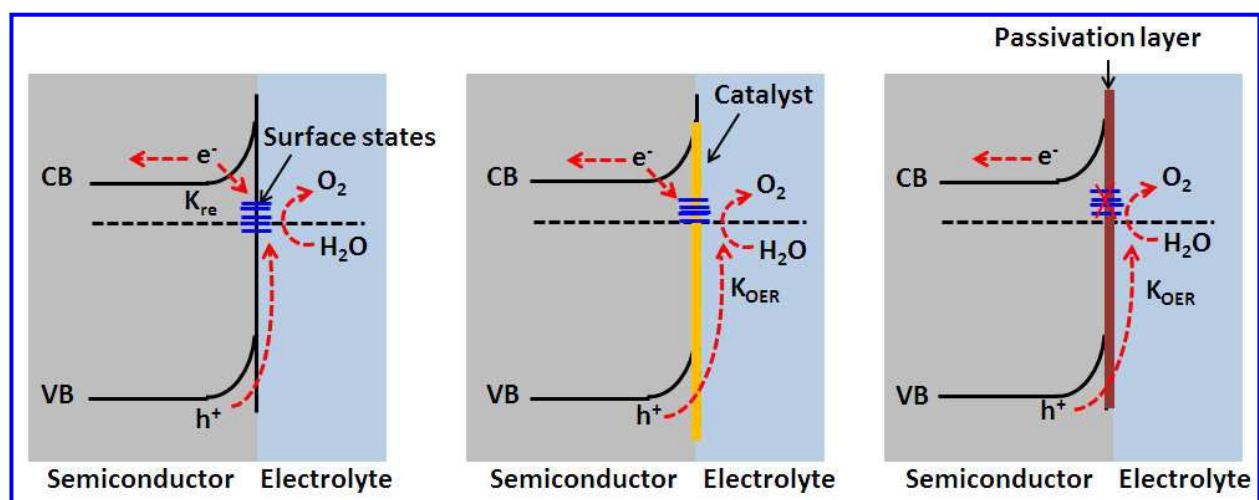

Figure 14. Comparison of the band structure of an n-type semiconductor photoanode in the presence and absence of passivation layers inside a PEC cell. (a) High charge recombination at surface defects and inefficient water oxidation by the photogenerated holes. (b) Use of an OER catalyst layer, which promotes facile hole transfer across the interface to the electrolyte for improving water oxidation; (d) use of a thin non-catalytic passivation layers which suppress surface recombination and improve water oxidation.

Several noncatalytic oxide layers on hematite have also been shown to affect surface OER behavior, even though no catalytic sites exist to enhance the charge transfer process. Hisatomi *et al.* deposited 13-group oxides such as Al_2O_3 , Ga_2O_3 , or In_2O_3 on ultrathin hematite film (27–30 nm thick) photoanodes using a chemical bath deposition technique, which led to 70, 250 and 150 mV cathodic shift in onset potential compared to the bare hematite respectively. It has been proposed that the corundum-type overlayers released the lattice strain of the ultrathin hematite layer and decreased the density of surface states.¹²⁹ Similarly, Le Formal and co-workers have found that an ultra-thin coating of Al_2O_3 deposited on the state-of-the-art nanostructured Fe_2O_3 photoanode reduces the overpotential as much as 100 mV and increases the photocurrent by a

factor of 3.5 at +1.0 V *vs.* RHE under standard illumination conditions (Fig. 15(a)). More importantly, this effect was distinguished from a catalytic effect by the subsequent addition of Co^{2+} ions as a catalyst. The cobalt treatment further decreases the overpotential, suggesting that surface passivation strategies can be combined with catalytic approaches.⁶⁰ They have also found that after one ALD cycle the photocurrent onset was dramatically shifted cathodically and resistive behavior characterized by a slow and linear rise of the photocurrent with applied voltage was observed. This behavior is possibly due to a high degree of disorder in the amorphous Al_2O_3 overlayer that inhibits hole injection from Fe_2O_3 into the electrolyte. After annealing in air at 300 °C the electrode's photocurrent curve regained a shape similar to before the ALD. It was also apparent from transient photocurrent measurements that photoanodes with 3 ALD cycles of Al_2O_3 overlayer showed enhanced charge injection efficiencies at three different potentials (evidenced from anodic and cathodic current spikes) (Fig. 15 (b)). However this approach is limited by the photoelectrochemical dissolution of the Al_2O_3 layer after long term exposure in 1M NaOH (*ca.* 1 h) under an applied potential of 1.03 V *vs.* RHE and 1 sun illumination.⁶⁰

Recently, Yang *et al.* reported that treatment of the hematite surface by ultrathin TiO_2 using atomic layer deposition (ALD) showed a 100 mV cathodic shift from the 'turn on' potential.¹³⁰ Previously Le Formal *et al.* studied ALD-grown TiO_2 as a surface passivation layer but did not report a cathodic shift from the turn-on voltages.⁶⁰ The difference is suspected to be from the difference in growth conditions as well as from the post growth annealing temperatures.¹³⁰ Ti-doped Fe_2O_3 with Al^{3+} treatment has also been reported by Fu *et al.* to passivate the surface states, which displayed a 100 mV cathodic shift from the onset potential and a notable improvement in the photocurrent density.¹³¹ This cathodic shift from the onset potential is comparable with the values obtained by using an Al_2O_3 surface passivating over-layer.⁶⁰ Interestingly, the photocurrent density increased about 10 times at 1.23 V *vs.* RHE. It has been found that a passivating over-layer of Al_2O_3 decreases the photocurrent density at high potentials, while surface treatment with Al^{3+} increases the photocurrent density at high potentials. The results suggest that enhancement in photocurrent density and shift in onset potential are not caused by accelerated OER kinetics.¹³¹ Xi *et al.* also demonstrated a very thin ZnO overlayer from a solution of ZnAc on top of a thin film of hematite and found an increase in the photocurrent and a reduced onset potential.¹³² After 3 cycles of ZnAc treatment, the

photocurrent increased more than 40% to 1.08 mA cm^{-2} at $0.23 \text{ V vs. Ag/AgCl}$ with a -170 mV shift in onset potential. It has been proposed that the ZnO overlayer changes the flat band potential of hematite, which is likely to be the result of electron donation from ZnO to the Fe_2O_3 interface, and reduces the surface defects. This thin layer of ZnO may also act as an electron blocking layer to prevent electrons leaking from hematite into the electrolyte.¹³²

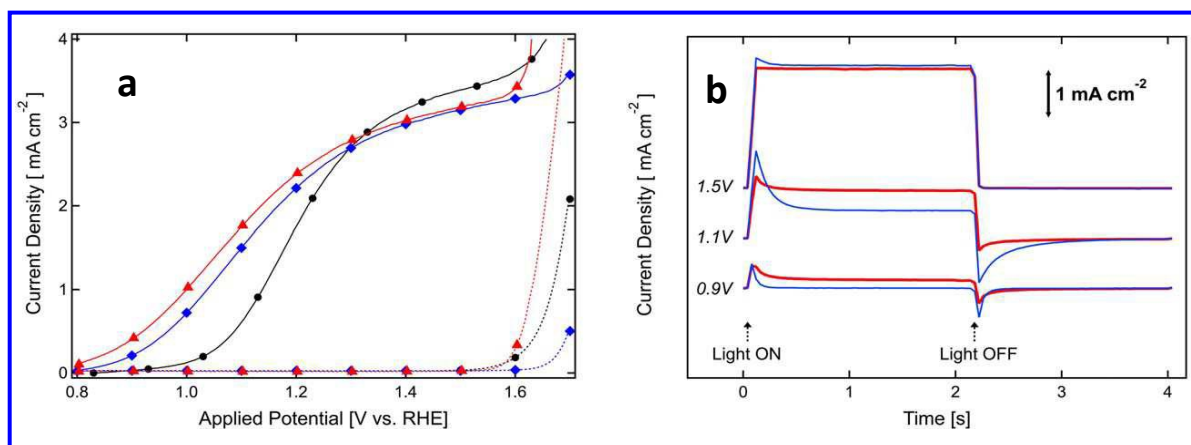

Figure 15. (a) J-V curves in the dark (broken lines) and under simulated solar illumination (AM 1.5G, 100 mW cm^{-2} , solid curves). (a) Black circles represent the hematite photoanode before ALD treatment, blue diamond represent it after 3 ALD cycles of alumina and annealing to $400 \text{ }^\circ\text{C}$ and red triangles represent it after subsequent cobalt treatment. (b) Transient photo-response is shown by light chopping current densities as a function of time. Red line and blue lines represent comparison of the transient behavior of iron oxide photoanodes with and without 3 ALD cycles of Al_2O_3 overlayer. Adapted from *Chem. Sci.*, 2011, 2, 737-743.

Surface doping with metal ions has also been proven to be an alternative way to achieve an enhanced PEC performance from $\alpha\text{-Fe}_2\text{O}_3$ photoanodes by promoting charge migration and/or creating a doped overlayer to catalyze the surface water oxidation reaction. For example Xi *et al* reported current improvement in Fe_2O_3 nanorod arrays treated by surface Sn doping, was mainly attributable to a reduced electron-hole recombination at the hematite-electrolyte interface through the formation of a $\text{Fe}_x\text{Sn}_{1-x}\text{O}_4$ layer.¹²⁴ This has been achieved by treating hydrothermally grown iron oxyhydroxide (FeOOH) nanorod arrays with Sn(IV) aqueous solution before subsequently annealing at $750 \text{ }^\circ\text{C}$ in air for 30 min. During annealing, the solvent was evaporated and a very thin layer of SnO_2 was formed coating the hematite nanorods. Following a

solid-state diffusion reaction, Sn(IV) is gradually incorporated into hematite forming an $\text{Fe}_x\text{Sn}_{1-x}\text{O}_4$ layer. The presence of this layer is thought to passivate surface defects as well as suppress the tunneling of electrons from the hematite core.¹²⁴ Similar to this approach, an $\alpha\text{-Fe}_2\text{O}_3$ nanotube photoanode with a thin $\text{Ni}_x\text{Fe}_{2-x}\text{O}_3$ overlayer on the surface showed a $\sim 280\%$ enhancement of the photoconversion efficiency relative to the pristine $\alpha\text{-Fe}_2\text{O}_3$ nanotube photoanode.¹³³ This enhancement was induced by the $\text{Ni}_x\text{Fe}_{2-x}\text{O}_3$ overlayer and was attributed to the promoted charge migration, accelerated surface oxygen evolution, and inhibition of low-energy photoexcited hole recombination at the semiconductor-liquid junction. Remarkably, the onset potential of photocurrent of the Ni-doped sample was also cathodically shifted by ~ 100 mV, and the slope of photocurrent of Ni-doped sample was 2–3 times greater than that of the pristine sample (Fig. (16)). To illuminate the surface acceleration action of $\text{Ni}_x\text{Fe}_{2-x}\text{O}_3$, the authors used a Ni-based catalyst on the surface of a pristine sample as a reference sample. They found lower electron-hole recombination which was claimed to be due to the passivated surface trap states by $\text{Ni}_x\text{Fe}_{2-x}\text{O}_3$ layer as well as by accelerated OER process, considering amount of trap states of Fe^{2+} presented on the surface of pure hematite. The possible mechanism of the $\text{Ni}_x\text{Fe}_{2-x}\text{O}_3$ overlayer followed by catalyst deposition, catalyzing the water oxidation reaction could be proposed in Fig. 16. Recently, an $\text{Ag}_x\text{Fe}_{2-x}\text{O}_3$ passivating layer with a thickness of 2-3 nm has also been demonstrated on Ag-doped Fe_2O_3 nanorod films. It has been reported that this ultrathin layer not only increased the carrier density in the near-surface region but also accelerated the surface oxidation reaction kinetics, synergistically contributing to the improved photoelectrochemical performances.¹³⁴

It has been suggested that it is possible to address the problems of surface trap recombination and sluggish reaction kinetics independently by employing surface passivation layers and catalysts sequentially.⁵⁵ However, convincing evidence that a surface treatment can perform as a true catalyst is still elusive. Rather, it seems more likely that catalysts can act to passivate surface states if they are present or, in the case of already-passivated electrodes, decrease electron-hole recombination by increasing band bending.

7.3. Surface chemical corrosion

Surface corrosion can improve photocatalytic oxygen evolution reaction by changing the chemical state of the electrode's surface. In some semiconductor photoelectrodes, such as Si,^{135, 136} ZnO,¹³⁷ Cu₂O,^{138, 139} and some binary or ternary metal sulfides, surface corrosion has dual benefits - interfacial charge transfer assistance and surface recombination inhibitors. However, hematite is kinetically stable under oxidizing conditions, hence surface corrosion helps to

passivate surface states and thereby oxidize water at low applied potentials.¹²³ Recently, Li *et al.* reported hydrogen-treated hematite nanostructures which have been prepared by a simple pyrolysis of NaBH₄ in a crucible.⁹⁹ The hydrogen treated photoanode showed over 2.5 times higher photocurrent density and 120 mV cathodic shift in the onset potential than that for pristine hematite. The significant improvement of the photocurrent was claimed to be attributed to increased oxygen vacancies after the H₂ treatment while the cathodic shift of the onset potential was attributed to the surface effect of H₂ treatment. The authors used X-ray absorption spectroscopy to examine the oxygen vacancy and they found that the oxygen vacancy mainly affects the bulk property but has no contribution to the onset potential. They suggested two possible reasons for the decrease in onset potential. First, the optimized oxygen vacancy content in the surface may lower the onset potential by improving the conductivity of hematite thereby reducing the recombination of photoexcited holes with electrons. Second, reaction of H₂ at the electrode surface may result in surface corrosion by taking oxygen atoms away from the hematite. It has been reported that the presence of surface defect states of Fe²⁺ in hematite is the reason for high onset potential. However, the XAS results in this report indicated that after the H₂ treatment, Fe²⁺ exists on the surface of hematite with oxygen vacancies. The surface-sensitive soft X-ray absorption spectroscopy also confirmed the electronic structure change of the surface of H₂-treated hematite. The XAS results clearly confirm that the oxygen vacancies only exist on the surface of the H₂-treated hematite samples, suggesting that the onset potential shift between H₂- treated hematite and oxygen-deficiency treated hematite should be attributed to the surface effect by the H₂ treatment. As we mentioned earlier, a hematite photoanode with the lowest intrinsic onset potential (0.58 V *vs.* RHE) was recently prepared by heating iron foil in a H₂-O₂ flame at ca. 1700 K for 10s.¹⁰¹ It has been stated that due to slow diffusion of oxygen from the surface to the bulk during the H₂-O₂ flame treatment gradient structure composed of hematite outer layer followed by Fe₃O₄ and FeO interlayers has been formed. The extremely low onset potential observed is mainly ascribed to the passivation of surface trap states by high temperature heat treatment and the facile charge migration facilitated by the gradient structure of the photoanode. Moreover, by further depositing a Co-Pi catalyst, they obtained the lowest ever reported onset potential of the hematite photoanode (0.50 V *vs.* RHE). In August 2013, Cao *et al.* published a report on surface corrosion of Ti⁴⁺ doped Fe₂O₃ with an HCl acid solution which showed 100 mV cathodic shift in the photocurrent onset potential (Fig. 17 (a)).¹⁴⁰ Unlike other

reports, the authors argue that the cathodic shift of the onset potential was not from accelerating water oxidation kinetics, passivating surface states or ion adsorption rather it was due to suppressing the back reaction of electrons. From the dark current results (Fig. 16 (b)), the onset potential shifted anodically after surface corrosion, which is contrary to the cathodic shift of the photocurrent onset potential, suggesting that accelerating water oxidation kinetics is not the reason for the onset potential shift. To examine surface atomic composition before and after corrosion they used XPS and ICP analysis. The XPS and ICP results suggested that there was obvious TiO_2 segregation which possibly formed a $\text{Fe}_2\text{O}_3\text{-TiO}_2$ solid solution on the Ti^{4+} doped hematite surface. After the surface treatment, the Ti-rich layer was partly removed. Therefore, the surface corrosion effect on the onset potential shift mainly comes from the Fe^{3+} dissolution and not from Ti^{4+} dissolution. The cathodic shift of the onset potential is observed both on pure and doped Fe_2O_3 samples. Therefore, it has been argued that the surface corrosion effect on the onset potential shift mainly comes from Fe^{3+} dissolution and not from Ti^{4+} dissolution. Previously the same group used a similar surface corrosion method to improve the performance of a Mo doped BiVO_4 photoanode.¹⁴¹ In that work, they found that the surface pretreatment only had an effect on a Mo doped BiVO_4 , but not on the pure samples. In that case, removing MoO_x segregation on the surface, which played a role as a recombination center, was considered to be the main reason.

Related to the surface corrosion of hematite electrodes, Hu *et al.* showed bias-free water reduction using a surface modified (CoF_3 aqueous solution) Ti-doped iron oxide photoelectrode.¹⁴² It was stated that the adsorption of fluoride on the electrode's surface shifts the conduction band to a potential more negative than the redox level of H_2/H^+ , allowing the photogenerated electrons to directly reduce water to H_2 . A further increase in the photocurrent was observed when glucose was used as the electron donor (rather than hydroxyls) in the electrolyte, helping to bypass the relatively slow oxygen evolution reaction by providing a source of electrons to rapidly consume photogenerated holes. Table 3 summarizes recent approaches to enhancing the water oxidation reaction kinetics of hematite photoanodes.

♣ Potential vs Ag/AgCl

8. Photogenerated charge separation

As mentioned in the previous sections, with a band gap of 2.1 eV hematite can achieve a solar-to-hydrogen efficiency of $\sim 15.3\%$. However its practical PEC performance is severely limited by the low charge separation efficiency, which is caused by its very short excited state lifetime (3–10 ps) and a small hole diffusion length (2–4 nm). So far various approaches have been employed to enhance the charge separation efficiency of hematite photoanodes such as nanostructuring, doping, formation of heterojunctions, incorporation of conductive scaffolds. Nanostructuring helps to overcome the trade-off between the relatively low absorption coefficient and the short hole diffusion length (2–4 nm) of hematite.^{82, 89} The ideal hematite nanostructure to fulfill these criteria is therefore a nanowire array with diameter of 5–10 nm for efficient hole transport to the electrolyte and length of 400–500 nm for complete light absorption as shown schematically in Fig. 18.³⁴ In case of planar electrodes which comprise thicker hematite films, only holes generated few nanometers from the surface of the electrode can diffuse in to the electrolyte and oxidize water. An obvious solution to this problem is to use nanostructured electrodes. For example, an array of single crystal nanorods/nanowires with diameters in the 10 nm range allowing photogenerated holes to efficiently reach the SCLJ and would eliminate grain boundaries and provide a direct path for electron collection. In section 2 we discussed various efficient photonic nanostructured hematite photoanodes that can enhance both the charge separation efficiency and photon absorption simultaneously. In this section we will focus on other approaches such as doping, the formation of heterojunctions, and the incorporation of conductive scaffolds to improve the low charge separation efficiency.

Figure 18. Comparison of electron-hole recombination in planar and nanostructured Fe₂O₃ electrodes.

8.1. Doping

The aim of doping is well established and has been proven to be beneficial to many semiconductor systems for enhancing the bulk carrier concentration and hence their conductivity and charge separation efficiency. Compared to the common n-type semiconductors such as TiO₂, WO₃, and BiVO₄, pure hematite has very low electrical conductivity (*ca.* 10⁻¹⁴ ohm⁻¹ cm⁻¹),¹⁴⁴ carrier concentration (10¹⁸ cm³) and electron mobility (10⁻² cm² V⁻¹ s⁻¹).¹⁴⁵ For comparison some of the electrical properties of these semiconductors are listed in table 4. Since that the total conductivity of an intrinsic semiconductor is the same as the sum of the conductivities due to the motions of electrons in the conduction band and holes in the valence band ($\sigma = n e \mu_e + p e \mu_p$), increasing carrier concentration (*i.e.* n or p) by doping is often used to compensate for the low electron (μ_e) and hole (μ_p) mobilities.³⁴ Due to naturally occurring oxygen vacancies in the bulk, hematite is an n-type semiconductor. Therefore doping with tetravalent and pentavalent metal ions should induce increased donor levels and thus hematite will remain as n-type, whereas doping with monovalent or divalent ions is thought to increase positive charge carriers, thus hematite becomes p-type. Doping with mono-atomic ions of charge greater than 3+ will introduce additional majority carriers and create steeper voltage gradients (thinner space-charge layers) and thereby enhance charge separation. Whereas doping with metal atoms in oxidation state I or II will convert hematite to a p-type semiconductor, *i.e.* a form that will tend to deliver electrons rather than holes to the electrode/solution interface when illuminated.

Table 4. Electrical properties of common n-type intrinsic semiconductors

Semiconductor	Hole diffusion length (nm)	Electron diffusion length (nm)	Carrier mobility (cm ² V ⁻¹ s ⁻¹)	Carrier life time (ps)
Fe ₂ O ₃	2-4 ^{29, 54}	*	0.01-0.1 ^{145, 146}	3-10ps ^{52, 89, 147}
WO ₃	150 ^{148, 149}	500 ¹⁵⁰	16 ¹⁵¹	1-9ns ¹⁴⁹
TiO ₂ (rutile)	10 ¹⁵² , 20 ¹⁴⁸	8.5-12.5 μ m ¹⁵³ ,	1 ¹⁵⁴	*
BiVO ₄	100 ^{155, 156} ,	300 ¹⁵⁷	0.2 ¹⁵⁵	40ns ¹⁵⁸

* Not mentioned in literature

So far hematite has been modified with various dopants such as Ti, Sn, Si, Zr, Pt, Ni, Ge, Mg, Mo, using a variety of methods, such as hydrothermal growth, electrodeposition, chemical vapor deposition, ALD, drop casting and other vapor deposition methods. Among these dopants Ti has been widely used for doping of hematite. Pu *et al.* anticipated that coupling of Ti-doping and oxygen vacancies in hematite nanostructure can effectively achieve water oxidation photocurrent 4.1 mA m^{-2} at 1.5 V vs. RHE .¹⁵⁹ Ti has also been doped after the growth of hematite nanostructures (*i. e.* post-growth doping) by depositing titanium precursor (Ti(OBu)_4) solution and subsequent annealing in air.¹⁶⁰ A maximum photocurrent density of 0.67 mA m^{-2} at 1.23 V vs. RHE was achieved by depositing Co catalyst. The enhanced performance was attributed to the increased donor density as a result of Ti-doping, which was found to be $9.5 \times 10^{19} \text{ cm}^{-3}$. Uniform thin Ti-doped hematite film deposited on FTO using ALD was used by Zandi *et al.*¹⁶¹ ALD allows control of the morphology and thickness of the hematite film as well as the concentration and distribution of Ti atoms. An optimum doping level of 3 atom% Ti, photocurrent of 0.8 mA m^{-2} at 1.7 V and APCE value of 50% at 400 nm and 1.8 V vs. RHE were observed. With other transition metal dopants, enhanced efficiency for photoelectrochemical water splitting was observed with Pt-doped hematite films. 5% Pt doping showed a 74% increase in photocurrent (from 1.26 to 2.19 mA m^{-2}).⁴⁸ Although the absolute current value was higher, due to the better performance of pristine hematite, the improvement by Pt-doping is qualitatively consistent with the report of Hu *et al.*¹⁶² Doping of hematite with the transition metal Zr gave donor densities on the order of 10^{19} cm^{-3} , conductivities $\sim 0.1 \text{ W}^{-1}\text{cm}^{-1}$, and an electron mobility of $0.1 \text{ cm}^2\text{V}^{-1} \text{ s}^{-1}$.¹⁶³

Among hematite non-transition metal dopants Si, Ge and Sn have been widely used. Lukowski *et al* reported Si doped hematite NWs synthesized using a thermal oxidation method.¹⁶⁴ For post doping of Si, a silane (SiH_4) coating was deposited on the NWs using chemical vapor deposition followed by annealing. They have found that after doping the average resistivity significantly improved from $4 \times 10^2 \pm 4 \times 10^2 \text{ }\Omega\cdot\text{m}$ to $4 \times 10^{-3} \pm 6 \times 10^{-3} \text{ }\Omega\cdot\text{m}$. Recently, a Ge-doped hematite film has also been prepared by Liu *et al* using hydrothermal approach and highly reactive Ge colloidal solutions as a dopant source.⁷³ Ge-doped $\alpha\text{-Fe}_2\text{O}_3$ nanosheet arrays showed a photocurrent density of 1.4 mA m^{-2} at 1.23 V vs. RHE , which was more than 50 times that of undoped $\alpha\text{-Fe}_2\text{O}_3$ nanorod arrays. This improvement is thought to originate from the two orders

of magnitude higher donor density of Ge-doped α -Fe₂O₃ than that of undoped sample which enhanced the electrical conductivity. Sn has also been used to dope hematite to boost its conductivity. For example, Ling *et al* reported intentionally Sn-doped hematite nanocorals that showed a remarkable photocurrent density of 1.86 mA m⁻² at 1.23 V vs RHE, which is approximately 1.5 times higher than that of the nanowires synthesized by the same method.⁷² It has been reported that unintentional diffusion of Sn from the FTO substrate into the Fe₂O₃ nanostructure during high temperature annealing also significantly enhances the conductivity of hematite nanostructures grown on fluorine doped SnO₂ (FTO) coated glass substrates. This unintentional Sn doping acts as electron donor and increases the carrier density of hematite. Unlike other studies; in our group we have found that the diffusion of Sn formed a typical gradient distribution which in turn results in the formation of multiband bending.⁴⁵ In addition to increasing carrier concentration, this gradient Sn doping can result in upward multiband bending regions, which help to form built-in electric fields to facilitate the minority carriers moving toward the electrode/electrolyte interface.

It has been reported that p-type hematite can be synthesized by doping with divalent metal dopants, such as Zn, Mg, Cu and Ni, replacing Fe³⁺ in the hematite lattice and forming hole carriers.¹⁶⁵⁻¹⁶⁷ A theoretical study using density function theory (DFT) calculations on Cu and Ti doped hematite showed that the conduction band minima (CBM) of Cu doped hematite is sufficient to facilitate hydrogen generation.¹⁶⁷ Thus, the energy levels of the valence and conduction bands are able to drive both photoinduced oxygen and hydrogen production from water without the application of a voltage bias. However, there is very little experimental indication that the conduction-band edge of hematite can be shifted sufficiently by typical metal-ion dopants to make the material energetically viable as a photocatalyst for water reduction. Hu *et al.* demonstrated bias free water reduction using a Ti-doped iron oxide photoelectrode by modifying the surface with CoF₃ aqueous solution.¹⁴² It was stated that the adsorption of fluoride on the electrode's surface shifts the conduction band position to a potential more negative than the redox level of H₂/H⁺, thereby allowing the photogenerated electrons to directly reduce water to H₂.

It was also found that codoping with two cations exhibits higher activity than single cation doping. Our group has shown that gradient Sn doped Fe_2O_3 can achieve a photocurrent density of 0.86 mA m^{-2} at 1.23 V vs. RHE . When codoped with Zr, the photocurrent density increased to 1.34 mA m^{-2} . This was ascribed to the synergetic effect of codoping (Sn, Zr) which led to 1.6 fold enhancement in charge separation efficiency at 1.23 V than that of the monodoped (Sn) Fe_2O_3 photoanode.⁴⁵ Hahn *et al.* and Wand *et al.* also independently reported hematite doped Ti and Sn co-doped hematite photoanodes.^{168, 169} It has been argued in both studies that the enhanced PEC performance of the codoped sample was due to the synergetic effect of Ti and Sn on improving the electron transport and suppression of recombination at the film-electrolyte interface due to the stronger electric field near the surface. Recently, Mirbagheri and co-workers reported hematite electrodes modified with Ti^{4+} and Zn^{2+} , which reached a photocurrent density 1.5 mA m^{-2} at 1.23 V vs. RHE that was 2.5 times higher than that of pristine hematite electrode.¹⁷⁰ The improved performance of the Ti/Zn-modified hematite stemmed from the combination of the enhanced electrical conductivity along with the facilitated charge transport in the bulk phase and at the surface of hematite. It was reported that the effect of Zn-doping was correlated with the interfacial catalysis of water oxidation, which resulted in 218 mV decrease in the overpotential of the reaction. To summarize, introducing optimum doping concentrations have been shown to be beneficial in altering the electronic properties of pristine hematite which in turn enhancing the plateau photocurrent of PEC cells.

8.2. Heterojunction

The strategy of using simple hematite nanostructures faces inherent limitations, due to the reliance on a single material to carry out the functions of both light absorption and charge transport.¹⁷¹ This can be overcome by combining hematite with other semiconductor electrodes together, with proper conduction and valence band positions. Heterojunction formation confers three major contributions namely: to enhance visible light absorbance, improve charge separation, and increase in lifetime of charge carriers. The electron transfer between the two semiconductors can facilitate charge separation through the formation of an internal electric field at the heterojunction interface and thereby suppress the electron-hole recombination.¹⁷² Moreover, hematite has been demonstrated to form heterojunction with small band gap

semiconductors to increase its visible light photoactivity.^{172, 173} The small band gap semiconductor is mainly responsible for sensitizing the hematite electrode through electron or hole injection by enhanced visible light absorption.¹⁷³ Various hematite based heterojunction photoelectrode structures such as Si/Fe₂O₃, TiO₂/Fe₂O₃, WO₃/Fe₂O₃, MgFe₂O₄/Fe₂O₃, Fe₂O₃/BiVO₄ have been shown to enhance the PEC performance of hematite photoanode. In this section we will focus on hematite heterojunctions which have suitable band edge positions for photogenerated charge separation.

In 2007 Wang *et al* reported SrTiO₃/Fe₂O₃ heterojunction that showed higher photocurrent and higher IPCE values than those of single SrTiO₃ or Fe₂O₃ films.¹⁷⁴ This was due to the electric field formed by the junction at the interface and the special band structures of SrTiO₃ that favor the transfer of holes from Fe₂O₃ to SrTiO₃, and the improved charge separation at the SrTiO₃/Fe₂O₃ interface. Miao *et al.* and McDonald *et al.* independently reported Fe₂O₃/ZnFe₂O₄ heterojunction photoanodes that exhibit a significantly enhanced photocurrent response compared to the bare Fe₂O₃ electrode.^{175, 176} The enhanced electron-hole separation was stemmed from the conduction and valence band edge position of ZnFe₂O₄ situated at *ca.* 200 mV negative from that of Fe₂O₃. The authors also modified the surface of the Fe₂O₃/ZnFe₂O₄ composite electrode with Al³⁺ ions and Co²⁺ ions to reduce surface states and enhance catalytic abilities, respectively. The photocurrent showed further enhancement when the surface was modified by an Al³⁺ treatment due to the formation of thin ZnFe_{2-x}Al_xO₄ or Fe_{2-x}Al_xO₃ layers that reduce surface states. The photocurrent onset was further shifted in a negative direction by *ca.* 50 mV when Co²⁺ ions were introduced to the surface of composite electrodes as oxygen evolution catalysts. Similarly, a 3DB Co-Fe₂O₃/MgFe₂O₄ heterojunction was reported by Hou *et al.* The 3DB heterojunction was prepared by hydrothermal deposition of Co-Fe₂O₃-NA on Ti mesh, with subsequent coating of MgFe₂O₄ by a simple wet impregnation, followed by annealing. The heterojunction demonstrated enhanced photocurrent density (3.34 mA m⁻², AM 1.5 G), which is 2.69, 1.95, and 1.78 times higher than that of Fe₂O₃, Co-Fe₂O₃, and Co-Fe₂O₃/MgFe₂O₄ photoanodes at 0.8 V vs. Ag/AgCl, respectively. Fe₂O₃/CdS corn-like nanocomposites have been synthesized by Shi *et al.* by growing CdS nanoparticles on single-crystalline Fe₂O₃ nanorods using a simple and mild one-step wet-chemical method.¹⁷⁷ They have found that the corn-like nanocomposites exhibited superior photocatalytic performances under visible light irradiation

compared to pure Fe_2O_3 nanorods and CdS nanoparticles. The authors argued that the enhanced PEC performance was associated with the larger surface area of the cornlike structure, the crystalline nature of the materials and the synergy in light absorption and charge separation between Fe_2O_3 and CdS.

Similarly, $\text{WO}_3/\text{Fe}_2\text{O}_3$ heterojunction photoanodes have also been investigated. In $\text{WO}_3/\text{Fe}_2\text{O}_3$ electrodes, the conduction band of WO_3 is higher than that of Fe_2O_3 , which makes the transfer of photogenerated electrons easier and minimizes the recombination. $\text{WO}_3/\text{Fe}_2\text{O}_3$ interface improved the photocurrent and IPCE of the composite structure. Sivula *et al.* have demonstrated the effectiveness of this concept using a nanostructured host scaffold (WO_3) prepared by atmospheric pressure CVD to support a thin layer of Fe_2O_3 nanoparticles deposited by a similar method.¹⁷⁸ Using this host-guest electrode they found a 20% increase in the photocurrent compared to control films with the same amount of hematite deposited without the host scaffold. Using a similar approach a composite oxide photoelectrode comprised of Fe_2O_3 and WO_3 crystals has been investigated.¹⁷⁹ The composite films exhibited a water oxidation photocurrent onset potential as low as 0.43 V vs. RHE, a value considerably lower than that of pure Fe_2O_3 photoanodes prepared in comparable synthesis conditions. NiO in the p-n junction functioned as a hole extractor to conduct the holes. Li *et al.* fabricated a p-n junction photoanode by depositing p-type NiO nanoparticles on the Fe_2O_3 thin film.¹⁸⁰ The more important feature of this approach is the dual effect of NiO for separation of electron and holes *via* the p-n junction and for reducing the overpotential of oxygen evolution. In 2012 Hou *et al.* reported a heterojunction array of $\text{Fe}_2\text{O}_3/\text{graphene}/\text{BiV}_{1-x}\text{Mo}_x\text{O}_4$ core/shell nanorod for photoelectrochemical water splitting.¹⁸¹ The heterojunction yielded a pronounced photocurrent density of 1.97 mA cm^{-2} at 1.0 V vs Ag/AgCl and a high photoconversion efficiency of 0.53% at -0.04 V vs Ag/AgCl under the irradiation of a Xe lamp (Fig. 19). The improved photoelectrochemical properties benefited from (1) the enhanced light absorption due to behavior of the “window effect” between the Fe_2O_3 cores and $\text{BiV}_{1-x}\text{Mo}_x\text{O}_4$ shells, and (2) the improved separation of photogenerated carriers at the Fe_2O_3 / $\text{graphene}/\text{BiV}_{1-x}\text{Mo}_x\text{O}_4$ interfaces. The possible charge transport mechanism across the heterojunction is schematically shown in Fig. 19(c). Other hematite based heterojunctions such as $\text{Si}/\text{Fe}_2\text{O}_3$ ¹⁷⁴ and $\text{TiO}_2/\text{Fe}_2\text{O}_3$ ¹⁸²⁻¹⁸⁴ have also been shown to enhance the absorption efficiency by capturing a wide solar spectrum. For example Mayer *et al.* have grown hematite on vertically

aligned Si nanowires (NWs) using ALD to form a dual-absorber system.¹⁸² Si NWs absorb photons that are transparent to hematite ($600 \text{ nm} < \lambda < 1100 \text{ nm}$) and convert the energy into additional photovoltage to assist photoelectrochemical (PEC) water splitting by hematite.

(c) Schematic for the Energy Band Structure of the Fe₂O₃-NA/RGO/BiV_{1-x}Mo_xO₄ heterojunction and proposed mechanism of PEC Water Splitting. Adapted from *Nano Lett.* 2012, 12, 6464–6473.

8.3. Conducting scaffolds

Another efficient approach to enhancing the charge separation efficiency of hematite is to incorporate electron conducting scaffolds in to the hematite nanostructure. During illumination charge carriers are generated, from which electrons can be collected in the conductive scaffolds and readily transported away to the current collector whereas holes are transferred to the semiconductor-liquid junction (SLJ) to oxidize water. It is well known that graphene is widely recognized to serve as a good electron collector and transporter to efficiently hinder recombination of photogenerated electron-hole pairs resulting in high photocatalytic activity performance, due to its unique physicochemical, electronic and optoelectronic properties.^{181, 185, 186} This has been coupled with hematite as an electron conducting scaffold so as to enhance the poor charge separation efficiency of hematite. For example Meng *et al.* reported that incorporating hematite nanoparticles to the reduced graphene oxide (rGO) nanosheets suppresses charge recombination and enhances charge separation.¹⁸⁷ Similarly He *et al.* reported N-doped graphene-Fe₂O₃ nanocomposite for photoelectrochemical water oxidation and for photocatalytic colorless pollutant degradation.¹⁸⁸ It has been claimed that the N doping further increases the charge transportation capacity of graphene. Our group has also demonstrated reduced graphene oxide modified 3D urchin-like hematite photoanode for photoelectrochemical water oxidation.¹⁸⁹ Ultra-thin rGO was found to have two functions; as an electron conducting scaffold and as a surface passivation layer. We achieved 1.82 times higher charge separation efficiency at 1.23 V and 1.67 times higher charge injection efficiency at 1 V vs. RHE after hematite was modified with rGO. In addition to graphene-hematite composite nanostructures, graphene can also be act as a mediator between two core/shell heterojunction arrays. This concept was demonstrated by Hou *et al.*¹⁸¹ who reported a novel heterojunction of α -Fe₂O₃/graphene/BiV_{1-x}Mo_xO₄ core/shell nanorod arrays for PEC water splitting. Graphene boosts charge separation of the photogenerated carriers at the α -Fe₂O₃/BiV_{1-x}Mo_xO₄ interfaces by shuttling electrons between the two electrodes. Carbon nanotubes (CNT) have also been used as a charge separation scaffold when combined with hematite photoanode. For example Kim and coworkers reported a Fe₂O₃ photoanode modified with multi-wall CNT which exhibited 66% increment in photocurrent generation relative to unmodified Fe₂O₃ electrode.¹⁹⁰ With the help of electrochemical impedance

spectroscopy they found that multi-wall CNT modification dramatically decreases resistance over the entire electrode and increases capacitance at the interface between CNTs and the conducting substrate, suggesting an increased electron passage from the hematite to the conductive oxide substrate. Later the same group introduced graphene–CNT composite as a better conducting scaffold for Fe_2O_3 particles than pristine CNT.¹⁹¹ They have found that the Fe_2O_3 –composite photoanode showed a photocurrent enhancement of 530% compared to the bare Fe_2O_3 photoanode at 1.23 V vs. RHE, while the increment was only 200 and 240% for Fe_2O_3 –CNT and Fe_2O_3 –graphene photoanodes, respectively. The authors claimed that this remarkable performance enhancement by the composite scaffold was attributed to synergistic effects induced by the formation of a 3D-like architecture from 1D CNT and 2D graphene. Another highly conductive and suitably high surface area TiSi_2 nanonets was demonstrated by Lin *et al.*¹⁹² The nanonets have dual role as a structural support and an efficient charge collector, allowing for maximum photon-to-charge conversion. As illustrated in Fig. 20 (a), when a thin Fe_2O_3 layer is interfaced with a TiSi_2 nanonet, the longest distance from anywhere in the semiconductor to the SLJ or transported by TiSi_2 can be shorter than the charge-diffusion distance, permitting effective charge collection. The authors also argued that the uniform Fe_2O_3 coating around the TiSi_2 nanonet (Fig. 20 (b)) and the defect-free interface between Fe_2O_3 and TiSi_2 (Fig. 20 (c)) allows enhanced charge transfer from Fe_2O_3 to TiSi_2 without significant impedance. They report an external quantum efficiency of 46% at $\lambda = 400$ nm without intentional doping in a water-splitting environment. The same group previously presented a $\text{TiO}_2/\text{TiSi}_2$ core/shell heteronanostructure synthesized by CVD and ALD methods.¹⁹³ The networked TiSi_2 structure provides a structural support with high surface area to improve the photon absorptions of TiO_2 and enhance the charge transport due to its high conductivity.

Figure 20. (a) Schematic illustration of the design principle, which involves the use of conductive TiSi_2 nanonet as an effective charge collector. The electronic band structure is shown in the enlarged cross-sectional view. (b) Low-magnification transmission electron microscopy (TEM) image showing the structural complexity of a typical heteronanostructure and its TiSi_2 core/hematite shell nature. (c) High-resolution TEM data. Insets: (left) lattice-fringe-resolved HRTEM image showing the hematite lattice spacing for (110) (0.250 nm) and (330) (0.145 nm); (right) electron diffraction pattern of hematite. Adapted from *J. Am. Chem. Soc.*, 2011, 133, 2398-2401.

9. Conclusion and outlook

Solar water-splitting is a promising approach for the production of sustainable clean fuels, with high theoretical efficiencies for converting solar energy to a dense, portable chemical energy form. To date, the achieved efficiencies of water-splitting by semiconductor-based photoelectrochemical cells are still lower than that needed in a practical device, due to either a lack of suitable candidate materials, or stability limitations under harsh reaction conditions. Among the various water splitting photoanode materials, hematite ($\alpha\text{-Fe}_2\text{O}_3$) has several promising properties, including smaller band gap (1.9 ~ 2.2 eV) that maximizes absorption of the solar spectrum, stability in aqueous environment under typical operating conditions, abundance, and affordability. Therefore, it is the best candidate for the proof-of-concept demonstrations to use as a practical water splitting photocatalyst. However, to date the maximum solar-to-hydrogen efficiency (STH) of hematite achieved is nearly 5%, which is by far from its theoretical STH (15.3, at the band gap of 2.1 eV).¹⁰⁴ In this review, we have critically discussed the factors that limit the water splitting efficiency of hematite and various recent and past approaches used to overcome the limitations. We clustered our discussion in to three basic categories, charge separation efficiency, charge injection efficiency and light absorption efficiency. Since morphology causes various limitations, such as light absorption, charge injection and charge separation, the progress in morphology from the late thicker planar films to the most up-to-date ultrathin nanocone type of morphologies have been discussed. Special emphasis is given to ultrathin film approaches which have a promise to improve the tradeoff between poor carrier collection and poor light absorption of hematite. Poor oxygen evolution reaction kinetics (charge injection efficiency) of hematite electrode is one of the major challenges that limit its solar conversion efficiency thus requiring a large applied potential to drive water oxidation. We discussed three different approaches to minimize the oxygen evolution overpotential, using earth abundant cocatalysts, using surface passivation layers and using surface chemical corrosion techniques. The other factor that limits the practical PEC performance of hematite is low charge separation efficiency, which is caused by its very short excited state lifetime (3-10 ps) and a small hole diffusion length (2-4 nm). Extreme doping, the formation of heterojunctions, incorporation of charge separating scaffolds are the approaches to improve the poor charge separation efficiency. Because of the incapability to fully alleviate the limitations of hematite one

time, its efficiency did not reach for practical use. It is evident that significant achievements have been achieved in past decades in the structure, design, catalytic mechanisms, material combination, *etc* of Fe₂O₃. From recent advances on photocatalytic water splitting on hematite-based photocatalysts, much better understanding on the complicated photocatalytic process of water splitting could be obtained. Because the solar energy conversion efficiency (η) is largely determined by the corresponding individual efficiencies in the sequential photocatalysis courses, such as, light harvesting, charge separation, and charge migration and transport for solar fuels generation. Many studies tried to alleviate each limitation independently and showed fascinating improvements. It is important to consider improving the efficiency of all of these processes simultaneously in an integrated system.
