Abstract

A conformational and vibrational analysis of an antiproliferative spermine-based dinuclear Pd(II) complex (Pd_2 -Spm) is reported. Density Functional Theory coupled to all-electron basis sets was used to perform quantum mechanical calculations, aiming at determining the best suited strategy for accurately representing this molecule, and achieve an optimal accordance with the experimental data. The structural parameters and the vibrational frequencies predicted by the calculations are compared with the corresponding experimental data. The results support a relationship between the strength of the metal-ligand bonds and the antitumor activity of the compound.

Keywords

palladium(II); spermine; metal-ligand bond; anticancer; vibrational spectroscopy; quantum mechanical calculations

1. INTRODUCTION

Palladium(II) complexes are an emerging class of inorganic compounds bearing recognized anticancer properties,¹⁻⁵ challenging the initial belief that complexes containing this metal centre would be inactive. This conviction started to materialize activity parent with the lack of biological of their compound cisdiamminedichloropalladium(II) (cDDPd),⁶ as opposed to its Pt(II) homologue (cisplatin, cis-diamminedichloroplatinum(II), cDDP) that was justified by the higher lability of palladium(II) complexes relative to the platinum(II) ones. However, this problem has been circumvented by different synthetic strategies, most of them aiming at lowering this kinetic lability by coordination of the metal to polydentate or bulky ligands, yielding compounds with interesting therapeutic properties, largely determined by the nature of the ligands.⁷⁻¹² Kovala-Demertzi and co-workers¹³ published an interesting study in which the substitution of a hydrogen for a methyl group in a bulky ligand has turned a biologically inactive compound into an active one. This shows that there is still much to be understood at the molecular level to unveil the physico-chemical phenomena that rule the behaviour of these metal-based compounds in living systems - their structure-activity relationships (SAR's) being of paramount importance. Pd(II) complexes are particularly interesting compounds to perform SAR's studies, as the effect of the ligand on their biological activity is generally more pronounced than for their Pt(II) counterparts.

The present study focuses on a polynuclear Pd(II) chelate with a biogenic polyamine (spermine) $- \{\mu - \{N, N'-bis[(3-amino-\kappa N)propyl]butane-1, 4-diamine-\kappa N:\kappa N'\}\}$ tetrachloro-dipalladium (II), Pd₂-Spm (Figure 1.A).¹⁴

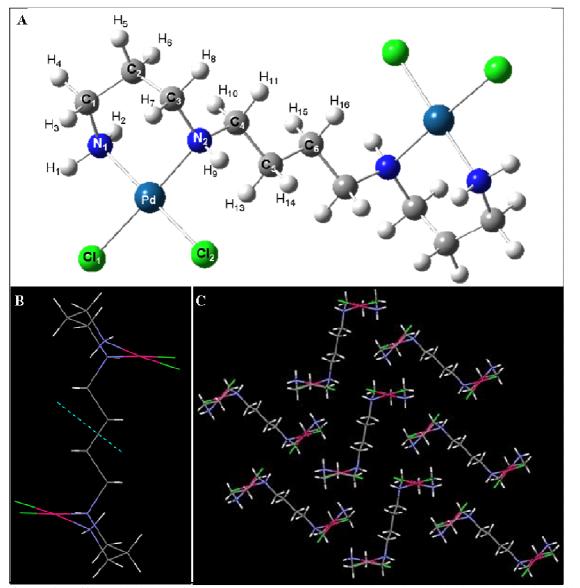

Figure 1 – (**A**) Optimized structure (LANL2DZ/6-31G*) for the Pd₂-Spm isolated molecule, and corresponding atom numbering. (**B**) X-ray structure for Pd₂-Spm. (Preferred conformation in the solid state with the inversion center highlighted by the blue dashed line). (**C**) Crystal structure arrangement for Pd₂-Spm.

This complex was shown to display interesting antiproliferative properties against cancer cells,^{15,16} although it presents a quite different chemical composition and structure from the array of active Pd(II) compounds reported in the literature to date. The understanding of the SAR's ruling this type of compound's activity is fundamental for interpreting the biochemical mechanisms underlying their biological effect (*e.g.* cytotoxic), thus allowing a rational design of new Pd-based anticancer drugs.

Vibrational spectroscopy has proven to be one of the most powerful techniques for performing conformational studies in biologically relevant molecules (including inorganic compounds). Inelastic neutron scattering (INS) spectroscopy is particularly well suited to study materials containing hydrogen atoms, since the scattering cross section for hydrogen (¹H) (about 80 barns) is much larger than for most other elements (at most *ca.* 5 barns). The neutron scattering cross-section of an element is a characteristic of each isotope and independent of the chemical environment. During the scattering event, a fraction of the incoming neutron energy can be used to cause vibrational excitation, and the vibrational modes with the largest hydrogen displacements will dominate the spectrum. Therefore, INS can be especially important in solids in which the molecular units are linked together by hydrogen close contacts, with the lowest-frequency vibrations expected to be most affected. Combining experimental vibrational spectroscopy results with quantum mechanical calculated data allows a deeper understanding of the correlation between the system's molecular properties (structure and conformation) and the corresponding spectra.

In this study, quantum mechanical calculations were carried out for Pd_2 -Spm at the DFT level, since this approach has shown to deliver accurate results for this type of systems.¹⁷⁻¹⁹ A theoretical model previously reported by the authors for a mononuclear Pd(II) compound bearing non-chelating ligands¹⁷ was presently evaluated as to its suitability for the highly flexible polynuclear polydentate chelate Pd₂-Spm. The accuracy of the calculated results was assessed by comparison with the experimental data available on this chelate – both reported X-ray structural information¹⁴ and the vibrational results gathered in this work.

2. EXPERIMENTAL

2.1 Synthesis of Pd₂-Spm

Potassium tetrachloropalladate(II) (K_2PdCl_4 , 98%) and spermine (\geq 97%) were acquired from Sigma (Sintra, Portugal) and used without further purification.

The synthesis of Pd_2 -Spm was carried out following an optimized procedure based on the published synthetic route.¹⁴ Briefly, 2 mmol of K₂PdCl₄ were dissolved in a minimal amount of water, and an aqueous solution containing 1 mmol of spermine was added drop wise under continuous stirring, for about 24 h. Solid (PdCl₂)₂(Spm) was formed, which was filtered and washed with pure acetone. Upon drying in an oven at 40°C overnight yellow crystals were obtained.

Yield: 68%. Elemental analysis was carried out at the Atlantic Microlab, Inc., Georgia, USA. Calculated - C: 21.56%; H: 4.70%; N: 10.06%, Cl: 25.46% and Found: C: 21.22%; H: 4.68%; N: 9.60%, Cl: 25.88%.

2.2 Vibrational Spectroscopy

Room-temperature Fourier transform Raman (FT-Raman) spectra were acquired on an RFS-100 Bruker Fourier transform Raman spectrometer, with near-infrared excitation provided by the 1064 nm line of a Nd:YAG laser. A laser power of 150 mW at the sample position was used. Each spectrum was the average of three repeated measurements of 150 scans, at 2 cm⁻¹ resolution.

The Fourier transform infrared (FTIR) spectra at room-temperature were recorded over the 400-4000 cm⁻¹ region, on a Mattson 7000 FTIR spectrometer, using a globar source, a deuterated triglycine sulfate (DTGS) detector and potassium bromide pellets.

Each spectrum was composed of 32 scans, with 2 cm^{-1} resolution and triangular apodization.

The INS spectrum of the complex was obtained at the ISIS Pulsed Neutron Source of the STFC Rutherford Appleton Laboratory (United Kingdom), using the TOSCA spectrometer, an indirect geometry time-of-flight, high resolution (*ca.* 1.25% of the energy transfer), broad range spectrometer.²⁰ A crystalline sample of the complex (2-3 g) was wrapped in a 4×4 cm aluminium foil sachet, which filled the beam, and placed in a thin walled aluminium can. To reduce the impact of the Debye-Waller factor on the observed spectral intensity, the sample was cooled to *ca.* 15 K. Data was recorded in the energy range -24 to 4000 cm⁻¹ and converted to the conventional scattering law, S(Q, v) *vs* energy transfer (in cm⁻¹) through standard programs.

2.3 Computational Details

All calculations were performed using the Gaussian 03W (G03W) package.²¹ Both isolated molecule and two-molecule geometry were fully optimized by the Berny algorithm, using redundant internal coordinates. While the initial conformational study was carried out without symmetry constraints, once the best conformer was selected subsequent calculations were subject to symmetry constraints (C_i symmetry group). In all cases, vibrational frequency calculations were performed, at the same level of theory, to verify that the geometries corresponded to a real minimum in the potential energy surface (no negative eigenvalues) and to simulate the vibrational spectra.

Two approaches were used to describe the palladium atom: by relativistic pseudopotentials developed by Hay and Wadt,²² in a double-zeta splitting scheme, as

New Journal of Chemistry Accepted Manuscript

implemented in G03W (keyword LANL2DZ); or by an all-electron (AE) contracted Gaussian basis set developed by Friedlander.²³ Inclusion of a polarization function at the Pd atom, by augmenting the valence shell with an f-function (ζ_{Pd} =1.472), was also tested in combination with LANL2DZ.²⁴ For the non-metal atoms, several AE basis were tested: 6-31G*, 6-31G**, 6-31+G(2d) and 6-31+G(2df) (as defined in G03W), either alone or simultaneously in distinct combinations schemes for different atoms (mix 1 and mix 2), as described in Table 1. Natural Bond Orbital (NBO) analysis was also performed. The basis sets were tested at the DFT theory level, using the mPW1PW method which comprises a modified version of the exchange term of Perdew-Wang and the Perdew-Wang 91 correlation functional,^{25,26} which has been shown to be advantageous over other DFT functionals for both linear amine ligands and their Pt(II)/Pd(II) complexes.^{17,18,27} The B97D DFT, which includes semi-empirical corrections for dispersion, was also tested.²⁸ In order to account for the basis set superposition error (BSSE) in the two-molecule model calculation, geometries were optimized within the scheme of Boys-Bernardi²⁹ (as implemented in G03W, by use of the keyword counterpoise). The SCRF (self-consistent reaction field) calculations were performed considering the aqueous solution (ϵ =78.39) using default parameters for the UAHF (United Atom Topological Model) radii model.²¹

3. Results and Discussion

3.1 Conformational analysis

The reported X-ray structure for the Pd_2 -Spm molecule¹⁴ (Figure 1) comprises both $Pd(dap)Cl_2$ units (dap=1,3-diaminopropane, $H_2N(CH_2)_3NH_2$)) in a relative *trans* arrangement. The chelate ring assumes a chair conformation, while the central putrescine-like moiety has an all-*trans* geometry. Careful inspection of this crystalline

lattice structure (Figure 1.C) suggests the formation of intermolecular H-bonds between the Pd(dap)Cl₂ fractions of adjacent molecules, namely $Cl_1;Cl_2...H_1,H_2(N_1)$ and $Cl_2...H_9(N_2)$, as well as a $Cl_1...H_{10}(C_4)$ interaction. The more hydrophobic methylene groups, in turn, should not be involved in this type of close contacts.

Taking the determined x-ray geometry as the starting point, a rotational conformational analysis was performed for the Pd₂-Spm isolated molecule (Figure S1 of the supplementary material), in the light of a previous work on the cDDPd mononuclear complex.¹⁷. We were interested in testing the relative stability of different *cis/trans* conformations (regarding the two metal centres relative to each other), all-trans and non-trans configuration of the amine linker and the presence or absence of co-planarity of the metal central relative to the central amine linker. The minimum energy conformer obtained for Pd₂-Spm differs significantly from the reported X-ray structure. As the present work aims at a study to understand the properties of a molecule in the solid state, this type of single molecule conformational studies may not be adequate to accurately represent these large polynuclear systems, since the intermolecular interactions between neighbouring molecules in the crystal lattice (Figure 1.C) impact their structure to a much larger extent than for mononuclear complexes playing a nonnegligible role on the maintenance of the overall chelate's conformation. The number of rotational conformers turns this type of study prohibitive for a system such as this one as it is too large and presents too many degrees of freedom.

In fact, taking the isomer that we knew that was the one present in the solid state, we screened it with the license free program Avogadro³⁰ (using molecular mechanics (UFF)) which predicted 242 conformers. Twenty of them, among the ones with small energy, were chosen to perform a more thorough study (Figure S1) as we were

interested mainly in testing the relative stability of cis/trans conformations (regarding the two metal centres relative to each other), all-*trans* and non-*trans* configuration of the amine linker and co-planarity regarding the metal central relative to the central amine linker.

Although plane-wave calculations have been carried out by the authors³¹⁻³⁴ to predict solid state arrangements, this type of approach is not easily accessible for this particular dinuclear chelate due to the large dimensions of the corresponding unit cell. In view of these limitations, and taking into account that the aim of this study is to predict the properties of Pd₂-Spm in the solid state, the lowest-energy conformer found for the isolated molecule (conformer 1, Figure S1) was not considered in the further analysis, but rather the optimized Pd₂-Spm isolated molecule that matches the X-ray data (Figure 1.A).

3.2 Structural analysis

The single molecule of Pd₂-Spm taken from the X-ray file which was previously optimized without symmetry constraints (conformer 5, Figures S1 and 1.A) was then reoptimized under symmetry constraints (C_i symmetry group), yielding the structural parameters comprised in Table 2. Also presented, are the differences between the experimental and calculated values (Δ -values), and the corresponding overall errors ($\Delta\Delta$ -values), calculated as previously described for cisplatin¹⁸. In general, the larger deviations from the experimental values are verified for the Pd(dap)Cl₂ moiety. It was hypothesized that these could be mainly due to: (i) poor description of the metal centre and/or (ii) neglecting the intermolecular interactions present in the crystal lattice.

Considering hypothesis (i), the LANL2DZ ECP was augmented with an fpolarization function at the Pd centre, and the all-electron basis set of Friedlander²³ was tested in the metal ion. While augmenting the Pd valence shell did not lead to a significant change (results not shown), the use of an AE basis at the Pd ion caused clear changes in the complex's structural parameters. From analysis of Table 2, it is evident that the use of an AE basis set on Pd(II) greatly improves the prediction of the Pd-N bond length, which had been previously overestimated by all theoretical approaches. However, this leads to a worsening of the Pd-Cl bond length values (as well as of some bond angles involving chlorine), in the order: for the Pd-Cl bond, LANL2DZ/6-31G* > $AE/mix1 > AE/6-31G^* - AE/mix2 > AE/6-31G+(2d) > AE/6-31G^{**}$; for the Cl-Pd-Cl angle, LANL2DZ/6-31G* > AE/6-31G** > AE/mix2 > AE/mix1~AE/6-31G* > AE/6-31G+(2d); for the Cl-Pd-N angle, LANL2DZ/6-31G* > AE/6-31G** > AE/mix2 > $AE/mix1\sim6-31G^* > AE/6-31G+(2d)$. Interestingly, the addition of a polarization function to the hydrogen atom (AE/6-31G* \rightarrow AE/6-31G**) leads to a better overall agreement relative to the experimental values of the Cl-Pd-Cl and N-Pd-Cl angles, which can probably be due to a better description of the neighbouring molecular groups bearing hydrogens. However, including higher polarization functions on the nonhydrogen atoms (AE/6-31+G(2d)) did not lead to an enhancement of the overall $\Delta\Delta$ values. Coupling the AE basis set tested for Pd(II) with a combination of different AE basis sets for the remaining atoms (mix1 or mix2) yielded better $\Delta\Delta$ values but did not solve the problem entirely. While mix1, which involves more extensive basis sets for the chlorine and nitrogen atoms (Table 1), led to a significant improvement of the Pd-Cl bond length, it did not produce more accurate values for the bond angles. In turn, while mix2, which extends the improvement of the basis set to the carbon, chlorine and nitrogen atoms (Table 1), yields better Δ values for the angles, it worsens some of the bond lengths.

New Journal of Chemistry Accepted Manuscript

Regarding hypothesis (ii), calculations for a two-molecule species (Figure S2, supplementary material) based on the X-ray structure reported for the complex, were performed to verify if accounting for intermolecular interactions could improve the results. Considering this model led to an improvement of the calculated Pd-N bond length, at the cost of a worsening of the values for the Pd-Cl bond (Table S1, supplementary material). However, although the bond angles involving the metal centre were greatly improved, the overall error was not much lower than that obtained for the isolated molecule. The reason for this probably lies on the fact that only two Pd₂-Spm molecules are not enough to represent all the intermolecular interactions occurring in the solid lattice, where one Pd₂-Spm entity is surrounded by six neighbouring molecules (Figure 1.C). Accounting for a six-molecule model using the present theoretical approach is, however, not feasible. A calculation for the two-molecule structure was also performed with the new B97D DFT, which accounts for dispersion corrections allowing a better description of the intermolecular interactions, but without significant improvement in the results (not shown). Although the structural experimental parameters are given for the solid state, SCRF results were also performed as an assessment for intermolecular interactions, not between similar molecules, but with other molecules such as the ones occurring when simulating an aqueous solution. The results gathered in Table 2 show that, interestingly, SCRF results are the ones that present the lowest bond lengths deviations obtained for the linking amine fragment N₁-C₁-C₂-C₃-N₂ and N₂-C₄. It also presents the lowest deviation values for the Cl₁-Pd-Cl₂, N_1 -Pd- N_2 and Cl_1 -Pd- N_1 angles, the ones more prone to establish intermolecular interactions. The reason for an improvement of these results when compared to the twomolecule structures, even when comparing different physical states, may be the

limitation of considering only a two-molecule system instead of a higher one with at least two layers of molecules, below and above. These results shed some light and hope on a very accurate prediction when plane-wave tools become available for the study of these compounds.

The theoretical estimate of the chelate's structural parameters is of the utmost importance for the prediction of reliable SAR's for the complex. When comparing the experimental bond lengths for different compounds of the same type, it is interesting to verify that within Pd₂-Spm, the Pd-N bonds (203.2 pm average value, Table 2) are shorter relative to the parent mononuclear compound cDDPd (206.0 pm)³⁵, while the Pd-Cl ones are longer (231.5 pm *vs.* 227.5 pm).³⁵ Natural Bond Orbital (NBO) calculations through the calculated Wiberg bond indexes - an indicator that reflects the strength of the bond - also predict this trend which is interestingly correlated with the biological activity of the complexes involved (Figure 2). In fact, regarding the human breast cell line MDA-MB-231 cell line, the IC₅₀ obtained at 24h are for cDDPd \geq 100µM, for Pd(dap)Cl₂ > 100 µM and for Pd₂-Spm = 4.7µM.

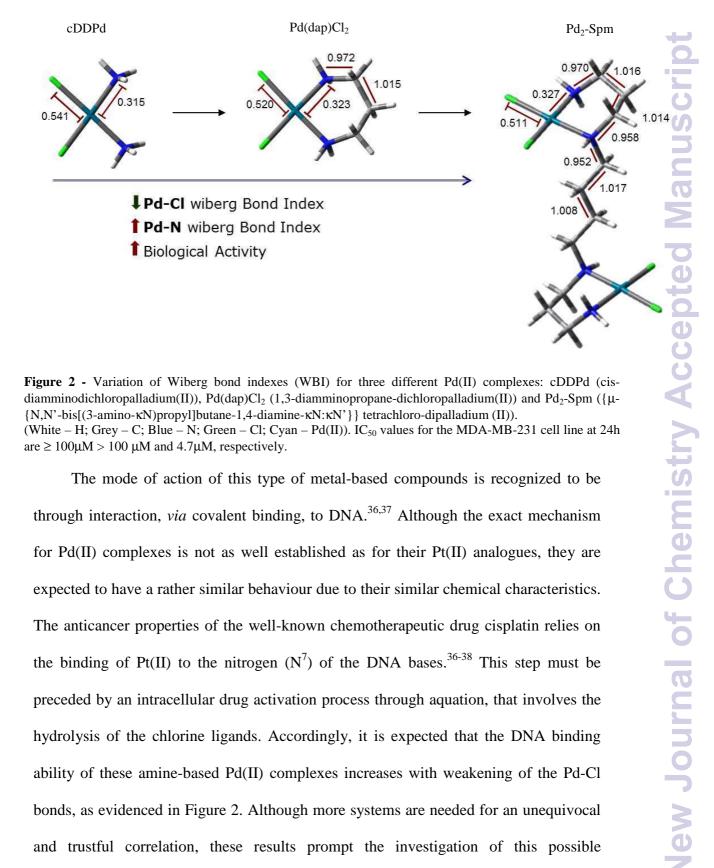

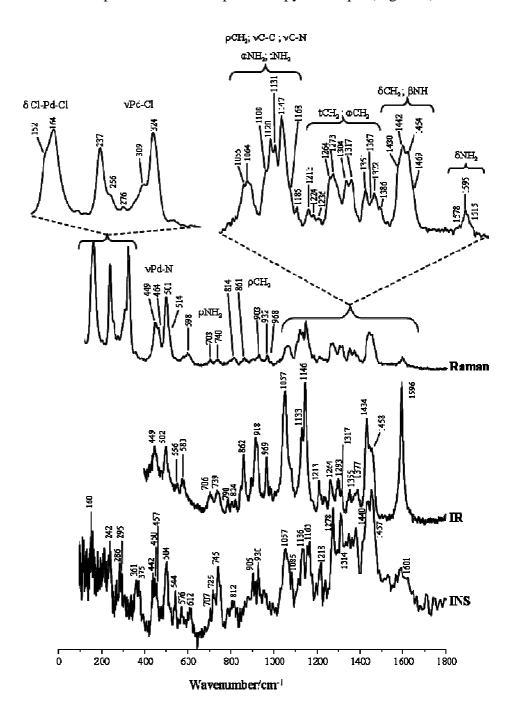

Figure 2 - Variation of Wiberg bond indexes (WBI) for three different Pd(II) complexes: cDDPd (cisdiamminodichloropalladium(II)), $Pd(dap)Cl_2$ (1,3-diamminopropane-dichloropalladium(II)) and Pd_2 -Spm ({ μ - $\{N,N'-bis[(3-amino-\kappa N)propyl]butane-1,4-diamine-\kappa N:\kappa N'\}$ tetrachloro-dipalladium (II)). (White – H; Grey – C; Blue – N; Green – Cl; Cyan – Pd(II)). IC₅₀ values for the MDA-MB-231 cell line at 24h are $\geq 100 \mu$ M > 100 μ M and 4.7 μ M, respectively.

The mode of action of this type of metal-based compounds is recognized to be through interaction, *via* covalent binding, to DNA.^{36,37} Although the exact mechanism for Pd(II) complexes is not as well established as for their Pt(II) analogues, they are expected to have a rather similar behaviour due to their similar chemical characteristics. The anticancer properties of the well-known chemotherapeutic drug cisplatin relies on the binding of Pt(II) to the nitrogen (N⁷) of the DNA bases.³⁶⁻³⁸ This step must be preceded by an intracellular drug activation process through aquation, that involves the hydrolysis of the chlorine ligands. Accordingly, it is expected that the DNA binding ability of these amine-based Pd(II) complexes increases with weakening of the Pd-Cl bonds, as evidenced in Figure 2. Although more systems are needed for an unequivocal and trustful correlation, these results prompt the investigation of this possible correlation and stress the importance of this type of study, even in the solid state.

3.3 Vibrational analysis

 Pd_2 -Spm has 132 vibrational modes, 66 of A_u symmetry (infrared active) and 66 bearing A_g symmetry (Raman active). All the modes are INS active, since there are no selection rules for this non-optical vibrational spectroscopy technique (Figure 3).

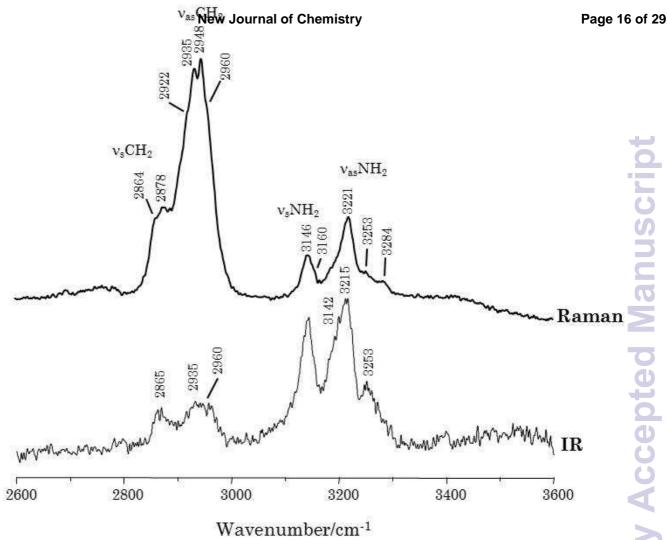

Figure 3 – Experimental vibrational spectra (Raman, IR and INS) for Pd₂-Spm.

The assignment of the vibrational spectra of Pd_2 -Spm, as well as the calculated wavenumbers at the LANL2DZ/6-31G* theory level are presented in Table 3. It has been shown previously that the small enhancement obtained with higher theory levels is not worth the associated computational cost.^{17,18} Some vibrational modes (as well as the corresponding nomenclature used throughout the text) are schematically represented in Figure 4.

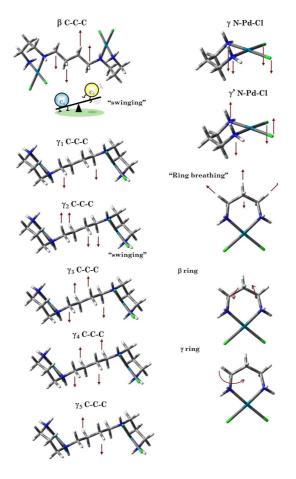

Figure 4 – Schematic representation of selected vibrational modes for Pd₂-Spm (and nomenclature used along this work).

As the metal units are linked by the aliphatic amine spermine, some low frequency vibrations are similar to the reported LAM and TAM modes previously assigned for this polyamine.^{40,41} However, they were given alternative designations in this work since Pd-coordinated Spm does not constitute a free "linear bead system" as illustrated in Figure 4.

The inspection of Figure 3 allows to determine the importance and complementarity of the different techniques used. Raman spectroscopy features more intense CH_2 stretching bands and also presents more prominent bands regarding the metal atoms. Also, the different bands regarding the organic moiety of the molecule are not quite well resolved appearing broad and overlapped. Nonetheless, the resolution of

New Journal of Chemistry Accepted Manuscript

the band relative to the metal centre using Raman technique allows to distinguish the different vibrational frequencies, particularly for the Pd-N bond. As the environment of Pd-N₁ is different from Pd-N₂, these modes are not degenerated and it is possible to identify 4 bands for the vPd-N vibration instead of 2 bands if their environment was the same, i.e., having a symmetrical centre. This feature is not as clear when using the other vibrational techniques. IR and INS bands in turn appear much more defined in the region ranging from 400-1800 cm⁻¹ allowing the detection of a higher number of vibrational modes. Particularly important and characteristic of the IR technique is the very intense and well defined deformation band of NH₂ at 1596 cm⁻¹. When analysing the crystal structure packing unit, only one intermolecular hydrogen bond is available to the NH₂ group $(N_1)H_2$ -Cl₂ (248.2 angstrom), the next shortest contact for NH₂ is a weak intramolecular interaction $(N_1)H_1$ -Cl₁ (268.7 angstrom). This quite defined δNH_2 band, supports this occurrence as it is not as broad as the one expected for a group highly involved in strong hydrogen networking. The INS technique in turn perfectly resolves the lower rocking modes of the CH₂ and NH₂ oscillators (which are almost imperceptible by Raman), as well as the ring structure torsions bands (almost absent from the IR and Raman spectra). These features stress the importance of using these three complementary vibrational techniques, especially for this type of complexes which tend for form intramolecular ring structures.

The vibrational modes from the spermine ligand were reasonably predicted by the calculations, despite some deviations due to anharmonicity and/or intermolecular interactions. The major differences were verified for the modes involving the atoms directly bound to the metal atom, which cannot be justified in terms of anharmonicity since there is not a uniform pattern in the prediction of the wavenumbers. In order to

determine whether this was a particular effect of this chelate, calculations were performed, at the same theory level (LANL2DZ/6-31G*), for a few other Pd(II) complexes with different amine ligands. The data thus gathered is collected in Table 4 as the scaling factor needed to match the calculated wavenumbers to the experimental ones. In every case, the theoretically predicted Pd-N stretching mode was found to be underestimated, while v(Pd-Cl) and v(NH₃/NH₂) were overestimated. Hence, this lack of accordance is independent of the type of complex investigated, the main issue probably remaining to be the description of the modes involving the metal centre.

Additionally, neither the AE approach to describe the metal centre nor the twomolecule model calculations led to a noticeable improvement of the corresponding vibrational modes. In fact, it was previously verified by the authors¹⁷ that an enhancement in the calculated structural parameters is not always accompanied by a corresponding improvement of the accuracy of the vibrational frequencies.

Although a straightforward comparison with the SCRF results (Table 3) cannot be performed, some comments are in order. Actually, the vibrations relative to the stretching modes of NH₂ and CH₂ groups are greatly improved and comparable to the experimental values. Also, the symmetric stretching mode Pd-N is also improved, but not the antisymmetric one. A better agreement with the experimental value is also obtained for the C-N-C torsion of the ring structure. However, many other vibrational modes are poorly predicted, such as the NH₂ and CH₂ scissoring and most wagging, twisting and rocking modes of the CH₂ groups. Moreover, many stretching vibrational modes for the C-C and C-N bonds fail to be predicted, as well as the v(Pd-Cl) ones. Nonetheless, the improvement obtained for the groups expected to be strongly involved

in intermolecular interactions should be of reference for future studies on this type of systems.

4. CONCLUSIONS

In the present work, a complete vibrational study of a dinuclear Pd(II) complex displaying a promising antiproliferative activity was undertaken, by a combined spectroscopic and quantum mechanical calculations methodology. FTIR, Raman and INS spectra were recorded and the theoretical analysis was carried out at the DFT level, for both the isolated molecule and a two-molecule model.

It was shown that the intermolecular interactions within the crystal lattice are of the utmost importance for this type of polynuclear polyamine chelates. A simple isolated molecule calculation was found not to suffice for predicting the molecular properties of such a system, as opposed to what has been reported (by the authors) for their mononuclear counterparts. Although the calculations performed for the twomolecule species yielded slightly better results, the structural improvements were not noteworthy. Furthermore, whenever there are no X-ray data available and several possible two-molecule geometries to be tested, this type of approach becomes excessively demanding (in terms of computational costs).

In order to further improve the representation of this kind of Pd(II)-amine complexes, it is of paramount importance to develop new basis sets as was recently carried out for Pt(II) complexes^{19,41} (which was out of the scope of this work). At the moment, it seems that the precise estimate of one type of metal-ligand bond length leads to the unbalance of the other one, and an improvement of the bond lengths implies a worse description of the bond angles. Therefore, when considering only the prediction

of the structural parameters, some doubts can arise as to the most suitable theoretical approach. For the representation of the vibrational profiles, in turn, the LANL2DZ/6-31G* theory level was shown to attain a high degree of accordance with the experiment, while the enhancement obtained with higher theory levels was not worth the associated computational cost. Optimization of the theoretical methodology for this kind of polynuclear polyamine Pd(II) agents will hopefully allow the establishment of accurate and reliable SAR's and to predict other important properties relevant for their anticancer capacity. Finally, while plane-wave calculations are of utmost importance for estimating the properties of a molecule in the solid state, an up-to-date all-electron basis set for palladium(II) is also crucial, since studies for an isolated molecule cannot be ruled out for large polynuclear complexes bearing biological properties.

The data obtained in this work shows an inverse relationship between the strength of the Pd-Cl bond and the antiproliferative effect of Pd₂-Spm against cancer cells, i.e., the weaker the Pd-Cl bonds the higher the complex's activity. The antiproliferative activity of such a compound is determined by several other factors. However, this evidence may indicate that these Pd(II)-amine chelates (comprising cisplatin-like moieties) could display a similar mode of action to that of cisplatin, involving chloride hydrolysis inside the cell as their major activation step.

^{*a*}Wavenumbers above 700 cm⁻¹ were scaled by 0.9499, accordingly to Merrick *et al.*³⁸ ^bWavenumbers scaled by 3 different scaling factors $\lambda 1=0.93$, $\lambda 2=1.01$ and $\lambda 3=1.11$ where $\lambda 1$ —vNH₃, δ_{as} NH₃, vPd–Cl, δ N–Pd–N; $\lambda 2$ — δ_{s} NH₃, ρ NH₃, γ N–Pd–Cl; $\lambda 3$ —vPd–N, δ N–Pd–Cl, according to Fiuza *et al.*¹⁷ ^cv = stretching; δ , β = in-plane deformation; ρ = rocking; τ = torsion; γ and γ =in phase and out of phase out-of-plane deformation, respectively.

Compound

cDDPd

[Pd(NH₃)₄]·2Cl·H₂O

[Pd(NH₃)₃(DMSO)]·2C1

[PdCl₂(en)]

[PdCl₂(dap)]

[Pd₂-Spm]
